Endpoint dilution ($TCID_{50}$) assays cannot count the number of infectious virions (IVs), and instead are limited to counting the number of specific infections caused by the sample (SIN). The latter quantity depends not only on whether virions are infectious, but also on the cells and the experimental conditions under which they interact. These interactions are random and controlled by infection parameters, such as the rates at which IVs lose infectivity, enter cells, or fail to replicate following cell entry. Here, we simulate stochastic $TCID_{50}$ assays to determine how the random number of infected wells relates to the infection parameters and the number of IVs in a sample. We introduce a new parameter estimation method based on the likelihood of observing a given $TCID_{50}$ assay outcome given the model-predicted number of IVs in the sample. We then successively evaluate how parameter estimation is affected by the use of: (1) the new likelihood function versus the typical assumption of Gaussian-distributed measurement errors; (2) IV versus SIN to represent virus in the mathematical model; and (3) a stochastic model rather than a deterministic ordinary differential equation (ODE) model to simulate the course of a virus infection. Unlike previous methods, the new likelihood intuitively handles measurements beyond the limits of detection, and results in non-Gaussian distributions for certain measurements. Expressing virus using units of IV makes it possible to impose physical constraints (one IV cannot infect more than one cell, the number of IVs cannot exceed the number of viral RNA, etc.), and yields more biologically useful parameters, e.g. the likelihood of mutation emergence depends on the total number of IVs, not SIN, produced. Using a stochastic rather than an ODE model had a negligible impact on parameter estimation, because in vitro infections are intentionally inoculated with enough IVs to guarantee infection will establish, resulting in negligible stochasticity. Instead, we show that the variability observed between triplicate in vitro virus infections is consistent with the level of stochasticity introduced by the $TCID_{50}$ assay, which can be reduced through better assay design. The new modelling and parameter estimation framework introduced herein offers several important improvements over current methods and should be widely adopted.

I. INTRODUCTION

Experimental measurements of the virus concentration in the supernatant of an infected cell culture or in samples from an infected host are the primary quantity through which infection progression is monitored and evaluated. Foldreduction in quantities such as peak or total viral yield under antiviral therapy is a common endpoint to quantify antiviral efficacy [1-8], and the degree to which viral yield correlates with disease severity or transmissibility is often investigated [9-17]. But total and peak viral yields are the result of many different aspects of virus replication and cell-virus interactions, such as the virus' affinity for a cell's surface receptors, the rate of virus production by an infected cell and the length of time for which an infected cell produces virus.

Mathematical models (MMs) enable us to bridge the gap between intra- and inter-cellular events (causes) and experimental observations (effects). They play a critical role in elucidating and challenging our understanding of the mechanisms behind the establishment and progression of virus infections in vitro and within hosts. MMs achieve this through a mathematical description of cell-virus interaction mechanisms, each characterized by one or more parameters controlling changes in mathematical variables which directly correspond or can be related to experimental measurements. We infer the most likely value of the MM parameters, and thus characterize the relative contribution of individual mechanisms, by matching MM-predicted variables to their corresponding experimental measurements.

FIG. 1. Random events can cause a time shift of infection curves. Infectious virion time courses for 100 SM simulations (grey solid lines) compared to the ODE solution (red dashed line), for an infection initiated with a single infectious virion. Infection parameters were taken from Simon et al. [34] with some adaptations for the MMs used herein as described in Methods, except for $\beta = 10^{-6}$ ml/(cell · h) which was reduced to enhance the variability in the curve timing.

It is therefore critical to correctly identify and mathematically represent the relationship between experimental measurements and their corresponding MM variables.

Infectious virions, the causative agents of the infection, are often one of the variables in MMs of viral infections. Experimentally, it is not the concentration of infectious virions in a sample that is measured, but rather a quantity related to the number of cells the sample is expected to infect. These experimental measures are obtained via two main assays: the plaque (or focus) forming assay and the endpoint dilution (or $TCID_{50}$) assay [18–25]. In a typical plaque (or focus) forming assay, the virus sample is serially diluted to an extent where ideally, within one well containing about one million cells, only about 30 cells will become infected so that only about 30 plaque forming units (PFUs) are counted. This is to avoid a count that is too low and therefore highly variable (1 to 5 plaques) or too high resulting in overlapped or merged plaques which would make counting ambiguous. For its part, the $TCID_{50}$ assay relies on estimating the dilution of the virus sample at which it would infect 50% of the cell culture wells and thus contain on the order of a single infection-causing dose. Both assays assume or rather define that one infection-causing dose inevitably causes an infection. There is, therefore, a fundamental difference between a sample's experimentally measured concentration of infectious virion is capable of but not assured to cause an infection.

Given that the endpoints of these assays are based on a small number of infection-causing doses, one might wonder to what extent stochastic effects, e.g. the random chance that one infectious virion fails to initiate an infection, affect the accuracy of the infection-causing dose estimated from the assays. Several past works using stochastic mathematical models (SMs) have evaluated the likelihood that an infection, starting from one or very few infectious virions or infected cells, will establish or will become extinct, and found this likelihood varies as a function of the SM parameters [26–33]. The relationship between the SM's infectious virions and the experimentally measured infectioncausing doses is therefore nontrivial. Importantly, it depends on the very quantities the MM aims to determine from these experimental measurements: its parameters.

Typical MMs of virus infections are deterministic, mean-field, ordinary differential equation (ODE) models. For an infection initiated with very few infectious virions or cells, the random nature of the first few infection events will determine whether the infection will fail or successfully establish. The timing of these early infection events will set the timing of the entire infection curve [35, 36]. Thereafter, as the number of infectious virions and cells continue to increase, the behaviour becomes deterministic, following the shape of the ODE-predicted infectious virus time course. The stochasticity, it would seem, translates the ODE-predicted curve to earlier or later times, but does not affect its overall shape, as illustrated in Figure 1. As such, for a given set of MM parameters, a stochastic infection will yield a family of time-offset curves which, if analyzed with an ODE model, could result in different parameter estimates.

In this work, we use a SM largely identical to that previously introduced [33] to study how its parameters affect the relationship between the actual number of infectious virions represented by the SM and the number of infection-causing doses that would be experimentally measured via an endpoint dilution (TCID₅₀) assay. Taking this relationship into consideration, we introduce a novel framework with which to interpret experimental infectious dose measurements and to relate them to their corresponding MM-predicted variables. We then compare results of the typical parameter

FIG. 2. Stochastic scheme to simulate an ED assay experiment. (A) The random number of infectious virions (IV) inoculated into each well $(V_0^{i,j})$ is drawn from a Binomial distribution, based on the known virus sample concentration $(C_{\text{actual}}$ in IV/ml), the dilution factor in that well's column $(\mathcal{D}_j \in (0, 1])$, the volume of a single virion (V_{vir}) , and the total inoculum volume placed in each well $(V_{\text{inoc}} = \text{diluted sample plus dilution medium})$. (B) The random outcome for each well, i.e. whether infection took place or not (1 or 0, respectively), is determined based on the number of IV received by the well $(V_0^{i,j})$ and the SM-predicted likelihood that infection will fail $(\mathcal{P}_{V \to \text{Extinction}})$. From this, the overall experimental assay outcome, namely the number of infected wells observed in each dilution column, is computed. (C) The midSIN calculator tool [25] is used to estimate the sample's most likely \log_{10} infectious dose concentration, in units of SIN/ml, based on the experimental outcome observed in (B). The well highlighted in yellow (row 5, column 6) illustrates how a well can receive one infectious virion and yet fail to cause an infection.

estimation approach using an ODE model against individual components of the new framework. We explore the implications of our findings on interpretations of present and past results.

II. RESULTS

A. Relationship between infectious virions and experimental measurements

A TCID₅₀ endpoint dilution (ED) assay is usually carried out in a cell culture plate consisting of a number of wells organized into rows and columns. Let us consider an example ED experiment in which the first 11 columns of the 96-well plate receive increasing dilutions of the virus sample, all 8 rows within a column receive the same dilution and thus serve as replicates, and the last (12th) column is reserved for the sample-free control. Figure 2A illustrates one possible random outcome for the number of infectious virions that would be received by each well of this simulated experiment given a virus sample with a known infectious virion (IV) concentration ($C_{actual} = 10^6 \text{ IV/ml}$). the dilution factor for each column ($\mathcal{D}_1 = 10^{-2}$, $\mathcal{D}_2 = 10^{-2.6}$, $\mathcal{D}_3 = 10^{-3.2}$, ..., $\mathcal{D}_{11} = 10^{-8}$), and the total volume of inoculum placed in each well ($V_{inoc} = 0.1 \text{ ml}$). See Methods for additional details.

The experimental readout of an ED assay is the number of wells that became infected at each dilution as a result of the number of infectious virions each well received given the virus sample's unknown concentration (Fig. 2B). Past work using SMs suggests that, over a wide range of viruses studied to date (influenza [30], HIV [27, 28, 31], SARS-CoV-2 [32, 33]) and for realistic infection conditions and parameters, an infection initiated with one or even a few infectious virions can randomly become extinct, i.e. fail to take hold or spread significantly. This is more likely to occur when the inoculum consists of only a few infectious virions or the virus' replicative fitness is such that each infected cell barely infects one other cell (basic reproductive number $R_0 \sim 1$). This means that an ED well might fail to become infected despite having received one or even a few infectious virions.

The work herein will make use of the virus infection stochastic model, and a related ODE model, largely identical to those introduced and studied previously in Quirouette et al. [33]. One additional equation was added to each MM

FIG. 3. Key parameters and terms of the ODE and stochastic models. The ODE and stochastic models describe the virus infection of a population of N_{cells} cells, bathed in a supernatant of volume s (see Methods). (A) Infectious virions (IV) in the supernatant are lost due to loss of infectivity at rate c or irreversible entry into cells at rate β/s . (B) When one IV is lost to cell entry, it either successfully infects it, resulting in γ infected cell per IV entry, or it does not $(1 - \gamma)$. (C) There is a delay of $\tau_E \pm (\tau_E/\sqrt{n_E})$ hours following a cell's infection (eclipse phase) before it begins releasing IV progeny. (D) Thereafter, it releases infectious virions into the supernatant at rate ρ , and total (infectious + non-infectious) virion progeny at rate ρ_{RNA} . (E) Virus release will persist for $\tau_I \pm (\tau_I/\sqrt{n_I})$ hours (infectious phase) after which the cell undergoes apoptosis. (F) An infected cell will produce on average $\mathcal{B} = \rho \cdot \tau_I$ IV over its infectious lifespan, but the actual number varies randomly cell-to-cell based on parameter n_I (graph modified from [33] where $\mathcal{B} = 19$ IV/cell). Each produced IV has a probability $\mathcal{P}_{V \to I}$ to cause the infection of another cell. The basic reproductive number, $R_0 = \mathcal{B} \cdot \mathcal{P}_{V \to I}$, corresponds to the average number of cells one infected cell will infect. In the illustration, the infected cell produced 10 IV progeny (based on \mathcal{B}, n_I) which went on (based on $\mathcal{P}_{V \to I}$) to productively infect 4 cells ($R_0 = 4$).

herein to represent total virions (V_{RNA}) corresponding to the number of viral RNA copies as measured by qRT-PCR in units of viral RNA (vRNA). Details of the two MMs are provided in the Methods, and the key parameters and expressions they share, are illustrated in Figure 3. In [33], we derived the probability that an infection initiated with a single infectious virion (IV) will become extinct ($\mathcal{P}_{V \to \text{Extinction}}$), and its dependence on the SM's parameters, namely

$$\mathcal{P}_{V \to \text{Extinction}} = \left[1 - \frac{\gamma}{1 + c/(\beta N_{\text{cells}}/s)}\right] + \frac{\gamma}{1 + c/(\beta N_{\text{cells}}/s)} \left[\frac{\mathcal{B}\left(1 - \mathcal{P}_{V \to \text{Extinction}}\right)}{n_I} + 1\right]^{-n_I} \tag{1}$$

for which only a numerical solution exists. The term $\mathcal{P}_{V \to I} = \gamma/[1 + c/(\beta N_{\text{cells}}/s)]$ appears twice and corresponds to the probability that one IV productively infects one cell, with $\gamma \in (0, 1]$ the probability that an IV's entry into a cell will result in the cell's productive infection. When re-written as $[\gamma\beta N_{\text{cells}}/s]/[\beta N_{\text{cells}}/s + c]$, it is the ratio of the rate at which target cells are lost to infection $(\gamma\beta N_{\text{cells}}/s)$ divided by the rate at which infectious virions are lost due to cell entry $(\beta N_{\text{cells}}/s)$ plus loss of infectivity (c). The first term in Eqn. (1), $1 - \mathcal{P}_{V \to I}$, is the probability that the IV fails to infect a cell, and the second is the probability that it infects a cell $(\mathcal{P}_{V \to I})$ times the probability that its IV progeny (or its progeny)'s progeny) fails to do the same. The latter depends on the random total number of IV produced by each infected cell, which varies cell-to-cell following a negative binomial distribution whose mean $(\mathcal{B} = \rho \cdot \tau_I)$ is the product of the infected cell's IV production rate (ρ) and the duration of its infectious period (τ_I) ,

FIG. 4. The effect of infection parameters on experimentally measured infection-causing doses. Violin plot (vertically stacked histograms) for the ratio of experimentally measured virus (SIN/ml), to the actual infectious virion (IV) concentration in the sample (10⁶ IV/ml), based on 10⁵ randomly simulated ED experiments, as a function of either (A) γ ; (B) the ratio between the rate of loss of virus due to cell entry over that due to loss of infectivity, $(\beta N_{\text{cells}}/s)/c$; (C) $\mathcal{B} = \rho \cdot \tau_I$; or (D) n_I . The experimentally measured SIN concentration reported for each simulated ED experiment corresponds to the midSIN-estimated highest likelihood SIN/ml concentration for that ED outcome [25]. The black curves join the median (thick), 68% (thin) and 95% (dashed) credible interval (CI) of the vertically stacked histograms. The ED assay experiment parameters were $C_{\text{input}} = 10^6 \text{ IV/ml}$, $\mathcal{D}_1 = 10^{-2}$, dilution factor $= 10^{-0.6}$, $V_{\text{inoc}} = 0.1 \text{ ml}$, $N_{\text{cells}}^{\text{well}} = 10^5 \text{ cells}$, using 11 dilutions and 8 replicate wells per dilution, as illustrated in Figure 2. Infection parameters were varied about their base value ($\gamma = 1 \text{ cell}/\text{IV}$, $(\beta N_{\text{cells}}/s)/c = 175$, $\mathcal{B} = 297 \text{ IV/cell}$, $n_I = 60$, where $N_{\text{cells}} = N_{\text{cells}}^{\text{well}}$ and $s = V_{\text{inoc}}$) taken from Simon et al. [34], with some adaptations for the new MM used herein (see Methods, Section IV B).

and its variance $(\mathcal{B} + \mathcal{B}^2/n_I)$ can be controlled independently of its mean via parameter n_I (Figure 3F). Smaller n_I lead to larger cell-to-cell variations in the number of IV produced. The basic reproductive number $(R_0 = \mathcal{P}_{V \to I} \cdot \mathcal{B})$ is the product of the mean number of IV produced per cell (\mathcal{B}) times the probability that one IV infects one cell $(\mathcal{P}_{V \to I})$. Eqn. (1) shows that $\mathcal{P}_{V \to \text{Extinction}}$ depends differently on γ , n_I , and on the parameter groupings $[\rho \cdot \tau_I]$ and $[(\beta N_{\text{cells}}/s)/c]$.

In Figure 2B, we use $\mathcal{P}_{V \to \text{Extinction}}$ to generate one random instance of the outcome of infection in each well of the ED assay, i.e. whether or not infection establishes (1 or 0, respectively), based on the probability that a well having received $V_0^{i,j}$ IVs will go extinct, $(\mathcal{P}_{V \to \text{Extinction}})^{V_0^{i,j}}$. In the example, this process resulted in (8,8,8,5,5,0,0,0,0,0,0) infected wells out of 8 wells in total at each of the 11 dilutions. From such an ED outcome, i.e. the number of wells infected at each dilution, the Reed-Muench [20] or Spearman-Kärber [18, 19] method is typically used to estimate the number of TCID₅₀/ml in the sample, wherein 1 TCID₅₀ is the dose at which a sample would be expected to infect 50% (4/8) of wells. Alternatively, from the same ED outcome, the online tool midSIN can be used to estimate the most likely \log_{10} number of infections the sample can cause per unit volume, expressed in units of specific infections or SIN/ml [25]. Figure 2C presents the midSIN-estimated posterior distribution for the \log_{10} SIN/ml concentration in the example sample, given the observed ED outcome. Here, the sample with an actual concentration of $C_{actual} = 10^6$ IV/ml would have been measured experimentally to contain $C_{measured} = 10^5$ SIN/ml. This means that, for the SM parameters employed here, ~10 infectious virions on average are required to cause one infection (10 IV/SIN).

In this example, the actual concentration of IVs in the sample is known, as are all the SM parameters. Normally,

FIG. 5. Recovering the actual infectious virus concentration by correcting the experimentally measured concentration. Violin plot for the ratio of the *corrected* experimentally measured virus concentration in IV^{\dagger}/ml , obtained by dividing the experimentally measured virus concentration in SIN/ml by the establishment probability $\mathcal{P}_{V \to \text{Establishment}}$, over the *actual* infectious virion concentration, based on simulated stochastic ED experiments, as a function of either (A) the probability of a successful cell infection post viral entry, γ ; or (B) the ratio between the virus entry rate and the rate of loss of virus infectivity, $(\beta N_{\text{cells}}/s)/c$. Everything else is generated and represented visually as in Figure 4.

the SM parameters are unknown and meant to be estimated based on experimental SIN measurements whose relations to the actual number of infectious virions is therefore also unknown. Figure 4 explores how the SM parameters affect the experimentally measured SIN/ml for a fixed, actual IV sample concentration of 10^6 IV/ml, based on ED assays randomly simulated as described above. As one decreases the probability (γ) that an IV's entry into a cell results in the cell's productive infection, an increasing number of IVs go uncounted by the ED assay, and the experimentally measured SIN increasingly underestimates the actual IV concentration in the sample (Figure 4A). To a lesser degree, as $(\beta N_{\text{cells}}/s)/c$ decreases (Figure 4B), there are fewer IV lost due to cell entry $(\beta N_{\text{cells}}/s)$ per IV losing infectivity (c), leading to fewer successful infections per infectious virion (smaller SIN/IV). In contrast, varying the mean and variance simultaneously (via $\mathcal{B} = \rho \cdot \tau_I$) or only the variance (via n_I) of the distribution for the random total number of IV produced by each infected cell (Figure 4C,D) has little to no effect on the number of measured infections per infectious virion (SIN/IV). This is in part due to the choice of SM parameters. More generally, if the mean number of IV produced by infected cells is too small, the infection of one cell might not lead to the infection of another. Similarly, lower n_I values mean larger cell-to-cell variation in the total number of IV each cell produces, leading to a greater probability that an infected cell randomly produces little or no virus progeny, and thus fail to infect another cell [33, 37]. While \mathcal{B} and n_I affect the likelihood of infection establishment only after a first successful cell infection, γ and $(\beta N_{\text{cells}}/s)/c$ act to prevent this first infection from ever taking place, providing a stricter bottleneck, leading more easily to infection extinction.

Perhaps unsurprisingly, the ratio of experimentally measured SIN per IV (Figure 4A,B), corresponds exactly to the probability that a single infectious virion will lead to the successful establishment of the infection, where $\mathcal{P}_{V \to \text{Establishment}} = 1 - (\mathcal{P}_{V \to \text{Extinction}})$. In other words,

$$\underbrace{\underline{C}_{\text{measured}}}_{\text{SIN/ml}} = \underbrace{\underline{C}_{\text{actual}}}_{\text{IV/ml}} \cdot \underbrace{\underline{\mathcal{P}}_{V \to \text{Establishment}}}_{\text{SIN/IV}} \quad . \tag{2}$$

This is demonstrated in Figure 5 where the experimentally measured titres presented in Figure 4A,B are divided by the establishment probability $\mathcal{P}_{V \to \text{Establishment}}$. This can be understood more intuitively when considering $\mathcal{P}_{V \to \text{Establishment}}$ for $n_I = 1$, namely

$$\mathcal{P}_{V \to \text{Establishment}}(n_I = 1) = \left[\mathcal{P}_{V \to I}\right] - \left[\frac{1}{\mathcal{B}}\right] = \left[\frac{\gamma}{1 + c/(\beta N_{\text{cells}}/s)}\right] - \left[\frac{1}{\rho \tau_I}\right]$$
(3)

Eqn. (3) shows why fewer infections per infectious virion (SIN/IV) are measured experimentally for low values of γ or $(\beta N_{\text{cells}}/s)/c$. It also shows that the mean burst size, $\rho \tau_I$, affects $\mathcal{P}_{V \to \text{Establishment}}$ only when it is very small $(\rho \tau_I \sim 1)$, and matters even less when $n_I > 1$. As such, $\rho \tau_I$ is expected to play an important role only when virus production is suppressed, for example by the action of an antiviral drug [33]. Similarly, small values of n_I might not be biologically common or even realistic [38–40], such that n_I likely rarely significantly affects $\mathcal{P}_{V \to \text{Establishment}}$. The average length of the eclipse phase (τ_E) , and the shape parameter of the Erlang-distributed eclipse phase duration

7

 (n_E) , do not affect the extinction probability, and therefore have no impact on the ratio of measured infections per infectious virion.

B. An alternative approach to parameter estimation

Collectively, results thus far show that infection parameters affect the establishment probability and, therefore, the conversion of a virus sample's actual infectious virion (IV) concentration into its experimentally measured concentration of infection-causing units (SIN). This means that the parameters affect the experimentally measured viral titres that are in turn used to estimate these same parameters. The typical approach with ODE models circumvents this issue by expressing the MM variable corresponding to infectious viral titre in the same units as the experimental measurements (V in PFU/ml or TCID₅₀/ml or SIN/ml). But as shown above, one experimentally measured infection-causing dose (e.g., PFU, TCID₅₀, SIN) could correspond to 10 or even 100 infectious virions, depending on $\mathcal{P}_{V \to \text{Extinction}}$. Consequently, important quantities such as the rate of mutation per infectious virion or the number of IV entry events required to cause the infection of one cell, cannot be determined, or only with poor accuracy, under some assumptions [37, 41–43].

Given these issues, we evaluate an alternative parameter estimation approach that takes into consideration the random nature of the virus infection process, the discrete nature of cells, virions, and infection events, as well as the random nature and limitations of experimental measurements of virus samples collected over the course of these infection. Compared to the standard approach, this alternative approach modifies three aspects of MM parameter estimation, namely

- using a stochastic model (SM) that describes the discrete number of infectious virions and cells in various states over the course of the in vitro virus infection, rather than an ODE model;
- expressing infectious viral titre in the MM (V in Eqn. (6)) using biologically useful ([V] = IV) rather than experimentally measurable ([V] = SIN) units, and relating the MM variable in IV to the experimentally measured SIN via the establishment probability, $\mathcal{P}_{V \to \text{Establishment}}$, which explicitly takes consideration infection failure in the ED assay;
- estimating MM parameters based on the likelihood of the experimentally observed ED assay outcome (\mathcal{L}_{ED}) for each measured sample (i.e. number of infected wells at each dilution), given the MM-predicted $\log_{10}(V)$ for a sample taken at that time, rather than using a likelihood that generically assumes normally distributed residuals (\mathcal{L}_{NR}) between the experimentally measured and MM-predicted $\log_{10}(V)$.

In order to compare the standard parameter estimation approach (ODE with [V] in SIN using \mathcal{L}_{NR}) to this alternative approach (SM with [V] in IV using \mathcal{L}_{ED}), we repeated the parameter estimation performed in Simon et al. [34] for the in vitro infection of A549 human lung carcinoma cells with a seasonal (A/New Caledonia/20-1999-like H1N1) influenza A virus (IAV) strain. Infections were performed in triplicate at two different virus inoculum concentrations (MOI of 3 PFU/cell and 0.01 PFU/cell) to produce a single-cycle (SC) and a multiple-cycle (MC) infection, with regular measurement of the concentration of infectious (via ED assay) and total (via qRT-PCR) viral titres [34]. A Markov chain Monte Carlo (MCMC) approach was used to estimate the MM parameters' posterior distribution, given the experimental measurements. In the sections that follow, we describe in more details and individually evaluate the impact of the three changes.

C. Likelihood of the experimentally measured infectious viral titres

We compare two different expressions for the likelihood of the infectious viral titres measured via the ED assay, given the MM used and the set of parameters ($\vec{\pi}$) to be estimated (see Methods for details). The standard one (\mathcal{L}_{NR}) is based on the assumption that the residuals between the experimentally measured and MM-predicted log₁₀ infectious titres follow a normal distribution,

$$\mathcal{L}_{\rm NR}(C_r^{\rm data}(t)|\sigma,\vec{\pi},{\rm MM}) = \exp\left\{-\frac{\left[\log_{10} C_r^{\rm data}(t) - \log_{10} C^{\rm model}(t|\vec{\pi})\right]^2}{2\sigma^2}\right\} ,\qquad(4)$$

where $C_r^{\text{data}}(t)$ is the experimentally measured concentration in SIN/ml estimated by midSIN [25] based on the ED assay performed on the sample taken at time t from the r^{th} infection replicate, $C^{\text{model}}(t|\vec{\pi})$ is the corresponding MM-predicted value, and σ is the estimated standard deviation of the residuals (see Methods). The alternative (\mathcal{L}_{ED})

FIG. 6. Visualizing the standard (\mathcal{L}_{NR}) and alternative (\mathcal{L}_{ED}) likelihood functions. Relative probability (y axis) of the three infectious titres measurements, given the $\log_{10}(SIN/ml)$ predicted by the MM (x axis), as computed according to either \mathcal{L}_{NR} (blue, solid) or \mathcal{L}_{ED} (orange, dashed). The relative probability shown is the combined probability for all 3 experimental measurements taken at the indicated times, indicated as black × along the bottom of each graph. The vertical dashed line in (A) corresponds to the lower limit of detection of the ED assay (C_{LLoD} , Table IV). A comparison of \mathcal{L}_{NR} vs \mathcal{L}_{ED} for all measurements taken over the SC and MC infections is provided in Methods (Figures 14 and 15).

is the likelihood of the observed ED assay outcome, e.g. the number of positive wells at each dilution (8, 8, 8, 5, 5, ...), given the MM-predicted infectious titre for a sample taken at that time,

$$\mathcal{L}_{\rm ED}(\vec{k}_r^{\rm data}(t)|\vec{n}_r^{\rm data}(t), \vec{\mathcal{D}}_r^{\rm data}(t), V_{\rm inoc}, \vec{\pi}, {\rm MM}) = \exp\left[-C^{\rm model}(t|\vec{\pi}) \cdot V_{\rm inoc} \cdot \sum_{\rm col} \mathcal{D}_r^{\rm col}(t) \left(n_r^{\rm col}(t) - k_r^{\rm col}(t)\right)\right] \\ \cdot \prod_{\rm col} \left(1 - \exp\left[-C^{\rm model}(t|\vec{\pi}) \cdot V_{\rm inoc} \cdot \mathcal{D}_r^{\rm col}(t)\right]\right)^{k_r^{\rm col}(t)} , \quad (5)$$

Eqn. (4) for \mathcal{L}_{NR} reduces the outcome of an ED assay to a single value, namely the most likely SIN/ml concentration $(C_r^{\text{data}}(t))$, and assumes the same uncertainty for all measurements (σ). In contrast, Eqn. (5) for \mathcal{L}_{ED} incorporates all the information provided by the ED assay, namely the number of infected and total wells at each dilution $(\vec{k}_r^{\text{data}}(t), \vec{n}_r^{\text{data}}(t))$, which includes information about the uncertainty of each measurement.

Another advantage of using \mathcal{L}_{ED} is the ability to meaningfully include a likelihood for measurements that fall beyond the detection limit of the ED assay. Over the course of the triplicate MC infections, 6 of the 36 samples resulted in no infected well in the ED assay (0,0,0,...,0). The midSIN estimator provides an unnormalizable posterior distribution for such ED outcomes [25], but it cannot provide a most likely SIN/ml concentration estimate, as is required by \mathcal{L}_{NR} , because none exists. In handling these 6 measurements using \mathcal{L}_{NR} , the residual is assumed to be zero ($\mathcal{L}_{\text{NR}} = 1$) when the MM-predicted SIN/ml concentration is less than or equal to the ED assay's lower limit of detection ($C^{\text{model}}(t|\vec{\pi}) \leq C_{\text{LLoD}}$), or is otherwise computed as the difference between the log₁₀ MM-predicted titre and the assay's lower limit of detection, i.e. using $C_r^{\text{data}}(t) = C_{\text{LLoD}}$ in Eqn. (4), where $C_{\text{LLoD}} = 10^{1.494}$ SIN/ml (see Methods). In contrast, using the \mathcal{L}_{ED} , these 6 measurements can be treated in the same manner as any other measurement.

Figure 6 shows the probability (y-axis), computed using either \mathcal{L}_{NR} or \mathcal{L}_{ED} , that the \log_{10} SIN concentration measured at a particular time t takes on a certain value (x axis), given the three experimental measurements from replicate MC infections taken at different times. Figure 6A shows the impact of having 2 out of 3 replicate measurements below the lower limit of detection. The \mathcal{L}_{NR} is a poor match for the correct \mathcal{L}_{ED} . Figure 6B shows that \mathcal{L}_{NR} can sometimes closely match \mathcal{L}_{ED} . Figure 6C,D suggest that the standard deviation, assumed in \mathcal{L}_{NR} to be the same for all MC infectious titre measurements (σ_{MC} , Table IV), is at times smaller (Figure 6C) or larger (Figure 6D) than the correct,

FIG. 7. Impact of the likelihood function on parameter estimation. (A–D) Triplicate infectious (A,C) or total (B,D) viral titre measurements (circles) over the course of triplicate SC (A,B) or MC (C,D) in vitro influenza A virus infections, along with the 95% CI for the MM-predicted viral time courses, based on using either the \mathcal{L}_{NR} (solid blue line) or \mathcal{L}_{ED} (dashed orange line) likelihood. (E–J) Marginalized posterior distributions (MPDs) of the MCMC-estimated parameters, where τ_E and τ_I are the mean duration of the eclipse and infectious phases (h), ρ_{RNA} and ρ are the total and infectious viral production rates (vRNA/h and SIN/h), γ is the number of cells infected per SIN lost due to cell entry (cell/SIN) and β is the rate of SIN loss due to cell entry (ml/[cell \cdot h]). (K–N) MPDs of biologically relevant quantities derived from the MCMC-estimated parameters, where $\mathcal{B} = \rho \tau_I$ is the mean number of SIN produced per cell, $\mathcal{P}_{V \to I} = \gamma/[1 + (c/\beta N_{cells}/s)]$ is the mean number of cells infecting time (see Methods), and R_0 is the basic reproductive number. (O) Paired MPD for correlated parameters γ and β .

 \mathcal{L}_{ED} -computed standard deviation. Of the 24 experimental samples taken over the course of the triplicate SC and MC infections (see Methods), \mathcal{L}_{NR} always overestimated the most likely $\log_{10}(SIN/ml)$ (e.g. by 2.3-fold in A, 11% in C, 15% in D), with the single exception of the measurement shown in Figure 6B, where it underestimates it by 2.6%.

Figure 7A–D shows the ODE-predicted infectious and total viral titres over the course of the SC and MC infections, and Figure 7E–J the corresponding marginalized posterior distributions (MPDs) for the 6 parameters estimated based on either \mathcal{L}_{NR} or \mathcal{L}_{ED} . All parameters have similar but not identical estimated values (Figure 7E–J). The \mathcal{L}_{ED} estimates a longer eclipse phase (τ_E , Figure 7E), shorter infectious phase (τ_I , Figure 7F), and higher total viral production rate (ρ_{RNA} , Figure 7G) than that obtained using the standard \mathcal{L}_{NR} . Notably, the effect of the longer eclipse phase is visible as a delay (right-shift) of the ODE-predicted viral curves in the SC infection (Figure 7A,B), and the shorter infectious phase appears as a shorter viral plateau and a more rapid transition to viral decay in the ODE-predicted MC infection time course (Figure 7C). These differences are not statistically significant (Tables I and II) and are unlikely to be biologically significant in comparison to typical inter-experimental variability [44].

TABLE II. *p*-values for pairwise comparison of variations^a

^a The *p*-value corresponds to the fraction of times the statement (A > B) or (A < B) is true (not both, i.e., one-tailed) for 1,000,000 pairwise comparisons of individual parameter values drawn at random from A and B with replacement, where A and B are the sets of MCMC-accepted parameters obtained using similar procedures that differed only in the aspect indicated in the column header.

^b Old refers to $(\mathcal{L}_{NR}, [V] = SIN, ODE)$ and new to $(\mathcal{L}_{ED}, [V] = IV, SM)$.

Figure 7K–N shows 4 biologically relevant quantities computed from the ODE-estimated parameters. Figure 7K corresponds to $\mathcal{P}_{V \to I}$ (see Figure 3), the probability that a cell becomes productively infected by one IV when [V] is expressed in units of IV. Since here [V] = SIN, and one SIN (observed infection) can represent several IV (infectious virions), it is possible for one SIN to infect more than one cell. As such, when [V] = SIN, $\mathcal{P}_{V \to I}$ can be larger than one (no longer a probability), and corresponds to the mean number of cells infected per SIN produced $(R_0/\mathcal{B}, \text{ with units of cell/SIN})$. The product of \mathcal{B} (mean total SIN progeny per infected cell) and $\mathcal{P}_{V \to I}$ (cell infected per SIN produced) corresponds to R_0 , the basic reproductive number. Use of \mathcal{L}_{ED} resulted in a larger $\mathcal{P}_{V \to I}$, smaller \mathcal{B} , and a smaller R_0 (Figure 7K,L,M, respectively), but these differences are not significant (Table I,II). The infecting time (t_{inf}) , first introduced in Holder et al. [38], represents the time for a newly infectious cell to cause the infection of its first cell, given an otherwise fully susceptible cell population, and neglecting virus loss of infectivity. Herein, the definition for t_{inf} neglects both virus loss of infectivity and loss to cell entry, and depends on $\rho \cdot \gamma \beta N_{\text{cells}}/s$ in the SC and MC infections (see Methods). It is estimated to be slightly shorter using \mathcal{L}_{ED} than \mathcal{L}_{NR} (Figure 7N), but not significantly so (Table I,II).

Parameter estimation with either likelihood functions results in a correlation (Figure 7O) between the rate of SIN loss due to cell entry (β , Figure 7J), and the number of cells infected per SIN cell entry (γ , Figure 7I). Even though γ and β are poorly constrained by the data (a lower bound of $\beta \geq 10^{-10}$ ml/(cell · h) had to be imposed), the derived quantities which depend on these parameters ($\mathcal{P}_{V \to I}$, R_0 , t_{inf}) are comparatively well-constrained. The (β , γ) correlation, and the reason for the need to impose a lower bound on β , are discussed in the next section. Paired MPDs for all parameter pairs using the \mathcal{L}_{NR} or \mathcal{L}_{ED} are provided in Methods.

D. Units used to express the infectious viral titre in the MM

ODE models typically express the infectious viral titre, variable V in Eqn. (6) (see Methods), using the same units as the experimentally measured infectious titre (e.g., PFU/ml, TCID₅₀/ml, SIN/ml) against which V is compared to estimate the MM parameters. In contrast, SMs track individual virions and cells, expressing these variables as whole numbers, and as such V in SMs corresponds to the number of infectious virions (IV). This requires converting the units of V (hereafter [V]) from IV to SIN to be compared against the experimentally measured infectious titre in SIN,

FIG. 8. Impact of the infectious viral titre (V) units on parameter estimation. MM-predicted viral time courses and MPDs for the ODE model, using the \mathcal{L}_{ED} , when [V] = SIN (solid orange) or [V] = IV (dashed purple). Panels (A–N) are as described in Figure 7, although a number of parameters (ρ , γ , β , $\mathcal{P}_{V \to I}$, \mathcal{B} , and $\mathcal{P}_{V \to \text{Establishment}}$) have a different biological meaning depending on whether [V] = SIN or IV, as explained in the text. (O) Paired MPD for γ and ρ , which shows a correlation only when [V] = IV, which physically requires that $\gamma \leq 1$ infected cell per IV entry into cell (vertical dashed line).

which can be challenging [41]. Fortunately, Eqn. (2) shows how this conversion can be performed using the infection establishment probability, $\mathcal{P}_{V \to \text{Establishment}}$.

To explore the impact of representing V in units of infectious virions ([V] = IV) rather than SIN ([V] = SIN), we repeat the parameter estimation with the ODE model using \mathcal{L}_{ED} , this time using [V] = IV. In the previous section, where [V] = SIN, the ODE-predicted SIN concentration at time t in the \mathcal{L}_{ED} likelihood (Eqn. (5)) corresponds to $C^{\text{model}}(t) = V(t)/s$, where s = 10 ml is the total volume of supernatant in the SC and MC in vitro infections. When instead [V] = IV, $C^{\text{model}}(t) = [V(t)/s \cdot \mathcal{P}_{V \to \text{Establishment}}(\vec{\pi})]$, where $\mathcal{P}_{V \to \text{Establishment}}(\vec{\pi})$ is the infection establishment probability in the ED assay where the sample is measured, not that in the SC and MC infections from which it was drawn. If the SC and MC infections are performed under the same conditions as the ED assays (same cells, temperature, sample diluent, etc.), they should share MM parameters (have the same $\vec{\pi}$), except often for the number of cells and the volume of supernatant, which tend to differ between infection and measurement assays, but are known rather than estimated (see Methods, Table IV). Unfortunately, the SC and MC infections considered here were performed in A549 cells, whereas the ED assays were performed using MDCK cells. For simplicity, we assume the SC and MC infection experiments and the ED assay differ only in the number of cells ($N_{\text{cells}} \le N_{\text{cells},\text{ED}}$) and supernatant volume (s vs V_{inoc}), as detailed in Methods. This assumption is necessary because the ED assay alone does not provides sufficient information to estimate its MM parameters. It is nonetheless incorrect, and its impact will be explored in the Discussion.

FIG. 9. Parameter degeneracy between γ and β when V is in units of SIN. ODE-predicted (A) SIN and (B) total viral concentration time course for the MC infection over the first 48 hpi using the maximum a posteriori (MAP) parameter set (Table I, ODE,SIN, \mathcal{L}_{ED}) where γ and β are modified so as to keep their product ($\gamma\beta$) constant while γ is varied. (C) Paired MPD for the product $\gamma\beta$ as a function of β , based on an imposed artificial lower bound requiring $\beta \geq 10^{-10} \text{ ml} \cdot (\text{cell} \cdot \text{h})^{-1}$.

Figure 8 shows the impact of expressing V in the ODE model in units of SIN, as is typically done, rather than in units of IV. The change of units has no effect on the ODE-predicted total and infectious viral titre time courses (Figure 8A–D), nor on the estimated value of parameters τ_E , τ_I , and ρ_{RNA} (Figure 8E–G, Table I,II). It affects estimates of the production rate of V (ρ in $[V]/(\text{cell} \cdot \mathbf{h})$), the rate of loss of V due to cell entry (β in ml · (cell · h)⁻¹), and the number of cells infected per V entry (γ in cell/[V]). This is because these parameters have different units, or at least a different biological meaning, depending on whether [V] = SIN or IV, and thus cannot be compared.

When [V] = SIN, the SIN production rate (ρ , Figure 8H) is well constrained by the experimental data, but β and γ are correlated (Figure 7O). As γ is decreased and β is increased so as to keep their product ($\gamma\beta$) fixed, the rate of cell infection per SIN cell entry ($\gamma\beta TV/s$) is unchanged, but the rate of SIN loss to cell entry ($\beta TV/s$) increases. This results in a slower SIN and total viral titer growth rate and an increasingly more pronounced SIN titre loss at the start of the MC infection (Figure 9A,B), when the MOI is low and the number of available target cells absorbing SIN is large ($T \sim N_{\text{cells}}$). Experimentally measured viral titres at these early time points therefore provide an upper bound on β , and a corresponding lower bound on γ . In the other direction, as β decreases, the rate of SIN loss due to cell entry ($\beta TV/s$) becomes negligible, and the rate of cell infection ($\gamma\beta TV/s$) depends only on the product $\gamma\beta$: their individual value no longer matters (Figure 9C). Therefore, when [V] = SIN, it is necessary to impose a lower bound on β (upper bound on γ) to allow for their MPDs to be finite and therefore normalizable, albeit incorrect.

When the establishment probability of an infection initiated with a single infectious virion is less than one $(\mathcal{P}_{V \to \text{Establishment}} < 1 \text{ SIN/IV})$, one infectious dose (1 SIN) represents more than one infectious virion (1 IV). This makes it possible for one SIN to infect more than one cell ($\gamma > 1 \text{ cell/SIN}$), since one SIN represents more than one IV. Previous work analyzing the same data presented herein with a similar ODE model estimated a 95% CI for γ (parameter 1/n therein) of [1.2, 121] cell/TCID₅₀ [37]. Other work based on influenza A virus infections in mice estimated values in the range [7, 10³] cell/PFU based on multiple data sets [42]. Both works assumed that $\gamma \geq 1$ cell per infectious titre unit (e.g., PFU, TCID₅₀), i.e. that at least one cell or more should be infected per infectious dose lost to cell entry. But the entry of one SIN into a cell could also occasionally fail to cause its infection such that γ could also plausibly be slightly less than 1 cell/SIN. Here, it is the data which imposes the lower bound on γ (upper bound on β), while the artificially imposed lower bound on $\beta (\geq 10^{-10} \text{ ml/(cell \cdot h)})$ was chosen to be low enough that a further decrease in β does not meaningfully change the posterior distribution (flat MPD once $\beta \leq 10^{-8} \text{ ml/(cell \cdot h)}$, Figures 7J, 9C).

When instead [V] = IV, the rate of infectious virions loss to cell entry is well constrained (β , Figure 8J), but ρ and γ are correlated (Figure 8H,I,O). Figure 10 shows the effect of individually varying β , ρ , or γ on the ODE-predicted MC infection time course in IV (Figure 10A–C), their conversion to SIN (Figure 10D–F), and the total virus concentration (Figure 10G–I). While (γ , β) similarly affect the growth rate of the ODE-predicted V in IV (Figure 10A,B), the IV production rate (ρ) affects both the growth rate and the peak titre (Figure 10C). This is the same (γ , β) degeneracy reported when V is directly expressed in SIN (Figure 7O and 9C). The shift from a (γ , β) to a (γ , ρ) correlation (Figures 7O to 8O) arises when the ODE-predicted V is converted from infectious virions to measured infections (IV to SIN) to be compared against the experimentally measured SIN titres. This is accomplished by multiplying the number of infectious virions (IV) by the establishment probability ($\mathcal{P}_{V \to \text{Establishment}}$) which varies as β , ρ , or γ are varied. When $\mathcal{B} = \rho \tau_I \gg 1$, as is the case here (Figure 8L), the productive infection establishes depends only on the probability that one IV productively infects a cell ($\mathcal{P}_{V \to \text{Establishment} \approx \mathcal{P}_{V \to I}$, Figure 8K, Table I). Rewriting $\mathcal{P}_{V \to I}$ as $\gamma(\beta N_{\text{cells}}/s) + c$] shows why varying β , appearing in both the numerator and denominator, has a marginal impact on $\mathcal{P}_{V \to \text{Establishment}}$ and on the conversion of IV to SIN (e.g., no impact on peak titre, Figure 10A).

FIG. 10. Parameter degeneracy between γ and ρ when V is in units of IV. ODE-predicted (A,B,C) IV, (D,E,F) SIN and (G,H,I) total viral titre concentration over the course of the MC infection using the MAP parameter set (Table I, ODE,IV, \mathcal{L}_{ED}), and varying (A,D,G) β , (B,E,H) γ or (C,F,I) ρ by factors log-uniformly spaced over $[10^{-0.7}, 10^{0.7}]$ about their MAP value. ODE-predicted (J) IV, (K) SIN, and (L) total viral titre concentration when varying $\gamma = [0.03, 0.1, 0.3, 1.0]$ cell/IV and ρ simultaneously so as to keep their product ($\gamma\rho$) constant. The (K) infectious (SIN/ml) and (J,L) total (vRNA/ml) viral titre (open circles) experimentally measured over the course of the triplicate MC infections are also shown for comparison. In (D,E,F,K), the concentration in SIN is obtained by converting the ODE-predicted time courses in (A,B,C,J) from IV to SIN by multiplying V in IV by the establishment probability ($\mathcal{P}_{V \to \text{Establishment}}(\vec{\pi})$, Eqn. (2)).

vs. D). In contrast, reducing γ by some factor, reduces $\mathcal{P}_{V \to \text{Establishment}}$ and the conversion of the V curve to SIN by approximately the same factor (e.g., same fold decrease in peak titre, Figure 10B,E). Thus, after the ODE-predicted curve in IV is converted to SIN, γ has the same effect as ρ (Figure 10E,F), altering both the growth rate and peak titre, resulting in a (γ, ρ) correlation (Figure 8O). Since viral titre peak, after conversion to SIN, is proportional to both γ and ρ , a 3-fold decrease in γ with a corresponding 3-fold increase in ρ , wherein $\gamma\rho$ remains constant, shifts the IV curve upwards (higher IV peak, Figure 10J) but leaves the converted SIN curve unchanged (Figure 10K).

Importantly, when [V] = IV, it becomes possible to impose appropriate physical constraints on γ , the number of cells infected per IV lost to cell entry. At most $\gamma \leq 1$ cell/IV since it is impossible for a cell to become infected without the entry of at least one IV into the cell, setting a corresponding lower bound on the IV production rate by infected cells, ρ . In the other direction, as γ and thus $\mathcal{P}_{V \to \text{Establishment}}$ decrease, ρ and the ODE-predicted IV curve get increasingly high (Figure 10J) so that the product of V in IV and $\mathcal{P}_{V \to \text{Establishment}}$ continue to match the experimentally measured titres in SIN (Figure 10K). But γ cannot decrease (and the IV curve shift upward) indefinitely because, physically, the ODE-predicted number of IV cannot exceed the total number of experimentally observed virions (infectious and not), i.e. the number of viral RNA copies measured via qRT-PCR (Figure 10K,L). This lower bound on γ (upper bound on ρ) is imposed by rejecting (assigning a likelihood of zero to) any parameter

set $(\vec{\pi})$ that results in an ODE-predicted initial IV inoculum (V) exceeding the experimentally measured number of viral RNA at that time (V_{RNA}) , as part of the MCMC process to estimate the MM parameters when [V] = IV. We furthermore impose that $\rho \leq \rho_{\text{RNA}}$, ensuring that the V curve in IV remains below the V_{RNA} curve. The latter constraint had no impact because the total and infectious viral titre remaining after the inoculum rinse at t = 0 in the SC infection provides the most stringent constraint on $\mathcal{P}_{V \rightarrow \text{Establishment}}$ in the ED assay (≤ 0.174 , see Methods). This constrains ρ and γ to relatively narrow 95% CIs, despite their correlation (Figure 8H,I).

Wider credible intervals (95%CI) for $\mathcal{P}_{V \to I}$ and \mathcal{B} are obtained when [V] = IV compared to [V] = SIN (Figure 8K,L), yet this results in a somewhat better constrained R_0 (Figure 8M). A slightly smaller R_0 and t_{inf} are estimated when [V] = IV rather than SIN (Table I,II), but these differences are unlikely to be biologically meaningful given typical inter-experimental variability [44].

The establishment probability ($\mathcal{P}_{V \to \text{Establishment}}$), a biologically interesting quantity, can be computed from infection parameters when [V] = IV (it is identical to $\mathcal{P}_{V \to I}$, Figure 8K) but not when [V] = SIN. This is because it is impossible to know the relation between measured infections (SIN) and infectious virions (IV) from SIN alone, and consequently parameters in SIN cannot be converted to IV. This constitutes yet another advantage of expressing MM variables and parameters using [V] = IV.

E. ODE versus stochastic models of infection

The likelihood function \mathcal{L}_{ED} is derived from the SM, and while it is deterministic, it accounts for the random nature of the infections taking place or not in the ED assay (shown in Figure 5). Beyond this, results presented so far rely on the ODE to simulate the time course of the SC and MC infections. Now, the effect of using either the ODE or stochastic model (Eqn. (6) in Methods) to simulate the SC and MC infections on the parameter estimation and the MM-predicted infection time course is explored, using the \mathcal{L}_{ED} likelihood with [V] = IV.

One challenge in estimating parameters using a SM is that any one parameter set randomly gives rise to different SM-predicted infection time courses, each with a different likelihood given the experimentally measured data. We circumvent this issue by adding the random number seed (RNS) to the parameter set to be estimated by the SM compared to the ODE ($\vec{\pi}_{\text{SM}} = \vec{\pi}_{\text{ODE}} \cup \{\text{RNS}\}$). The RNS is used to initialize the pseudorandom number generator at the start of the SM simulation such that any one SM parameter set ($\vec{\pi}_{\text{SM}}$) corresponds to a single, deterministic infection time course with its associated likelihood. This is not without cost: it adds an additional dimension to the parameter space the MCMC process must explore, one where the likelihood is jagged, i.e. small changes in the RNS result in random, non-monotonic changes in \mathcal{L}_{ED} . In fact, small changes in the RNS can result in large fluctuations in certain areas of the parameter space, e.g. $V(0) \sim 1 \text{ IV or } R_0 \leq 1$. The cost of this additional parameter space dimension is in addition to the higher computational cost of numerically solving the SM over the ODE. Altogether, obtaining the final parameter set for the SM took $\sim 15 \times$ longer than for the ODE (27.5 days vs 1.79 days, see Methods). Nonetheless, adding the RNS to the SM parameters to be estimated offers a simple, practical solution to parameter estimation when using a SM.

Figure 11 shows that the SM yields viral time courses nearly indistinguishable from those of the ODE, and only very slight (insignificant) changes in the estimated parameters' MPDs, except for t_{inf} , the average time it takes for a newly infectious cell to infect its first cell, when neglecting infectious virus lost to decay or cell entry. While $t_{inf} = \sqrt{2/(\rho \cdot \gamma \beta N_{cells}/s)}$ in the ODE model for any one parameter set $\vec{\pi}$, the same $\vec{\pi}$ in the SM yields a distribution of t_{inf} values whose average is $\sqrt{\pi}/2 \approx 89\%$ that of the ODE model's value (see Methods), i.e. for identical parameters the infecting time in the ODE model is longer than the SM's average infecting time. Importantly, with the exception of t_{inf} , differences in the parameter posteriors estimated by the ODE and SM are all statistically insignificant (Table II), are smaller than those seen for the different likelihood functions and the units used to express V, and are unlikely to be biologically meaningful. This suggests that random effects play a negligible role over the course of the experimental in vitro virus infections studied here. This is comforting in light of recent work showing that, at least in some parameter regimes, stochasticity can result in established infection time course curves that have the same shape but are markedly shifted in time relative to the ODE-predicted curves [35, 36] (see also Figure 1).

Figure 12 shows the infection time course predicted by the ODE model, the mean-field version of the SM (MFSM, see Methods), and 10,000 realizations of the SM, for established infections initiated with either a single infectious virion (V(0) = 1 IV, top row) or for the MAP initial inoculum in the low MOI, multi-cycle infection (2259 IV, bottom row), based on the experimental initial inoculum (620 SIN, Table IV) and the MAP $\mathcal{P}_{V \to \text{Establishment}}$ (Table I). With a single infectious virion, the probability of infection extinction is high ($[1 - \mathcal{P}_{V \to \text{Establishment}}]^{V_0=1}$ IV ~ 72%) and there is a noticeable time shift between the median and mean of the SM-predicted established infections and the ODE and MFSM solutions (Figure 12A–C). With the estimated initial inoculum of 2259 IV in the MC experiment, the probability of infection is very low ($[1 - \mathcal{P}_{V \to \text{Establishment}}]^{2259}$ IV $\approx 10^{-320}$), and the SM-predicted established infections are normally distributed (Figure 12E,F) about their mean and median, and in agreement with

FIG. 11. Impact of the random nature of infections on parameter estimation. MM-predicted viral time courses and MPDs using the \mathcal{L}_{ED} with [V] = IV for the ODE model (ODE, solid purple) or stochastic model (SM, dashed olive). Panels (A–N) are as described in Figure 7, except for (L) \mathcal{B} , (M) R_0 , and (N) t_{inf} which, for the SM, correspond to the average of the distribution of values these quantities can take for a given $\vec{\pi}$. The average of the \mathcal{B} and R_0 SM distributions matches the ODE model's expressions, but this is not the case for $t_{\text{inf}} \operatorname{SM} = \sqrt{\pi}/2 \cdot t_{\text{inf}} \operatorname{ODE}^{\text{ODE}}$, see Methods). In (N) average t_{inf} in the SM ($t_{\text{inf}}^{\text{SM}}$, dashed olive) and the t_{inf} obtained when SM parameters are used directly in the ODE model's expression ($t_{\text{inf}}^{\text{ODE}}$, dotted grey) are shown. (O) $\mathcal{P}_{V \to \text{Establishment}}$ is the probability that an infection starting from 1 IV will become established, given the cell density in the ED assay ($N_{\text{cells,ED}}/V_{\text{inoc}}$), used to convert IV to SIN as per Eqn. (2).

ODE and MFSM solutions. Indeed, experimental infections, even those conducted at a low MOI, are designed to robustly result in established infections, i.e. the initial inoculum (V(0)) is chosen so that $[\mathcal{P}_{V \to \text{Extinction}}]^{V_0} \approx 0$, to avoid wasteful, failed experimental infections. So while the parameters estimated herein can lead to infections in which significant random effects could be observed (Figure 12A), by design such effects are not expected to play a meaningful role in experimental infections because of the chosen inoculum sizes.

The relatively small variation amplitude among the 10,000 SM-predicted solutions, however, is at odds with the larger inter-replicate variability commonly observed in measured titres over the course of experimental infections (Figure 11C vs Figure 12D). Figure 13A shows SM-simulated triplicate IV titre curves evaluated at each sampling time, using the MAP parameter set for the SM (Table I) where the three replicates were generated by using three different random number seeds (RNS). As in Figure 12D, very little variation is observed in Figure 13A between the SM-simulated triplicate IV concentrations at each sampling time, inconsistent with the experimentally observed variability (Figure 11C). Next, each IV data point in Figure 13A is used to simulate one realization of a stochastic ED assay, as described earlier (Figure 2), to obtain a corresponding data point in SIN/ml (Figure 13B). This process results in noticeable variability between the simulated SIN measurements at each sampling time. Indeed, the level of

FIG. 12. Effects of stochasticity on the distribution of infection time courses for different initial inocula. (A,D) Number of infectious virions (IV) as a function of time for an infection initiated with (A,B,C) 1 IV or (D,E,F) 2259 IV, the MAP initial inoculum in the MC infection experiment. The individual trajectories of 10 000 stochastic realizations that led to established infections (having discarded extinct infection), each initiated with a different random number seed, are shown (solid pale grey) along with their median (SM median) and mean (SM mean). The infection time course obtained with the ODE model and the mean-field version of the SM (MFSM), both using the SM's MAP parameter set (Table I) are shown for comparison. (B,E) The distribution of times at which the virus load curves pass $10^{6.2}$ IV, indicated as a horizontal dashed line in (A,D). (C,F) The distribution of infectious virions ($\log_{10} V$) at the specified time (70 h or 36 h) post-infection, indicated as a vertical dashed line in (A,D).

variability due to the ED assay is consistent with that observed experimentally (Figure 13A vs. C). This suggests that the ED assay accuracy alone is sufficient to explain the variability observed in the experimentally measured titers, and that other factors that could affect inter-replicate variability, such as stochastic variability, are possibly minor and likely negligible compared to ED assay variability.

III. DISCUSSION

The course and outcome of experimental virus infections are tracked via repeated sampling over time, and subsequent measurement of the virus concentration in the samples. In particular, a sample's virus infectivity is measured using an infectivity assay, such as a plaque or focus forming assay or a $TCID_{50}$ assay, which counts the number of infections the virus-containing sample can cause per unit volume. But some or even all of the infectious virions contained in the inoculant of an infectivity assay's wells can randomly fail to cause or to establish an infection, go uncounted, and hence affect the resulting measured infection concentration. The stochastic nature of infections in either the infection experiments itself or in the measurement of its samples via an infectivity assay, could have an important effect on our interpretation of the infection time course and on the mathematical estimation of its infection parameters.

By simulating a TCID₅₀ endpoint dilution (ED) assay, we demonstrated that the mathematical parameters of the infection determine the probability that an infectious virion (IV) contained within a sample will result in an established infection, and thus be counted as an infection-causing dose (or specific infection, SIN) by the assay. Specifically, we found that this probability ($\mathcal{P}_{V \to \text{Establishment}}$) decreases when decreasing the probability of a successful cell infection post viral entry (γ) or, to a lesser degree, the ratio between loss of virus due to cell entry and that due to loss of infectivity ($(\beta N_{\text{cells}}/s)/c$). In contrast, the average total number of infectious virions released by an infected cell over its infectious lifespan (mean burst size, $\mathcal{B} = \rho \cdot \tau_I$) and the shape parameter of the Erlang-distributed time spent by infected cells in the infectious phase (n_I), quantities that can have an effect on the extinction probability in principle, had a negligible effect. This is mostly because, in contrast to γ and ($\beta N_{\text{cells}}/s$)/c, \mathcal{B} and n_I affect the likelihood of infection establishment. We demonstrated that the experimentally measured infection causing dose concentration in a sample (e.g., SIN/ml) corresponds exactly to the product of the actual infectious virion

FIG. 13. Sources of noise in experimental infections. (A) SM-predicted IV concentration over time for the MC experiment, based on the MAP parameters, simulated in triplicate by using three different random number seeds (RNS) and evaluated at each experimental measurement time (circles). The grey band, hardly visible, represents the 95% CI of the IV concentration based on 10,000 SM-simulated infections (shown in Figure 12D). (B) Simulated SIN concentration over time obtained by simulating an ED assay for each IV concentration data point in (A). The grey band represents the 95% CI of the SIN concentration at each time point, obtained by simulating 10,000 ED assay outcomes for the SM-predicted IV concentration over the course of the experimental measurement time, based on the MAP parameters. (C) Experimentally measured SIN concentration over the course of the experimental MC infections performed in triplicate (circles) shown against the simulated ED 95% CI from (B) for comparison. Infectious titers in SIN/ml below the lower limit of detection (dashed grey, Table IV) are placed on the line.

concentration (IV/ml) and the establishment probability ($\mathcal{P}_{V \to \text{Establishment}}$ or $1 - \mathcal{P}_{V \to \text{Extinction}}$) of an infection initiated with one such infectious virion. By affecting the establishment probability, the infection parameters also affect the observed time course of experimentally measured SIN/ml over the course of the infection, the very data that is used to estimate their value.

Thus, we next considered whether explicitly and correctly accounting for the parameters' effect on experimental titer measurements, on which parameters depend for their estimation, would hinder or even preclude parameter estimation altogether. This was achieved in three stages, and parameter estimation was performed at each stage using experimental data from influenza A virus infection experiments previously analyzed [34]. Firstly, we considered the effect of the likelihood function, i.e. the metric by which we measure agreement between the mathematical model's prediction and experimental measurements. We compared the typical likelihood function which assumes the experimental concentration of \log_{10} SIN in a sample follows a normal distribution (\mathcal{L}_{NR}) versus a novel expression that correctly computes the likelihood of having experimentally observed the number of wells infected at each dilution of the ED assay given the ODE-predicted number of SIN in that sample (\mathcal{L}_{ED}). Secondly, we compared the effect of expressing the variable representing infectious virus in the ODE model directly using the experimental measurement units ([V] = SIN) versus using the more physically meaningful units of infectious virions ([V] = IV), and then using the model's parameters, and their corresponding $\mathcal{P}_{V \to \text{Establishment}}$, to convert the ODE-predicted IV into SIN for use in the new likelihood function (\mathcal{L}_{ED}). Thirdly, we compared the effect of the typical ODE model versus using a stochastic model (SM) to represent the course of the in vitro infections.

Changing the likelihood function (\mathcal{L}_{NR} vs \mathcal{L}_{ED}) had the largest impact on the estimated parameters, shifting the average value of all estimated parameters. However, none of the changes were statistically significant (Table II). An important advantage of the new \mathcal{L}_{ED} is that it correctly and trivially handles measurements below the ED assay's limit of detection, i.e., when, at all dilutions of the performed ED assay, either no well is infected or all are.

Changing the units by which infectious virus is expressed in the ODE model ([V] = SIN vs IV) had no effect on half of the parameters — the duration of the eclipse (τ_E) and infectious (τ_I) phases of an infected cell's lifespan, and the total virus production rate per cell (ρ_{RNA}) — but drastically changed the posterior distribution for the estimated rate of infectious virus production (ρ), the rate of virion loss due to cell entry (β), and the rate of cell infection per virus entry into cell (γ). This is because the physical meaning of these three parameters (ρ , β , γ) changes when the units used to represent virus in the ODE model change. For example, ρ is the number of SIN produced per cell per hour when [V] = SIN but it is the number of IV produced per cell per hour when [V] = IV. Importantly, when [V] = SIN, experimental measurements (total and infectious viral titer) constrain the value of ρ and of the product ($\gamma\beta$), and impose a lower bound on γ (upper bound on β). The measurements do not, however, provide an upper bound on γ (lower bound on β), compromising the estimation of these two parameters. This is because one SIN (one observed infection) can correspond to multiple infectious virions, allowing more than one cell to become infected per SIN cell entry ($\gamma > 1$ cell/SIN). In contrast, when [V] = IV, experimental measurements constrain the value of β and of the product ($\gamma\rho$), and measurement of total virus (viral RNA) imposes a lower bound on γ (upper bound on ρ) since there cannot be more infectious virions (IV) than there are virions counted in total (viral RNA). This highlights the critical importance of tracking both infectious (SIN) and total (vRNA) virus to properly constrain these parameters. A physical upper bound can be imposed on γ (lower bound on ρ) since entry of one infectious virion into a cell can at most result in the infection of one cell ($\gamma \leq 1$ cell/IV), and allowing for the individual estimates of γ and ρ to be well constrained. This is an important advantage of expressing [V] in infectious virions.

Another important gain in expressing virus in units of infectious virions is that it yields physically meaningful quantities. Experimental measurements of a virus sample's infectivity in units such as $TCID_{50}$, SIN, PFU, or FFU, represent a count of infections caused, not a count of the number of virions physically capable of causing infection, whether they go on to do so or not. Indeed, while the former is a shared, combined property of the virion, the cells, and experimental conditions such as temperature, medium used, inoculum incubation time, etc., i.e., it is specific to the infection conditions, the latter is an absolute property of the virion alone, independent of all other factors. The ODE and stochastic models consistently estimated that 1 SIN corresponds to 1.1 to 5.8 infectious virions (95% CI of $1/\mathcal{P}_{V \to \text{Establishment}}$ in ED), under the conditions of the experiments analyzed herein. Over the course of its infectious lifespan, we estimate that one A549 cell produced on average a total of 400 to 2000 infectious virions (95% CI of \mathcal{B}). This quantity, i.e. the actual number of infectious virions rather than the conditions-dependent infectious dose, has been computed previously, but typically has not included the probability of failure of infection post virus entry into a cell (γ), and has relied on a guess as to the infectious virion production rate (ρ) and the rate of cell entry by infections virions (β), e.g. [27, 28, 32]. For example, in Pearson et al. [27], the average burst size ($\rho \cdot \tau_I$), hence ρ , is guessed to be 10 IV/cell and β is chosen in order to have a "sensible" value for the basic reproductive number (R_0), which is computed using the guessed burst size value. We found that it takes on average 1 to 5 infectious virion cell entry for one successful cell infection (95% CI of $1/\gamma$). To our knowledge, this is the first time that this quantity has been estimated. It is consistent with an earlier report that approximately 50% of influenza A virus cell entry fail to result in successful fusion of the virion with its endosome [45, 46]. This would correspond to 2 infectious virion cell entry per successful cell infection, but it could be less if some non-infectious virions are capable of cell entry, and it could be more if other steps than fusion contribute to infection failure of otherwise fully infectious virions, which are both likely.

Changing from an ODE to a stochastic model to simulate the course of the infection had the smallest impact out of the three stages, despite its important increase (15-fold) in the computational cost required to estimate the parameters. The amount of variability observed with the stochastic model is largest, and its solutions deviate most from those of the ODE model, when the infection's establishment probability is low. Since experimental virus infections in vitro, even those inoculated with a relatively low MOI, are designed to ensure infection will take hold, it is not surprising that our estimated establishment probability was essentially 100%, resulting in insignificant stochastic fluctuations per the stochastic model's predictions. Yet the low level of stochasticity predicted by the SM's solutions was inconsistent with the much greater amount of variability observed between infection replicates. When the SMpredicted number of infectious virions over the course of the infection was used in simulated stochastic ED assays, the resulting estimated SIN concentration at each of the simulated sampling time points was consistent with the experimental inter-replicate variability. These findings suggest that inter-replicate noise in infection experiments is introduced primarily by the infectivity measurement assays, such as the ED assay. This means inter-replicate variations could be reduced significantly by improving ED assay accuracy, e.g. by decrease the dilution factor or increasing the number of replicates per dilution of the ED assay [25].

There are a number of limitations to the analyses and results reported herein. Firstly, we assumed that one viral RNA, as measured via qRT-PCR, equals one virion. This assumption, which is highly dependent on having a wellvalidated standard curve, affects the lower bound constraint on γ when [V] = IV because we require that there be no more infectious virions than there are vRNAs. Herein, this constraint was imposed by a single pair of points: the total (vRNA) and infectious (SIN) viral titers measured after the inoculum rinse at t = 0 in the single-cycle infection experiment (see Methods). Secondly, we assumed that the state of the virions when they are sampled from the infection supernatant is the same as that when they were inoculated into the ED assay wells, i.e. the number of IV/ml is unchanged. Most likely, a fraction of the virions sampled from the infection experiments lost their infectivity either prior to freezing, as a result of being frozen, or post-thaw — by the time they were inoculated onto the ED assay wells to be measured. It has been reported that there can be a 10-fold reduction in the number of infections a sample will cause, measured by plaque assay, after each freeze/thaw cycle [47]. This means that there were more IV in the infection experiment than were counted in the ED assay. This could easily be remedied by performing two ED assays for a few samples: one immediately after they were harvested from the infection experiment and another after the sample was frozen and thawed, as per normal protocols. By comparing these two SIN measures, one could correctly account for the proportion of virion infectivity loss associated with the more convenient and common protocol. This assessment would have to be repeated whenever experimental conditions change, e.g. for different cell types or virus strains or if different buffers are added prior to freezing samples.

Thirdly, and perhaps most critically, we had to assume that the ED assay and infection experiments were conducted

But performing the infection experiments and the ED assay in different cell types is not only a concern for the methodology introduced herein, but more generally will result in misleading interpretations of virological data. Consider two viruses: virus A is more infectious in MDCK cells (more SIN/IV in the ED assay) than in A549 (fewer infections/IV in the infection experiment), but the opposite is true for virus B. If virus A and B are inoculated at equal MOI based on their ED assay-assessed infectivity, an equal number of SIN of virus A and B based on the ED assay will result in an actual infection MOI that is smaller for virus A than for virus B, i.e. virus A will cause the infection of possibly far fewer cells (at supposedly equal MOI). This will make virus A appear to take more time to reach peak titer (because it caused fewer initial infections), but will make it appear as though it reaches a higher peak titer (because titer is measured in MDCK cells). For these reasons, any future work should ensure that the ED assay and infection experiments are conducted in the same cells, under the same conditions (temperature, medium content, etc.), except for the number of cells and total inoculum volume which can be accounted for mathematically, as was done herein.

In conclusion, based on the analysis herein, we would recommend that future work: (1) measure both total and infectious virus titer over the course of experimental infections; (2) make use of the TCID_{50} ED assay to quantify virus infectivity; (3) that the ED assay and infections be performed in the same cells and under similar experimental conditions; (4) that parameter estimation be performed using the physically accurate likelihood function introduced herein (\mathcal{L}_{ED}); and (5) that units of infectious virions rather than infectious dose (e.g. TCID_{50} , SIN, PFU, FFU) be used to express virus in the mathematical model. We do not, however, recommend the use of a stochastic model to simulate the course of experimental infections in vitro because its higher computational cost did not translate to any meaningful differences in the estimated parameters.

IV. METHODS

A. Mathematical models

The ordinary differential equation (ODE) model and its stochastic model (SM) counterpart used herein are given by

$$\begin{aligned} \frac{dT}{dt} &= -\gamma\beta TV/s & T^{t+1} = T^t - N^{\inf} \\ \frac{dE_1}{dt} &= \gamma\beta TV/s - \frac{n_E}{\tau_E} E_1 & E_1^{t+1} = E_1^t + N^{\inf} - E_1^{out} \\ \frac{dE_i}{dt} &= \frac{n_E}{\tau_E} E_{i-1} - \frac{n_E}{\tau_E} E_i & E_i^{t+1} = E_i^t + E_{i-1}^{out} - E_i^{out} & i = 2, 3, ..., n_E \\ \frac{dI_1}{dt} &= \frac{n_E}{\tau_E} E_{n_E} - \frac{n_I}{\tau_I} I_1 & I_1^{t+1} = I_1^t + E_{n_E}^{out} - I_1^{out} & j = 2, 3, ..., n_I \\ \frac{dI_j}{dt} &= \frac{n_I}{\tau_I} I_{j-1} - \frac{n_I}{\tau_I} I_j & I_j^{t+1} = I_j^t + I_{j-1}^{out} - I_j^{out} & j = 2, 3, ..., n_I \\ \frac{dV}{dt} &= \rho \sum_{j=1}^{n_I} I_j - cV - \beta TV/s & V^{t+1} = V^t + V^{\text{prod}} - V^{\text{decay}} - V^{\text{enter}} \\ \frac{V_{\text{RNA}}}{dt} &= \rho_{\text{RNA}} \sum_{i=1}^{n_I} I_j - c_{\text{RNA}} V_{\text{RNA}} - \beta TV/s & V_{\text{RNA}}^{t+1} = V_{\text{RNA}}^t + V_{\text{RNA}}^{\text{prod}} - V_{\text{RNA}}^{\text{decay}} - V^{\text{enter}} \end{aligned}$$

and are largely identical to those introduced and used in [33]. The SM is similar to the ODE model, where SM variables denoted with a superscript t are whole numbers, e.g. T^t represents the discrete number of target cells at time t. The remaining terms in the SM, corresponding to changes in the SM variables, are random whole numbers, generated at each time step as described in Table III. V^{prod} is drawn from $\text{Binomial}(n = V^{\text{prod}}_{\text{RNA}}, p_{\pi} = \rho/\rho_{\text{RNA}})$ rather than $\text{Poisson}(\lambda = \Delta t \cdot \rho \sum_{j=1}^{n_I} I_j^t)$ as in [33] so that, at each time step, there is never more infectious than total virions

d

TABLE III. Random variables of the SM.

Random variable	Random number generator
E_i^{out}	Binomial $(n = E_i^t, p_E = \Delta t \cdot n_E / \tau_E)$ where $i = 1, 2,, n_E$
I_j^{out}	Binomial $(n = I_j^t, p_I = \Delta t \cdot n_I / \tau_I)$ where $j = 1, 2,, n_I$
V^{prod}	$\text{Binomial}(n = V_{\text{RNA}}^{\text{prod}}, p_{\pi} = \rho / \rho_{\text{RNA}})$
$V_{ m RNA}^{ m prod}$	$Poisson(\lambda = \Delta t \cdot \rho_{RNA} \sum_{j=1}^{n_I} I_j^t)$
$V^{\text{decay}}, V^{\text{enter}}, V^{\text{remain}}$	Trinomial $(n = V^t, p_1 = \Delta t \cdot c, p_2 = \Delta t \cdot \beta T^t / s, p_3 = 1 - p_1 - p_2)$
$V_{ m RNA}^{ m decay}$	$Binomial(n = V_{RNA}^t, p_d = \Delta t \cdot c_{RNA})$
N^{inf}	$ \{x_i x_i \in \mathcal{U}\{a=1, b=T^t\}, 1 \le i \le V^{\mathrm{suc}}\} ^{\dagger}$
	where $V^{\text{suc}} = \text{Binomial}(n = V^{\text{enter}}, p_V = \gamma)$

[†] N^{inf} is equal to the cardinality, i.e. the number of unique elements, of the set of V^{suc} random numbers drawn from the discrete uniform distribution over the interval $[0, T^t]$.

produced. The total number of virions, V_{RNA} , is expressed in units of vRNA and variable V corresponds either to the number of infection-causing doses (SIN) or infectious virions (IV). We further consider the mean-field solution to the SM (MFSM) wherein the distributions for the SM's random variables in Table III are replaced by their average. In the ODE, MFSM, and SM, cells and viruses are counts (e.g., T = 1.3 cells in ODE and MFSM, and either 1 or 2 in the SM) rather than concentrations.

In numerically solving the SM, the duration of the discrete time steps, Δt , are computed at each iteration step t as

$$\Delta t = \frac{p_{\text{events}}}{\max\left\{\frac{\beta T^t}{s}, c, c_{\text{RNA}}, \frac{n_E}{\tau_E}, \frac{n_I}{\tau_I}\right\}}$$
(7)

where $p_{\text{events}} = 0.05$ (or 5%) is the probability of occurrence of the most likely event (see Table III), which was shown in Quirouette et al. [33] to correspond to sufficiently small steps so as to provide an accurate solution.

An important feature of the SM is that an infection can become extinct rather than established, i.e. it can randomly fail to take hold or spread significantly. The extinction probability of an infection given that there is initially one infectious virion, $\mathcal{P}_{V\to \text{Extinction}}$, was derived in [33] for this SM and is given in Eqn. (1). The establishment probability of an infection given that there is initially one infectious virion, $\mathcal{P}_{V\to \text{Extinction}}$, was derived in [33] for this SM and is given in Eqn. (1).

B. Base infection parameters

The base infection parameters, used in Figures 1, 4 and 5, were adapted from those reported in Simon et al. [34] for the seasonal influenza A virus strain A/Canada/RV733/2003 (a A/New Caledonia/20/1999-like clinical isolate), i.e. $\tau_E = 7$ h, $n_E = 60$, $\tau_I = 41$ h, $n_I = 60$, c = 0.0573 h⁻¹. The ODE model in Simon et al. [34] does not have separate terms to represent rate of virions loss to cell entry ($\beta TV/s$) and rate of cell loss to infection ($\gamma\beta TV/s$) and did not estimate γ . Unless otherwise stated, base values of $\gamma = 1$ cell/IV and s = 1 ml were used. Additionally, infection parameters that include units of tissue culture 50% infectious dose (TCID₅₀) were modified to have units of infectious virions (IV) by assuming that 1 TCID₅₀ ≈ 0.56 SIN [23] and 1 SIN ≈ 1 IV for simplicity. Parameter $\beta_{\text{TCID}_{50}}$ in Simon et al. [34] corresponds roughly to $\gamma\beta/s$ in our SM and thus was set to $\beta_{\text{TCID}_{50}} \cdot s \cdot (1 \text{ TCID}_{50}/0.56 \text{ SIN}) \cdot (1 \text{ SIN}/1 \text{ IV}) =$ $10^{-5.0}$ ml/(cell \cdot h). The infectious virus production rate per volume in Simon et al. [34], $\rho_{\text{TCID}_{50}}$, corresponds to $\rho \cdot s$ in our SM and thus was set to $\rho_{\text{TCID}_{50}}/s \cdot (0.56 \text{ SIN}/1 \text{ TCID}_{50}) \cdot (1 \text{ IV}/1 \text{ SIN}) = 10^{0.86} \text{ IV}/(\text{cell} \cdot \text{h}).$

C. Simulations of endpoint dilution (ED) assay experiments

The process of simulating an ED assay outcome, illustrated in Figure 2, was used to produce Figures 4, 5, and 13B. A simulated ED assay experiment for a virus sample with an actual infectious virion concentration C_{actual} begins by determining the random number of IV deposited in each well of replicate row *i* in dilution column *j*, $V_0^{i,j}$. These random numbers are drawn from $\text{Binomial}(n_j = V_{\text{inoc}}\mathcal{D}_j/V_{\text{vir}}, p = C_{\text{actual}}V_{\text{vir}})$ where V_{inoc} is the total volume of inoculum placed in each well, $\mathcal{D}_j \in (0, 1]$ is the dilution factor for column *j*, and $V_{\text{vir}} = 5.236 \times 10^{-16}$ ml [48] is the volume of a single influenza A virion (see Cresta et al. [25] for details). To determine whether any one well becomes

Parameter	Symbol	Value
Infectious virus clearance rate	с	$0.0573 \ h^{-1}$
Total virus clearance rate	$c_{\rm RNA}$	$0.001 \ h^{-1}$
# of eclipse compartments	n_E	60
# of infectious compartments	n_I	60
# of cells in SC/MC infections	$N_{\rm cells}$	1.9×10^6 cells
Total volume in SC/MC infections	s	10 ml
Dilution due to sampling in SC/MC infections	$f_{\rm sampling}$	0.95
SC initial infectious titre pre-rinse	$V(-1 h)_{\rm SC}$	based on MOI=3
SC initial infectious titre post-rinse	$V(0)_{\rm SC}$	$10^7 \ \mathrm{SIN}^b$

TABLE IV. Fixed initial conditions a and parameters of the MM and likelihood function

^a In the SM, initial conditions for cells and virus are rounded to the nearest integer.

^b When [V] = IV, Eqn. (2) is used to convert SIN to IV based on the MM parameters.

infected, a uniform random number $r \in [0, 1)$ is drawn, and the well is uninfected if $r < (\mathcal{P}_{V \to \text{Extinction}})^{V_0^{1,j}}$, and infected otherwise. As a final step, the most likely \log_{10} infectious dose concentration $(\log_{10}(\text{SIN/ml}))$ is determined by providing the number of infected wells in each dilution column to the midSIN calculator [25].

D. Simulating the single- and multiple-cycle infections

The ODE or stochastic models in Eqn (6) was used to simulate the experimental single-cycle (SC) and multiple-cycle (MC) infections described and analyzed in Simon et al. [34], following a similar procedure. In the SC experiment, the virus was inoculated onto the cells at t = -1 h to achieve a MOI of 3 within one hour, and the cell culture was rinsed at time t = 0 h to remove any virus still present from the high inoculum. The simulated SC infection was initiated at t = -1 h, with all cells considered uninfected and susceptible $(T(-1 \text{ h}) = N_{\text{cells}} = 1.9 \times 10^6 \text{ cells}$, and $E_i = I_j = 0$). The initial number of vRNA, $V_{\text{RNA}}(-1 \text{ h})_{\text{SC}}$, was set to the single qRT-PCR total viral concentration measurement taken at that time (vRNA/ml) multiplied by the inoculum volume s = 10 ml. The initial number of SIN or IV, $V(-1 \text{ h})_{\text{SC}}$, was set so as to achieve the experimental multiplicity of infection (MOI = 3) within the 1 h incubation time given the parameters ($\vec{\pi}$), as follows. The expected fraction of uninfected cells for a given multiplicity of infection (MOI) is $\approx e^{-MOI}$ [49]. During the incubation period, which is shorter than the average length of the eclipse phase, one can assume that virus production is negligible. Therefore, the kinetics of target cells (T) and infectious titre (V) over this period of time can be represented by

$$\frac{\mathrm{d}T}{\mathrm{d}t} = -\gamma\beta TV/s$$

$$\frac{\mathrm{d}V}{\mathrm{d}t} = -cV - \beta TV/s \tag{8}$$

23

The initial amount of infectious virus $V(-1 \text{ h})_{SC}$ to achieve a given MOI at t = 0 can be determined by finding the root of the function that takes $V(-1 \text{ h})_{SC}$ as an argument and returns the difference $[T(0)/N_{\text{cells}} - e^{-\text{MOI}}]$, where T(0) is determined by numerically solving Eqn. (8) with initial conditions $V(-1 \text{ h})_{SC}$ which is to be determined and $T(-1 \text{ h})_{SC} = N_{\text{cells}}$. The number of SIN and vRNA post-rinse at time t = 0 h, $V(0)_{SC}$ and $V_{\text{RNA}}(0)_{SC}$, was set to the geometric mean of all experimental measurements from 0 hpi up to 3.5 hpi, in SIN/ml or vRNA/ml, multiplied by s. If the MM expresses $V(0)_{SC}$ in IV, the value in SIN is converted to IV as per Eqn. (2), where $\mathcal{P}_{V \to \text{Establishment}} = (1 - \mathcal{P}_{V \to \text{Extinction}})$ is determined based on the MM parameters (Eqn. (1)).

The MC infection is initiated at time t = 0 h with no rinse thereafter, since the inoculum is small in order to have multiple rounds of cell infections, i.e. multiple cycles. At t = 0, all cells are considered uninfected and susceptible $(T(0 \text{ h})_{\text{MC}} = N_{\text{cells}} = 1.9 \times 10^6 \text{ cells}$, and $E_i = I_j = 0$). The initial number of SIN and vRNA, $V(0)_{\text{MC}}$ and $V_{\text{RNA}}(0)_{\text{MC}}$, was set to the geometric mean of all experimental measurements up to 7 hpi in SIN/ml or vRNA/ml, multiplied by the volume of supernatant s = 10 ml. When $V(0)_{\text{MC}}$ is expressed in IV, SIN converted to IV using Eqn. (2), as in the SC simulation.

Over the course of both the SC and MC experimental infections, at each sampling time, 0.5 ml of the 10 ml supernatant is removed for virus quantification, and replaced with 0.5 ml of fresh media. In the ODE model, this dilution of the supernatant at each sampling time is implemented by multiplying V and V_{RNA} by factor $f_{\text{sampling}} = 1-(0.5 \text{ ml})/(10 \text{ ml}) = 0.95$. In the SM, a binomial random variable with a probability of success of $p = f_{\text{sampling}} = 0.95$ is used to determine how many V and V_{RNA} particles will remain after the sampling.

As in Simon et al. [34], the number of compartments for the eclipse and infectious phases were fixed so that time spent in the eclipse or the infectious phase follows a normal-like distribution [38], i.e. $n_E = n_I = 60$. The values of the rate of infectious and total viral decay were fixed to the values determined in Simon et al. [34], c = 0.0573 h⁻¹ and $c_{\rm RNA} = 0.001$ h⁻¹, based on a viral decay (mock-yield) assays performed therein. Table IV summarizes all the fixed parameters and initial conditions used in simulating these infections.

E. Measurements' likelihood and parameter estimation

The posterior probability of a given parameter set, $\vec{\pi}$, given the set of all total and infectious viral titre measurements over the course of the SC and MC infections, $\{\text{data}\} = \{C_{\text{SC}}^{\text{data}}, C_{RNA,SC}^{\text{data}}, C_{RNA,MC}^{\text{data}}\}$, is given by

$$\mathcal{P}_{\text{post}}(\vec{\pi}|\{\text{data}\}, \text{MM}) \propto \mathcal{L}_{V_{\text{RNA}}}(C_{\text{RNA}}^{\text{data}}|\vec{\pi}, \text{MM}) \cdot \mathcal{L}_{V}(...|..., \vec{\pi}, \text{MM}) \cdot \mathcal{P}_{\text{prior}}(\vec{\pi})$$
(9)

where $\mathcal{P}_{\text{prior}}(\vec{\pi})$ is the prior probability of $\vec{\pi}$ which includes any known physical constraints or any prior knowledge, and $\mathcal{L}_{V_{\text{RNA}}}$ and \mathcal{L}_{V} correspond to the likelihood of the observed experimental measurements of the total and infectious viral titre concentrations in the supernatant samples collected in triplicate at each time point over the course of the in vitro infections.

The likelihood of the total viral titre measured via qRT-PCR in units of vRNA/ml in both the SC and MC infections is given by

$$\mathcal{L}_{V_{\text{RNA}}}(C_{\text{RNA}}^{\text{data}}|\vec{\pi}, \text{MM}) = \prod_{r=1}^{3} \prod_{t=t_{\text{SC}}} \exp\left\{-\frac{\left[\log_{10} C_{\text{RNA,SC},r}^{\text{data}}(t) - \log_{10} C^{\text{model}}(t|\vec{\pi})\right]^{2}}{2\sigma_{\text{RNA,SC}}^{2}}\right\} \\ \cdot \prod_{r=1}^{3} \prod_{t=t_{\text{MC}}} \exp\left\{-\frac{\left[\log_{10} C_{\text{RNA,MC},r}^{\text{data}}(t) - \log_{10} C^{\text{model}}(t|\vec{\pi})\right]^{2}}{2\sigma_{\text{RNA,MC}}^{2}}\right\}$$
(10)

where $C_{\text{RNA,SC},r}^{\text{data}}(t)$ is the experimentally measured vRNA/ml, t are the sampling times which are distinct in the SC and MC infections, r = 1, 2, 3 is the infection replicate since both the SC and MC infections were performed in triplicate, and $C^{\text{model}}(t|\vec{\pi}) = V_{\text{RNA}}(t)/s$ is the MM-predicted vRNA for the simulated SC or MC infection divided by s = 10 ml, the total volume of supernatant in the SC and MC infections. The standard deviations of the \log_{10} total viral titre measurements, $\sigma_{\text{RNA,SC}} = 0.237$ and $\sigma_{\text{RNA,MC}} = 0.258$, were estimated individually for the SC and MC infections, and fixed to the standard deviation of the residuals between the three measurements of $\log_{10}(C_{\text{RNA}}^{\text{data}})$ at each sampling time and their mean, pooled over all time points.

For the likelihood of the infectious viral titre measured via an ED assay over the course of the SC and MC infections, $\mathcal{L}_V(...|..., \vec{\pi}, \text{MM})$ in Eqn. (9), two different distributions were explored. Figures 15 and 14 shows these two likelihood functions at each sampling time over the course of the SC and MC infections, computed at each time from the three measurements sampled from replicate infections.

FIG. 14. Standard (\mathcal{L}_{NR}) and alternative (\mathcal{L}_{ED}) likelihood functions over all MC infection samples. Comparison of the relative probability (y axis) of the three infectious titres measurements, given the $\log_{10}(SIN/ml)$ predicted by the MM (x axis), as computed according to either \mathcal{L}_{NR} (blue, solid) or \mathcal{L}_{ED} (orange, dashed). The relative probability shown is the combined probability for all 3 experimental measurements taken over all sampling times over the course of the MC infections, indicated as black × along the bottom of each graph. The vertical dashed line for measurements at ≤ 6 h corresponds to the lower limit of detection of the ED assay (C_{LLoD} , Table IV).

The standard likelihood function, denoted \mathcal{L}_{NR} , is based on the assumption of normally distributed $\log_{10}(V)$ residuals, as was used for the vRNA measurements, namely

$$\mathcal{L}_{V}(C^{\text{data}}|\vec{\sigma},\vec{\pi},\text{MM}) = \prod_{r=1}^{3} \prod_{t=t_{\text{SC}}} \mathcal{L}_{\text{NR}}(C^{\text{data}}_{\text{SC},r}(t)|\sigma_{\text{SC}},\vec{\pi},\text{MM}) \cdot \prod_{r=1}^{3} \prod_{t=t_{\text{MC}}} \mathcal{L}_{\text{NR}}(C^{\text{data}}_{\text{MC},r}(t)|\sigma_{\text{MC}},\vec{\pi},\text{MM})$$
(11)

where C^{data} are the midSIN-estimated SIN/ml concentrations of each measured sample, \mathcal{L}_{NR} is defined in Eqn. (4), and the standard deviations of the log₁₀ infectious titre measurements, $\sigma_{\text{SC}} = 0.247$ and $\sigma_{\text{MC}} = 0.240$, for the SC and MC infections, respectively, were estimated based on log₁₀(C^{data}) in the same manner as those for the vRNA measurements.

The alternative likelihood for the infectious viral titres, denoted \mathcal{L}_{ED} , is the likelihood of the observed ED outcomes

FIG. 15. Standard (\mathcal{L}_{NR}) and alternative (\mathcal{L}_{ED}) likelihood functions over all SC infection samples. Comparison of the relative probability (y axis) of the three infectious titres measurements, given the $\log_{10}(SIN/ml)$ predicted by the MM (x axis), as computed according to either \mathcal{L}_{NR} (blue, solid) or \mathcal{L}_{ED} (orange, dashed). The relative probability shown is the combined probability for all 3 experimental measurements taken over all sampling times over the course of the SC infections, indicated as black × along the bottom of each graph.

(number of positive wells in each dilution column of the assay) for each virus titre sample, namely

$$\mathcal{L}_{V}(\vec{k}^{\text{data}}|\vec{n}^{\text{data}}, \vec{\mathcal{D}}^{\text{data}}, V_{\text{inoc}}, \vec{\pi}, \text{MM}) = \prod_{r=1}^{3} \prod_{t=t_{\text{SC}}} \mathcal{L}_{\text{ED}}(\vec{k}^{\text{data}}_{\text{SC},r}(t) | \vec{n}^{\text{data}}_{\text{SC},r}(t), \vec{\mathcal{D}}^{\text{data}}_{\text{SC},r}(t), V_{\text{inoc}}, \vec{\pi}, \text{MM}) \times \prod_{r=1}^{3} \prod_{t=t_{\text{MC}}} \mathcal{L}_{\text{ED}}(\vec{k}^{\text{data}}_{\text{MC},r}(t) | \vec{n}^{\text{data}}_{\text{MC},r}(t), \vec{\mathcal{D}}^{\text{data}}_{\text{MC},r}(t), V_{\text{inoc}}, \vec{\pi}, \text{MM})$$
(12)

where $\{\vec{k}^{\text{data}}, \vec{n}^{\text{data}}, \vec{\mathcal{D}}^{\text{data}}\}$ is the set of all observed ED outcomes, when an outcome is something like $\vec{k}_{\text{SC},r}^{\text{data}}(t) = (8, 8, 8, 5, 5, 0, ...)$, for each measured sample, and \mathcal{L}_{ED} is defined in Eqn. (5).

The ODE model has 6 MM parameters, $\vec{\pi}_{\text{ODE}} = (\beta, \gamma, \rho, \rho_{\text{RNA}}, \tau_E, \tau_I)$, to be estimated from the total and infectious viral titre measurements taken over the SC and MC infections. The SM has one additional parameter: the random number seed (RNS). Linear uniform priors are assumed for $\tau_E \in [0, \infty)$, $\tau_I \in [0, \infty)$, and RNS. Based on numpy's random module, RNS must be an integer $\in [0, 2^{32})$. A \log_{10} uniform prior was assumed for all other estimated parameters such that

$$\mathcal{P}_{\rm prior}(\vec{\pi}) \propto \frac{1}{\gamma \cdot \beta \cdot \rho \cdot \rho_{\rm RNA}} \tag{13}$$

where $\rho_{\text{RNA}} \in [0, \infty)$, and bounds on the remaining parameters depends on the units of [V]. When [V] = SIN, both ρ and $\gamma \in [0, \infty)$, but $\beta \in [10^{-10} \text{ ml/(cell} \cdot h), \infty)$ because the data does not inform β 's lower bound, as explained in the text. When [V] = IV, $\beta \in [0, \infty)$, $\gamma \in [0, 1]$ IV/cell, and $\rho \in [0, \rho_{\text{RNA}} \times (1 \text{ IV/vRNA})]$ since we cannot produce more IV than we produce virions. In addition to these bounds on individual parameters, we further constrain $\vec{\pi}$ by rejecting unphysical outcomes when [V] = IV. Specifically, we require that all initial infectious titers, which are expressed in SIN in Table IV ($V(-1 \text{ h})_{\text{SC}}$, $V(0)_{\text{SC}}$, $V(0)_{\text{MC}}$), once converted to IV (wherein $V_{\text{IV}} = V_{\text{SIN}}/\mathcal{P}_{V \to \text{Establishment}}$), result in no more IV than there are virions (vRNA) measured at that time ($V_{\text{RNA}}(-1 \text{ h})_{\text{SC}}$, $V_{\text{RNA}}(0)_{\text{SC}}$, $V_{\text{RNA}}(0)_{\text{MC}}$), i.e. $V_{\text{IV}} = V_{\text{SIN}}/\mathcal{P}_{V \to \text{Establishment}} \leq V_{\text{RNA}}$ or $\mathcal{P}_{V \to \text{Establishment}} \geq V_{\text{SIN}}/V_{\text{RNA}}$. Of all infectious and total viral titers pairs, those measured post-rinse in the SC infection impose the highest (and thus the only relevant) lower bound, namely $\mathcal{P}_{V \to \text{Establishment}} \geq (10^{7.01}/10^{7.77}) = 0.174$.

A Markov chain Monte Carlo (MCMC) method, as implemented by phymcmc [50] which itself relies on the emcee Python module [51], was used to estimate the parameter posterior distributions (PDs). Given the high degree of correlation between γ and β when [V] = SIN, parameters (γ,β) are replaced with $(a_{SIN} = \gamma \cdot \beta, b_{SIN} = \gamma/\beta)$ in $\vec{\pi}$ as the parameters to be estimated, such that $\gamma = \sqrt{a_{SIN} \cdot b_{SIN}}$, $\beta = \sqrt{a_{SIN}/b_{SIN}}$, and $\mathcal{P}_{prior}(\vec{\pi}) = (a_{SIN} \cdot b_{SIN} \cdot \rho \cdot \rho_{RNA})^{-1}$. Replacing the two highly correlated parameters (γ,β) , with two orthogonal quantities (a_{SIN}, b_{SIN}) allows for faster convergence because the product $\gamma \cdot \beta$ is well-constrained by the data. Similarly, when [V] = IV, γ is highly correlated with ρ , and (γ,ρ) are replaced with $(a_{IV} = \gamma \cdot \rho, b_{IV} = \gamma/\rho)$ in $\vec{\pi}$, such that $\gamma = \sqrt{a_{IV} \cdot b_{IV}}$, $\rho = \sqrt{a_{IV}/b_{IV}}$, and $\mathcal{P}_{prior}(\vec{\pi}) = (a_{IV} \cdot b_{IV} \cdot \beta \cdot \rho_{RNA})^{-1}$. Two-dimensional pairwise marginalized posterior distributions (MPDs) for all MM variants are provided in Figures 16–19.

The MCMC runs for each variation explored herein were composed of multiple sequential rounds of 300 walkers performing 10 000 MCMC steps, each started from the end of the previous one, except for the first round which was normally distributed around a reasonable parameter set. The emcee-provided function autocorr.integrated_time was used to estimate the amount of autocorrelation between successive MCMC steps, which in turn was used to choose the number of steps to discard at the start of the first chain ($\sim 2.5 \times$ the autocorrelation time) to eliminate any residual effect from the chosen initial starting positions, and the thinning factor to apply to each chain (at least half of the autocorrelation time). The final posterior distribution for each variation, after the 2 000 step burn-in and the thinning, keeping one step out of every [50, 180] steps, were applied, comprised 500 000 steps.

Computationally, each of the sequential MCMC round of 300 chains of 10 000 steps took ~ 4.3 h with the ODE model compared to ~ 22 h with the SM, using all threads of the 36 cores, dual-threaded, 3.5 GHz Intel Xeon 8360Y processors. The autocorrelation time for the ODE with [V] = IV was the shortest (~100 steps), followed by the ODE with [V] = SIN (~200 steps), with the longest being that for the SM with [V] = IV (~300 steps). This means that, in addition to taking 5× longer to accept 10 000 steps, 3× more MCMC rounds had to be performed to account for the 3× higher thinning factor applied to chains for the SM. In total, obtaining the final 500 000 independent parameter sets took ~ 15× longer using the SM (27.5 days) compared to the ODE model (1.79 days).

The 95% CI for the MM-predicted viral time courses (e.g., panels (A–D) in Figures 7, 8, 11), were obtained by drawing 10,000 parameter sets at random with replacement from the 500 000 parameter sets that make up the MCMC-estimated posteriors, and using them to generate 10 000 time courses. The upper and lower 95% CI curves shown correspond to the largest and smallest value of y (viral titer) after rejecting the upper and lower 2.5% of the trajectories at each time (x value).

F. Derivation of the ED assay-based likelihood, \mathcal{L}_{ED}

The expression for \mathcal{L}_{ED} in Eqn. (5) herein is derived from Eqn. (5) in Cresta et al. [25] which, following the notation therein, gives the probability of observing a number of infected wells in each column of the assay (\vec{k}_J) given $q_{\text{noinf}}(\vec{\pi})$, the probability that the well will not become infected given parameter set $\vec{\pi}$, namely,

$$\mathcal{L}_{\rm ED}(\vec{k}_J | \vec{n}_J, \vec{\mathcal{D}}_J, V_{\rm inoc}, \vec{\pi}) = \mathcal{Q}(\vec{k}_J | q_{\rm noinf}(\vec{\pi})) = \left[\prod_{j=1}^J \left(1 - \left[q_{\rm noinf}^i(\vec{\pi})\right]^{\mathcal{D}_j}\right)^{k_j^i}\right] \left[q_{\rm noinf}^i(\vec{\pi})\right]^{\sum_{j=1}^J \mathcal{D}_j\left(n_j^i - k_j^i\right)}$$
(14)

where J is the total number of columns, \mathcal{D}_j is the dilution factor in column j, k_j is the number of infected wells in column j, and n_j is the total number of wells in column j. In Cresta et al. [25], q_{noinf} is the probability of observing no infection in an ED well, having drawn a volume V_{inoc} of the sample containing C_{measured} infectioncausing units (SIN) per millilitre into that well. This probability is given by the binomial probability mass function, Binomial($k = 0 | n = V_{\text{inoc}}/V_{\text{vir}}, p = C_{\text{measured}} \cdot V_{\text{vir}}$), evaluated for no success, i.e. no infection (k = 0), where V_{vir} is the volume of one virion, $p = C_{\text{measured}} \cdot V_{\text{vir}}$, is the probability of success for each draw, and $n = V_{\text{inoc}}/V_{\text{vir}}$ is the number of draws.

FIG. 16. Pairwise MPDs for the ODE model ([V] = SIN) obtained using the \mathcal{L}_{NR} likelihood.

Here we define \tilde{q}_{noinf} the probability that the well will not become infected given a sample's actual infectious virion concentration C_{actual} in IV/ml. Since it is possible to draw an infectious virion and yet fail to infect the well, we now need to account for additional outcomes: the probability that k > 0 virions are drawn but all k infectious virions fail

FIG. 17. Pairwise MPDs for the ODE model ([V] = SIN) obtained using the \mathcal{L}_{ED} likelihood.

FIG. 18. Pairwise MPDs for the ODE model ([V] = IV) obtained using the \mathcal{L}_{ED} likelihood.

FIG. 19. Pairwise MPDs for the stochastic model ([V] = IV) obtained using the \mathcal{L}_{ED} likelihood.

to cause an infection, $(\mathcal{P}_{V \to \text{Extinction}})^k$. Therefore,

$$\widetilde{q}_{\text{noinf}} = \sum_{k=0}^{n} \left(\mathcal{P}_{V \to \text{Extinction}} \right)^{k} \cdot \text{Binomial}(k|n = V_{\text{inoc}}/V_{\text{vir}}, p = C_{\text{actual}} \cdot V_{\text{vir}})$$

$$= \sum_{k=0}^{n} \left(\mathcal{P}_{V \to \text{Extinction}} \right)^{k} {\binom{n}{k}} p^{k} (1-p)^{n-k}$$

$$= \sum_{k=0}^{n} {\binom{n}{k}} (p \cdot \mathcal{P}_{V \to \text{Extinction}})^{k} (1-p)^{n-k} .$$
(15)

Using the Binomial theorem, the above equation can be written as

$$\widetilde{q}_{\text{noinf}} = [(1-p) + p \cdot \mathcal{P}_{V \to \text{Extinction}}]^n = [1 - p(1 - \mathcal{P}_{V \to \text{Extinction}})]^n = [1 - p \cdot \mathcal{P}_{V \to \text{Extablishment}}]^{V_{\text{inoc}}/V_{\text{vir}}}, \quad (16)$$

and using the same approximation used in Cresta et al. [25],

$$\ln(1-x) \overset{|x|\ll 1}{\approx} -x$$

$$\ln(\tilde{q}_{\text{noinf}}) = \frac{V_{\text{inoc}}}{V_{\text{vir}}} \ln(1-p \cdot \mathcal{P}_{V \to \text{Establishment}}) = \frac{V_{\text{inoc}}}{V_{\text{vir}}} \ln(1-C_{\text{actual}} \cdot V_{\text{vir}} \cdot \mathcal{P}_{V \to \text{Establishment}})$$

$$\ln(\tilde{q}_{\text{noinf}}) \approx \frac{V_{\text{inoc}}}{V_{\text{vir}}} (-C_{\text{actual}} \cdot V_{\text{vir}} \cdot \mathcal{P}_{V \to \text{Establishment}}) = -C_{\text{actual}} \cdot V_{\text{inoc}} \cdot \mathcal{P}_{V \to \text{Establishment}}$$

$$\tilde{q}_{\text{noinf}} \approx \exp[-C_{\text{actual}} \cdot \mathcal{P}_{V \to \text{Establishment}} \cdot V_{\text{inoc}}] .$$
(17)

Eqn. (5) replaces $q_{\text{noinf}}(\vec{\pi})$ with $\tilde{q}_{\text{noinf}}(\vec{\pi})$ in Eqn. (14), and expresses $\tilde{q}_{\text{noinf}}(\vec{\pi})$ as $\exp[-C^{\text{model}}(t|\vec{\pi}) \cdot V_{\text{inoc}}]$ when the MM expresses V in SIN or as $\exp[-C^{\text{model}}(t|\vec{\pi}) \cdot \mathcal{P}_{V \to \text{Establishment}} \cdot V_{\text{inoc}}]$ when [V] = IV/ml, where $\mathcal{P}_{V \to \text{Establishment}}(\vec{\pi})$ is the establishment probability of an infection initiated with one infectious virion, given parameter set $\vec{\pi}$.

G. Lower limit of detection for an ED assay

Let us consider $\mathcal{L}(\vec{k}_J|q_{\text{noinf}})$, the probability of observing a number of infected wells per column \vec{k}_J given q_{noinf} the probability that the well will not become infected given a sample's measured infection concentration C_{measured} . This expression is given in Cresta et al. [25] (Eqn. (5), $\mathcal{Q}(\vec{k}_J|q_{\text{noinf}})$, therein) as follows,

$$\mathcal{L}(\vec{k}_J|q_{\text{noinf}}) = \left[\prod_{j=1}^J (1 - q_{\text{noinf}}^{\mathcal{D}_j})^{k_j}\right] q_{\text{noinf}}^{\sum_{j=1}^J \mathcal{D}_j(n_j - k_j)}$$
(18)

where J is the total number of columns, \mathcal{D}_j is the dilution factor in column j, k_j is the number of infected wells in column j, and n_j is the total number of wells in column j. The probability of observing no infected wells ($\vec{k}_J = \mathbf{0}$) given q_{noinf} is then given by the following expression, namely,

$$\mathcal{L}(\mathbf{0}|q_{\text{noinf}}) = \left[\prod_{j=1}^{J} (1 - q_{\text{noinf}}^{\mathcal{D}_j})^0\right] q_{\text{noinf}}^{\sum_{j=1}^{J} \mathcal{D}_j(n_j - 0)} = q_{\text{noinf}}^{\sum_{j=1}^{J} \mathcal{D}_j n_j}$$
(19)

The lower limit of detection could then be defined as the concentration in SIN/ml (C_{LLoD}) at which the probability of observing no infected wells given q_{noinf} , $\mathcal{L}(\mathbf{0}|q_{\text{noinf}})$, is 0.5 or 50%. This can be determined by solving the following equation, and using $q_{\text{noinf}} = \exp[-C_{\text{inf}} \cdot V_{\text{inoc}}]$ (Eqn. (2) in Cresta et al. [25]) where C_{inf} corresponds to C_{LLoD} which we seek to determine, namely

$$0.5 = q_{\text{noinf}}^{\sum_{j=1}^{J} \mathcal{D}_j n_j}$$

$$0.5 = \exp\left[-C_{\text{LLoD}} \cdot V_{\text{inoc}} \cdot \sum_{j=1}^{J} \mathcal{D}_j n_j\right]$$

$$-\ln(0.5) = C_{\text{LLoD}} \cdot V_{\text{inoc}} \cdot \sum_{j=1}^{J} \mathcal{D}_j n_j$$

$$C_{\text{LLoD}} = \frac{-\ln(0.5)}{V_{\text{inoc}} \cdot \sum_{j=1}^{J} \mathcal{D}_j n_j}$$
(20)

where C_{LLoD} is the ED assay's lower limit of detection in SIN/ml. Herein, $V_{\text{inoc}} = 0.05 \text{ ml}$, $n_j = 4 \forall j$, and $D_j = \{10^{-1}, 10^{-2}, ..., 10^{-8}\}$ such that $C_{\text{LLoD}} = 10^{1.494} \text{ SIN/ml}$.

H. Infecting time in the stochastic model

Let us derive the probability that the infecting time (t_{inf}) is of time t, i.e. the probability that it takes time t for an infectious cell to cause at least one cell to be newly infected, given an uninfected population of cells and neglecting virus loss through loss of infectivity or entry into cells.

In this case, the relevant SM equations, the equations representing E_1^{n+1} the number of cells in the 1st eclipse compartment (i.e. newly infected) and V^{n+1} the number of infectious virions, both at time $t = (n+1)\Delta t$, can be simplified to

$$E_1^{n+1} = E_1^n + N^{\inf}$$
$$V^{n+1} = V^n + M^n$$

where N^{\inf} is drawn from $\text{Binomial}(V^n, p_{\inf} = \Delta t \cdot \gamma \beta N_{\text{cells}}/s)$ and M^n is drawn from $\text{Poisson}(\lambda = \Delta t \cdot \rho) \ (\equiv Q(M^n)$ for convenient notation). The probability that there is no newly infected cell over the next time interval Δt is given by $\text{Binomial}(0|V^n, p_{\inf}) = (1 - p_{\inf})^{V^n}$. V^n can also be expressed as $\sum_{m=0}^{n-1} M^n$. Therefore, the probability that the infecting time $t_{\inf} = (n+1)\Delta t$ given the set of values $\{M^n\}$, can be expressed as

$$\mathcal{P}(t_{\inf} = (n+1)\Delta t | \{M^n\}) = \left[\prod_{m=1}^{n-1} (1-p_{\inf})^{\sum_{l=0}^{m-1} M^l}\right] \left[1 - (1-p_{\inf})^{\sum_{m=0}^{n-1} M^m}\right]$$
$$= (1-p_{\inf})^{\sum_{m=0}^{n-2} (n-1-m)M^m} - (1-p_{\inf})^{M^{n-1} + \sum_{m=0}^{n-2} (n-m)M^m}$$
(21)

The probability that the infecting time $t_{inf} = (n+1)\Delta t$ is given by averaging the conditional probability $\mathcal{P}(t_{inf} = (n+1)\Delta t | \{M^n\})$ over the distribution $Q(M^n)$ for all values of $\{M^n\}$, namely,

$$\mathcal{P}(t_{\rm inf} = (n+1)\Delta t) = \left\langle (1-p_{\rm inf})^{\sum_{m=0}^{n-2}(n-1-m)M^m} - (1-p_{\rm inf})^{M^{n-1} + \sum_{m=0}^{n-2}(n-m)M^m} \right\rangle_Q$$
$$= \left\langle (1-p_{\rm inf})^{\sum_{m=0}^{n-2}(n-1-m)M^m} \right\rangle_Q - \left\langle (1-p_{\rm inf})^{M^{n-1} + \sum_{m=0}^{n-2}(n-m)M^m} \right\rangle_Q$$
(22)

The random variables $\{M^n\}$ are independent, hence,

$$\mathcal{P}(t_{\inf} = (n+1)\Delta t) = \prod_{m=0}^{n-2} \left\langle (1-p_{\inf})^{(n-1-m)M^m} \right\rangle_Q - \left\langle (1-p_{\inf})^{M^{n-1}} \right\rangle_Q \prod_{m=0}^{n-2} \left\langle (1-p_{\inf})^{(n-m)M^m} \right\rangle_Q = \prod_{m=0}^{n-2} \left[e^{-\lambda} \sum_{M^m=0}^{\infty} \frac{[(1-p_{\inf})^{(n-1-m)}\lambda]^{M^m}}{M^m!} \right] - \left[e^{-\lambda} \sum_{M^{n-1}=0}^{\infty} \frac{[(1-p_{\inf})\lambda]^{M^{n-1}}}{M^{n-1}!} \right] \prod_{m=0}^{n-2} \left[e^{-\lambda} \sum_{M^m=0}^{\infty} \frac{[(1-p_{\inf})^{(n-m)}\lambda]^{M^m}}{M^m!} \right]$$
(23)

Using the power series representation of the exponential function, i.e. $\exp(x) = \sum_{k=0}^{\infty} x^k / k!$, Eqn. (23) can be simplified to

$$\mathcal{P}(t_{\inf} = (n+1)\Delta t) = \prod_{m=0}^{n-2} \exp\left(\left[(1-p_{\inf})^{(n-1-m)}-1\right]\lambda\right) - \exp\left(\left[(1-p_{\inf})-1\right]\lambda\right) \prod_{m=0}^{n-2} \exp\left(\left[(1-p_{\inf})^{(n-m)}-1\right]\lambda\right) = \exp\left(-(n-1)\lambda + (1-p_{\inf})^{n-1}\lambda \sum_{m=0}^{n-2} (1-p_{\inf})^{-m}\right) - \exp\left(-p_{\inf}\lambda - (n-1)\lambda + (1-p_{\inf})^n\lambda \sum_{m=0}^{n-2} (1-p_{\inf})^{-m}\right)\right)$$
(24)

The partial sums are of geometric series, therefore, Eqn. (24) can be evaluated to

$$\mathcal{P}(t_{\inf} = (n+1)\Delta t)$$

$$= \exp\left(\frac{(1-p_{\inf}) - (1-p_{\inf})^n}{p_{\inf}}\lambda - (n-1)\lambda\right) \left[1 - \exp\left(-p_{\inf}\lambda - (1-p_{\inf})\lambda + (1-p_{\inf})^n\lambda\right)\right]$$
(25)

To obtain the probability density function for the infecting time t_{inf} from the above probability mass function, we need to take the following limit,

$$\mathcal{P}(t_{\inf} = t) = \lim_{\Delta t \to 0} \frac{\mathcal{P}(t_{\inf} = (n+1)\Delta t)}{\Delta t}$$
$$= \lim_{n \to \infty} \exp\left(\frac{\rho}{\alpha} \left[1 - \frac{\alpha t}{n} - \left(1 - \frac{\alpha t}{n}\right)^n\right] - \rho t + \frac{\rho t}{n}\right) \left[1 - \exp\left(-\frac{\alpha \rho t^2}{n^2} - \frac{\rho t}{n} \left[1 - \frac{\alpha t}{n} - \left(1 - \frac{\alpha t}{n}\right)^n\right]\right)\right] \frac{n}{t}$$
(26)

where $\alpha = \gamma \beta N_{\text{cells}}/s$. As the exponent of the exponential in the second term of Eqn. (26) is small as n approaches ∞ , we can use the Taylor series approximation $e^x \approx 1 + x$ to approximate this term, namely,

$$\mathcal{P}(t_{\inf} = t) = \lim_{n \to \infty} \exp\left(\frac{\rho}{\alpha} \left[1 - \frac{\alpha t}{n} - \left(1 - \frac{\alpha t}{n}\right)^n\right] - \rho t + \frac{\rho t}{n}\right) \left(\frac{\alpha \rho t^2}{n} + \rho \left[1 - \frac{\alpha t}{n} - \left(1 - \frac{\alpha t}{n}\right)^n\right]\right)$$
$$= \rho \left[1 - e^{-\alpha t}\right] \exp\left(\frac{\rho}{\alpha} \left[1 - e^{-\alpha t}\right] - \rho t\right)$$
(27)

Substituting $\alpha = \gamma \beta N_{\text{cells}} / s$ in Eqn. (27), we have

$$\mathcal{P}(t_{\rm inf} = t) = \rho \left[1 - e^{-\gamma \beta N_{\rm cells}/s \cdot t} \right] \exp \left(\frac{\rho}{\gamma \beta N_{\rm cells}/s} \left[1 - e^{-\gamma \beta N_{\rm cells}/s \cdot t} \right] - \rho t \right)$$
(28)

Let us now derive the mean infecting time using Eqn. (28),

$$\langle t_{\text{inf}} \rangle = \int_{0}^{\infty} t \cdot \mathcal{P}(t_{\text{inf}} = t) dt$$

$$= \int_{0}^{\infty} \rho t (1 - e^{-\alpha t}) \cdot e^{\frac{\rho}{\alpha} (1 - e^{-\alpha t}) - \rho t} dt$$

$$= -\frac{\rho}{\alpha^{2}} e^{\frac{\rho}{\alpha}} \int_{0}^{1} \ln(y) \cdot (1 - y) \cdot e^{-\frac{\rho}{\alpha} y} \cdot y^{\frac{\rho}{\alpha} - 1} dy$$

$$= \frac{1}{\alpha} e^{\frac{\rho}{\alpha}} \int_{0}^{1} e^{-\frac{\rho}{\alpha} [y - (1 - \frac{\alpha}{\rho}) \ln(y)]} dy$$

$$(29)$$

where $y = e^{-\alpha t}$. Let us then use Laplace's method to approximate the above integral, assuming ρ/α is a large number. To start, the function in the exponent $f(y) = -(\rho/\alpha) [y - (1 - \alpha/\rho) \ln(y)]$ can be written as a Taylor series approximation around $y_0 = 1 - \alpha/\rho$ where $f'(y_0) = 0$, namely,

$$f(y) \approx -\frac{\rho}{\alpha} \left(1 - \frac{\alpha}{\rho} - \left(1 - \frac{\alpha}{\rho} \right) \ln \left(1 - \frac{\alpha}{\rho} \right) + \frac{1}{2} \frac{1}{1 - \frac{\alpha}{\rho}} \left[y - \left(1 - \frac{\alpha}{\rho} \right) \right]^2 \right)$$
(30)

and Eqn. (29) can be approximated as

$$\langle t_{\rm inf} \rangle \approx \frac{1}{\alpha} \mathrm{e}^{\frac{\rho}{\alpha} \left[\frac{\alpha}{\rho} + \left(1 - \frac{\alpha}{\rho}\right) \ln\left(1 - \frac{\alpha}{\rho}\right)\right]} \int_{0}^{1} \mathrm{e}^{-\frac{1}{2}\frac{\rho}{\alpha} \frac{1}{1 - \frac{\alpha}{\rho}} \left[y - \left(1 - \frac{\alpha}{\rho}\right)\right]^{2}} \mathrm{d}y \tag{31}$$

FIG. 20. Infecting time distribution in the stochastic model. Density-normalized histograms for the infecting time of 10^5 SM simulations, compared to the theoretically predicted distribution, $\mathcal{P}(t_{inf})$, Eqn. (28), for different values of (A,B,C) ρ or (D,E,F) $\gamma\beta N_{\text{cells}}/s$. The mean and median of the 10^5 SM simulations are shown, along with the theoretically predicted SM mean of t_{inf} , Eqn. (32). The SM-simulated infecting time corresponds to the duration of SM simulations initiated with a single infectious cell ($I_1(0) = 1$ cell) that are terminated when at least one cell has become infected ($E_1(t_{inf}) \ge 1$ cell), in the absence of any virus loss (c = 0 h⁻¹, $\gamma = 1$ cell/IV). Unless otherwise stated, $\rho = 10^3$ IV/(cell · h) and $\gamma\beta N_{cells}/s = 10^{-3}$ cell/(IV · h). Though they do not have an effect on the infecting time, the other infection parameters were $n_E = n_I = 60$, $\tau_E = 7$ h, $\tau_I = 41$ h, $N_{cells} = 1.9 \times 10^6$ cells, s = 1 ml, and $\rho_{RNA} = c_{RNA} = 0$.

As ρ/α approaches ∞ , Eqn. (31) becomes

$$\langle t_{\rm inf} \rangle \approx \frac{1}{\alpha} \cdot \frac{1}{2} \cdot \sqrt{\frac{2\pi}{\rho/\alpha}}$$
$$\approx \sqrt{\frac{\pi}{2\rho \cdot \alpha}} = \sqrt{\frac{\pi}{2\rho \cdot \gamma\beta N_{\rm cells}/s}}$$
(32)

where here we have used the fact that the interval [0,1] covers approximately half of the neighbourhood of $y_0 = 1 - \alpha/\rho \approx 1$.

Figure 20 shows that the normalized histogram of the infecting time, generated from 10^5 SM simulations, is in agreement with Eqn. (28), over a wide range of infection parameters.
