The biophysical interactions between the T cell receptor (TCR) and its ligands determine the specificity of the cellular immune response. However, the immense diversity of receptors and ligands has made it challenging to discover generalizable rules across the distinct binding affinity landscapes created by different ligands. Here, we present an optimization framework for discovering biophysical rules that predict whether TCRs share specificity to a ligand. Applying this framework to TCRs associated with a collection of SARS-CoV-2 peptides we establish how co-specificity depends on the type and position of amino-acid differences between receptors. We also demonstrate that the inferred rules generalize to ligands not seen during training. Our analysis reveals that matching of steric properties between substituted amino acids is important for receptor co-specificity, in contrast with the hydrophobic properties that more prominently determine evolutionary substitutability. We furthermore find that positions not in direct contact with the peptide still significantly impact specificity. These findings highlight the potential for data-driven approaches to uncover the molecular mechanisms underpinning the specificity of adaptive immune responses.

Cellular immunity relies on the specific recognition of target molecules by T cells, mediated by the binding of the T cell receptor (TCR) to specific peptide-major histocompatibility complexes (pMHCs) [1, 2]. Given the pivotal role of T cells in the adaptive immune system, an ability to predict the specificity of a TCR *in silico* from its sequence would have many applications in disease diagnosis, surveillance, and treatment. Recent experimental advances [3–7] and the creation of databases cataloging known TCR-pMHC pairings [8–11] have thus propelled significant research efforts aimed at predicting TCR specificity using machine learning [12–19].

The premise behind using machine learning to predict pairings between the hypervariable receptors and their ligands is that there are learnable, generalizable biophysical rules that govern these interactions [3, 4]. While machine learning models are able to accurately identify alternative binders to pMHCs for which good quality high-volume TCR data exists, an ability to generalize to pMHCs unseen during training has yet to be demonstrated in independent benchmarks [20].

In high-dimensional multi-class classification problems a potentially easier path towards generalizable learning begins with learning similarity relationships between class members [21, 22]. Once a suitable metric or representation tailored to the general nature of the classification problem is learned, it can then be adapted with little training data to new classes. However, to date the most popular sequence similarity metrics for TCRs are heuristic and their parameters have not been learned from TCR sequence data. For instance, TCRdist [3] scores amino-

acid similarity based on the BLOcks SUBstitution Matrix (BLOSUM). This matrix is based on substitution frequencies observed in general protein evolution [23], and it is unclear how well these describe the impact of amino-acid changes on TCR-pMHC binding. Additionally, existing structures suggest that factors beyond the identity of substituted amino acids, such as the position of the substitution, likely influence the impact of sequence changes [24].

To address these challenges, we propose a pseudo-likelihood maximization approach to learn the biophysical rules that govern TCR co-specificity directly from data. Concretely, our aim is to learn a distance metric $d(\sigma, \sigma')$ that quantifies the probability that two TCRs, σ and σ' , bind to the same pMHC. To accomplish this, we expand on our ongoing efforts to quantify the statistics of TCR sequence similarity in pMHC-specific and background repertoires [25–27] by replacing predefined notions of sequence similarity with learnable metrics. To learn this metric we apply contrastive learning – a framework that we and others have previously used to train deep learning models for predicting TCR specificity [18, 19, 28, 29] – to optimize sequence alignment weights to discriminate between co-specific and background sequence pairs. We reason that the simplicity of these metrics might favor the inference of generalizable rules from limited data, which has remained a challenge in more flexible deep learning models using this supervised contrastive approach [18].

Our results demonstrate that generalizable TCR co-specificity rules exist and can be learned by contrastive

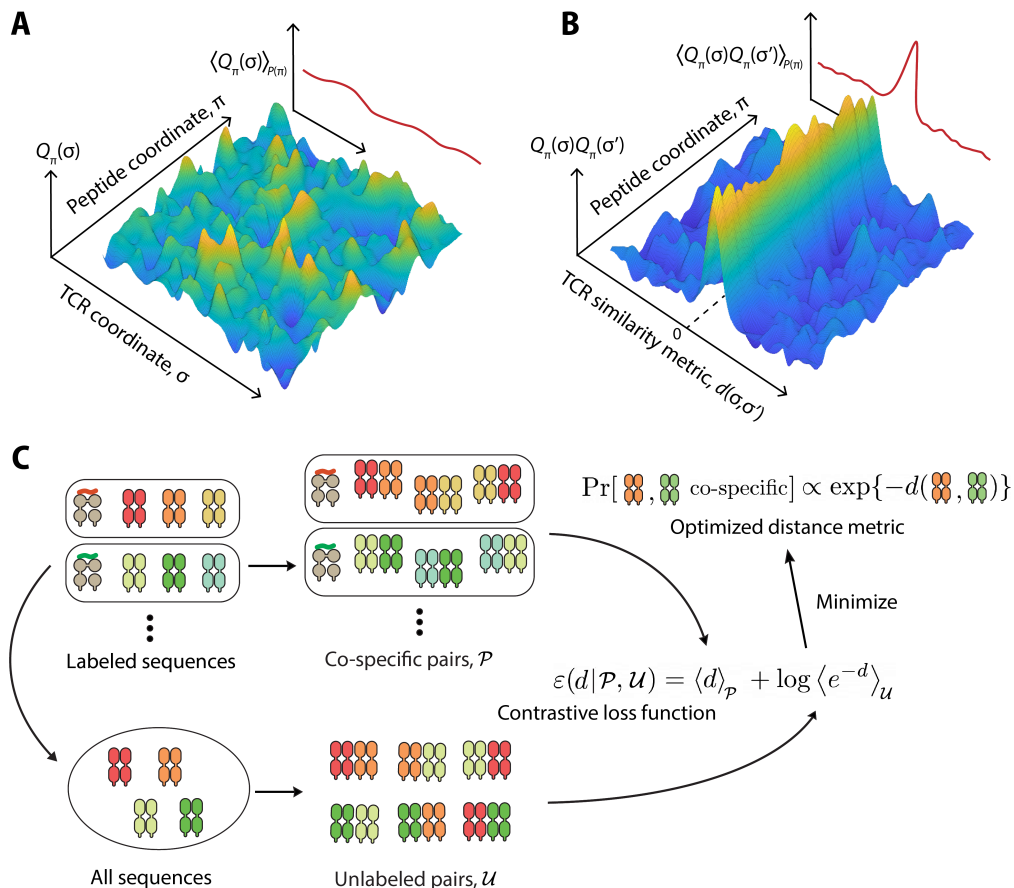

FIG. 1. Contrastive learning of rules that generalize across complex receptor-ligand maps. **A)** Cartoon disordered “landscape” of selection factors $Q_\pi(\sigma)$, which describe the varying binding affinities of TCRs σ to peptides π . Averaging selection factors over peptides, $\langle Q_\pi(\sigma) \rangle_{P(\pi)}$, will lead to a largely flat marginal distribution (inset), unless we are able to restrict the average to peptides with highly similar TCR landscapes. **B)** Cartoon “landscape” of co-selection factors $Q_\pi(\sigma)Q_\pi(\sigma')$, which relate to the probability with which two TCRs are specific to the same peptide, as a function of TCR similarity $d(\sigma, \sigma')$. In contrast to the previous scenario, co-selection factors have a non-trivial marginal distribution when averaged across unrelated peptides, $\langle Q_\pi(\sigma)Q_\pi(\sigma') \rangle_{P(\pi)}$ (inset). **C)** Sketch of the supervised contrastive learning paradigm. Experimentally-determined pairs of TCR sequences binding the same pMHC make up the set of co-specific pairs \mathcal{P} , and all pairs of TCR sequences irrespective of specificity make up the set of background unlabeled pairs \mathcal{U} . We optimize parameters θ of a family of distance metrics d_θ which minimize a contrastive loss (Eq. 7). The loss function minimizes the average distance between pairs in \mathcal{P} , while pushing apart unlabeled pairs in \mathcal{U} . Optimized parameters θ^* relate the sequence similarity between a pair of TCRs to the probability with which they share specificity to pMHC and provide biophysical insights into feature importance.

learning. Specifically, we show that co-specificity rules learned from data on SARS-CoV-2 specific TCR pairs [11] that differ by a single edit (i.e., single substitution, deletion, or insertion) in the Complementary Determining Region 3 (CDR3) of the TCR β chain, generalize to pMHCs held out during training, a validation set from an independent database [8], to TCR pairs differing by multiple edits, and to the TCR α chain. The learned rules are directly interpretable and we compare inferred parameters with biophysical expectations. Our results suggest that contrastive learning might be a broadly useful strategy to develop statistical theories of complex receptor-ligand maps.

I. TWO-POINT STATISTICS IDENTIFY ORDER IN RECEPTOR-LIGAND MAPS

To motivate our framework, it is useful to review the statistical inference problem posed by TCR-pMHC binding prediction. The ultimate objective is to infer the probability distribution $P_\pi(\sigma)$ of observing TCR sequence σ when sampling from the pool of T cells specific to pMHC π . This distribution can be fitted from known experimentally sampled TCR binders to the pMHC. However, there are only few pMHCs with substantial data, making the inference of such epitope-specific models challenging. To address this, it would be appealing to use generalizable rules as priors when inferring the selection landscape for a given pMHC.

One approach involves using the epitope-specific selection factors $Q_\pi(\sigma)$, such that $P_\pi(\sigma) = Q_\pi(\sigma)P(\sigma)$, where $P(\sigma)$ represents the highly non-uniform [30], but largely universal [31] baseline distribution resulting from VDJ recombination [25, 32, 33]. A naive strategy might average selection factors across pMHCs, $\langle Q_\pi(\sigma) \rangle_{P(\pi)}$ as an initial guess, where $\langle f(x) \rangle_{P(x)}$ denotes the average of $f(x)$ over the distribution $P(x)$. Yet, such a “mean-field” approach would obscure much of the information about TCR-pMHC specificity.

The binding energy landscapes associated with specific ligands peak in different regions of receptor sequence space (Fig. 1A), and averaging over these disordered landscapes is expected to result in a flat and non-informative marginal distribution (Fig. 1A, inset). Indeed, embeddings from masked language models trained to reproduce overall repertoire statistics demonstrate limited transfer learning capability for predicting TCR-pMHC specificity [18]. Furthermore, selection factors on observed naive or memory TCR repertoires relative to null expectations are largely driven by epitope-independent constraints on receptor function, such as those required for proper folding [32].

To overcome this problem, we have followed a different approach towards identifying reproducible statistical order across receptor-ligand maps, which rests on analyzing two-point statistics of selection $Q_\pi(\sigma)Q_\pi(\sigma')$ [18, 25–27]. The two-point statistics describe the likelihood that receptors σ and σ' are both specific to the same peptide π (Fig. 1B). These co-selection factors can have non-trivial averages across unrelated ligands (Fig. 1B, inset), even where one-point statistics do not. Intuitively, peak position vary across the selection landscapes, but the size and shape of peaks might not. Two-point statistics have also been successfully applied in the statistical physics of spin glasses to reveal otherwise hidden statistical order [34].

Using this approach, we previously demonstrated that co-selection factors decay predictably with the Levenshtein distance between TCR sequences, independent of the specific ligand [25]. These findings suggest that generalizable statistical order exists across receptor-ligand maps, which can inform metrics for TCR sequence analysis.

II. SUPERVISED CONTRASTIVE LEARNING AS PSEUDO-LIKELIHOOD MAXIMIZATION

A. Derivation of a loss function

We propose fitting available co-specificity data by optimizing parameters θ of a family of TCR sequence similarity metrics $d_\theta(\sigma, \sigma')$. The fitting is based on a supervised contrastive loss function, similar to others used in the machine learning literature [35]. In the following we provide a derivation of this loss function that clarifies its connection to pseudo-likelihood maximization – a technique

used by statistical physicists to infer Potts models for protein families [36].

The experimental data takes the form of a collection of TCRs $\{\sigma_1, \sigma_2, \dots, \sigma_N\}$, where each sequence σ_i is associated with a cognate pMHC π_i (Fig. 1C). To find an optimal metric we propose maximizing the pseudo-likelihood of all observed pairs of co-specific TCRs:

$$\mathcal{L} = \prod_{\substack{i \neq j \\ \pi_i = \pi_j}} Q_{\pi_i}(\sigma_i)Q_{\pi_i}(\sigma_j)P(\sigma_i)P(\sigma_j). \quad (1)$$

We have shown previously that co-selection factors between randomly chosen pairs of sequences at a given Levenshtein distance $d_{LD}(\sigma, \sigma') = \Delta$,

$$\langle Q_\pi(\sigma)Q_\pi(\sigma') \rangle_{P(\sigma, \sigma' | d_{LD}(\sigma, \sigma') = \Delta)}, \quad (2)$$

decay exponentially at small distances Δ with a typical, ligand-independent length scale [25]. In fitting a metric to maximize the pseudo-likelihood defined in Eq. 1 we thus focus on capturing the average behavior of co-selection factors across pMHCs,

$$Q(\sigma, \sigma') = \langle Q_\pi(\sigma)Q_\pi(\sigma') \rangle_{P(\pi)}, \quad (3)$$

according to an exponential ansatz,

$$Q(\sigma, \sigma') \propto e^{-d_\theta(\sigma, \sigma')}. \quad (4)$$

Although outside the scope of our study, it is clear that this metric could be improved for prediction on specific targets by exploiting ligand-dependent variation in these rules [26, 27], as we have previously demonstrated for protein language models [18]. Here, inference is instead by design restricted to co-specificity rules that generalize across ligands.

To complete the specification of the optimization problem, it remains to determine the proportionality constant in Eq. 4. We use a normalization condition $\langle Q(\sigma, \sigma') \rangle_{P(\sigma)P(\sigma')} = 1$, such that

$$Q(\sigma, \sigma') = \frac{e^{-d_\theta(\sigma, \sigma')}}{\langle e^{-d_\theta(\sigma, \sigma')} \rangle_{P(\sigma)P(\sigma')}}. \quad (5)$$

With sufficient data, the average over background TCR distribution in the denominator can be approximated using pairs of unlabeled TCRs, $\mathcal{U} = \{(\sigma_i, \sigma_j) | i \neq j, \forall i, j\}$. This means approximating the partition function with respect to $P(\sigma)P(\sigma')$ by an average of $e^{-d_\theta(\sigma, \sigma')}$ over the empirical distribution of unlabeled pairs $\mathcal{U}(\sigma, \sigma') = |\mathcal{U}|^{-1} \sum_{(s, s') \in \mathcal{U}} \delta_{\sigma, s} \delta_{\sigma', s'}$. We note that an alternative approach to calculate the denominator would be to calculate the average only with respect to pairs of TCRs with differing pMHC specificity or by using a large set of independently acquired TCRs, say from an unsorted blood sample. However, in line with prior work [18, 37] we found that the inclusion of co-specific pairs in the unlabeled set has a regularizing effect on the inference procedure.

To simplify notations, we similarly define the set of positive pairs, $\mathcal{P} = \{(\sigma_i, \sigma_j) | \pi_i = \pi_j, \forall i, j\}$, and the empirical probability of observing TCR pair (σ, σ') in the set of co-specific pairs, $\mathcal{P}(\sigma, \sigma') = |\mathcal{P}|^{-1} \sum_{(s, s') \in \mathcal{P}} \delta_{\sigma, s} \delta_{\sigma', s'}$. Plugging all definitions into Eq. 1 allows us to write the negative log-pseudo-likelihood per positive pair as

$$-\frac{\log \mathcal{L}}{|\mathcal{P}|} = \langle d_\theta(\sigma, \sigma) \rangle_{\mathcal{P}(\sigma, \sigma')} + \log \langle e^{-d_\theta(\sigma, \sigma')} \rangle_{\mathcal{U}(\sigma, \sigma')} + c, \quad (6)$$

where $c = -(\log P(\sigma)P(\sigma'))_{\mathcal{P}(\sigma, \sigma')}$ is a term that is independent of the distance metric d_θ . Optimal parameters θ^* maximize the pseudo-likelihood (Eq. 1), or equivalently, minimize terms in the negative log-likelihood dependent on d_θ , which yields the following loss function

$$\varepsilon(\theta | \mathcal{P}, \mathcal{U}) = \langle d_\theta(\sigma, \sigma') \rangle_{\mathcal{P}(\sigma, \sigma')} + \log \langle e^{-d_\theta(\sigma, \sigma')} \rangle_{\mathcal{U}(\sigma, \sigma')}. \quad (7)$$

A flowchart illustrating how the different sets of co-specific and unlabeled sequence pairs are constructed is shown in Fig. 1C.

B. Analytical solution for a simple case

To build intuition, we minimize Eq. 7 in closed form for a simple distance metric. We consider distance metrics defined in terms of a discrete-valued function g that maps each pair of TCRs to a finite set of K integers (e.g. for $K = 2$ a simple case would be: $g(\sigma, \sigma') = 1$ if there is an insertion or deletion and $g(\sigma, \sigma') = 0$ for an amino-acid substitution). Given the integer-valued function g , a family of distance metrics with trainable parameters can be defined by

$$d_g(\sigma, \sigma') = \sum_{i=1}^K \theta_i \delta_{g(\sigma, \sigma'), i}, \quad (8)$$

where $\theta_1, \theta_2, \dots, \theta_K$ are parameters assigned to the K possible value of g , and $\delta_{a,b} = 1$ for $a = b$ and $\delta_{a,b} = 0$ otherwise is the Kronecker delta function. Substituting Eq. 8 into the loss function (Eq. 7) yields

$$\varepsilon(\theta | \mathcal{P}, \mathcal{U}) = \sum_{i=1}^K \theta_i \langle \delta_{g(\sigma, \sigma'), i} \rangle_{\mathcal{P}(\sigma, \sigma')} + \log Z, \quad (9)$$

where $Z = \langle e^{-\sum_i \theta_i \delta_{g(\sigma, \sigma'), i}} \rangle_{\mathcal{U}(\sigma, \sigma')}$ is a normalizing constant. At the optimal θ_i^* , we have $\partial \varepsilon / \partial \theta_i = 0$. Taking the partial derivative of Eq. 9 with respect to θ_i yields

$$\frac{\partial \varepsilon}{\partial \theta_i} = \langle \delta_{g(\sigma, \sigma'), i} \rangle_{\mathcal{P}(\sigma, \sigma')} - \frac{e^{-\theta_i}}{Z} \langle \delta_{g(\sigma, \sigma'), i} \rangle_{\mathcal{U}(\sigma, \sigma')}. \quad (10)$$

Solving for θ_i^* by setting Eq. 10 to zero we derive

$$\theta_i^* = -\log \frac{\langle \delta_{g(\sigma, \sigma'), i} \rangle_{\mathcal{P}(\sigma, \sigma')}}{\langle \delta_{g(\sigma, \sigma'), i} \rangle_{\mathcal{U}(\sigma, \sigma')}} - \log Z. \quad (11)$$

This result shows that minimizing the contrastive loss function (Eq. 7) sets parameters based on the log-ratio between observed occurrences of particular features among positive pairs and a null expectation calculated across unlabeled pairs.

This analytical solution shows that contrastive learning using Eq. 7 is closely connected to how BLOSUM and related evolutionary amino-acid substitution matrices are traditionally defined in the bioinformatics literature [23, 38]. These matrices are also constructed by calculating log-odds ratios between observed and expected frequencies of amino acid pairs. However, contrastive learning extends this by accommodating more complex distance metrics that incorporate multiple substitution properties. Furthermore, empirical frequencies across unlabeled TCR pairs are used in the denominator, rather than assuming factorization as in BLOSUM. This is a more appropriate choice for TCRs, where VDJ recombination introduces correlations between sites even in the naive repertoire [30].

III. DATA PREPARATION

In order to learn rules that generalize to unseen pMHCs, we curated the training data to eliminate confounding factors and to reduce the complexity of the problem. We decided to restrict training to a single dataset of TCRs with experimentally annotated pMHC specificity to exclude confounding by data origin. Consequently, we used a large-scale dataset on TCRs with specificity to SARS-CoV-2 peptides obtained using a multiplexed assay called MIRA [11]. From this data we only used pairs of TCR CDR3 β sequences that differ by a single edit step to maximize the signal-to-noise ratio given potentially misannotated sequences [25]. Moreover, we only considered pairs of sequences with identical V genes, to ensure that learned rules only reflected amino-acid substitutions in the CDR3 β chain. We also excluded the (very small) number of pairs involving substitutions of cysteine to reduce overfitting, due to the rarity of cysteines within the CDR3 junction following negative thymic selection [32].

To reduce overfitting to less commonly observed sequence lengths, we restricted our analysis to TCR CDR3 β sequences with lengths between 11 and 15. These represented 72% of the sequences in the MIRA database and 76% of sequences in the VDJdb database. From the MIRA database, we identified 26 sets of TCRs specific to unique pMHCs, each containing at least 1000 TCR sequences. To mitigate the impact of varying sizes of specificity groups, we equalized all group sizes by subsampling without replacements to a 1000 sequences for pMHC. To still learn on all available data, we repeated the procedure 15 times and averaged performance across these training batches. Among the 26,000 TCRs included per training batch, we identified on average ≈ 6000 pairs of single-edit TCRs.

We evaluated the generalization of the inferred metric using hold-out epitopes from the MIRA database. To this end, we constructed sets of co-specific and background sequence pairs from 24 specificity groups, each containing between 400 and 999 TCR sequences, that were excluded during training. We again used subsampling to address class imbalance, generating 15 sets of 400 sequences for each specificity group. Furthermore, to assess generalization to TCR pairs differing by multiple edits, we identified TCR pairs with edit distances ranging from 1 to 6 in the same data set.

Using these data, we chose to test the ability of metrics to discriminate between co-specific (i.e. $\in \mathcal{P}$) and cross-specific TCR pairs (i.e. $\in \mathcal{C} = \{(\sigma_i, \sigma_j) | \pi_i \neq \pi_j, \forall i, j\}$). We note that this task represents an instance of positive-unlabeled classification [39], as cross-specific pairs are not tested experimentally for co-specificity. We have shown previously that about one in ten single edits maintain co-specificity [25], setting an upper bound on achievable classification accuracy. Nonetheless, we chose this task for its simplicity. Additionally, when considering TCR pairs differing by multiple edits the prevalence of co-specific pairs decreases, reducing the impact of this limitation.

To externally validate the predictive power of the inferred rules, we used data from VDJdb [40], excluding any pMHCs present in the MIRA dataset. In addition to TCR β sequences, VDJdb includes TCR α sequences for certain pMHCs, which we used to further test the biological generalizability of the inferred co-specificity rules. For the β chain validation task, we selected TCRs from 131 specificity groups, each containing at least 15 unique sequences. As before, this threshold was chosen to maximize the number of co-specific and background pairs included in the analysis after balancing the data across groups. For the α chain validation task, we identified 49 specificity groups meeting the same threshold of 15 sequences. Consistent with our previous methodology, we employed subsampling and identified TCR pairs with edit distances ranging from 1 to 6 across 15 balanced testing batches.

IV. INFERENCE OF OPTIMAL SEQUENCE SIMILARITY METRICS

A. Overview, notations, and baseline metric

Simple metrics of TCR sequence similarity have been widely used to predict TCR co-specificity [3, 4, 41, 42]. Among these, one of the most widely used metrics is TCRdist [3], which calculates distances between TCRs based on BLOSUM62-derived amino-acid dissimilarity penalties. Building on the principles of TCRdist, we applied the framework introduced in section II to optimize parameters within a family of simple distance metrics, that account for two critical physical factors influencing the effects of changes in the TCR hypervariable region:

the identity of the substituted amino acids and the position of the substitution.

Specifically, we define distance metrics in terms of edit steps, which characterize the difference between a pair of TCR sequences σ and σ' by a series of substitutions, deletions, and insertions (Fig. 2A). The simplest among these metrics, the total unweighted number of edit steps required to transform σ to σ' , is known as the Levenshtein distance [43]. In the following we describe the i th edit step between σ and σ' by $\Delta_i(\sigma, \sigma')$, the identity of substituted amino acids, and by $k_i(\sigma, \sigma')$, the substitution position along the TCR sequence (Fig. 2A).

In this notation, the baseline metric, TCRdist, is given by $d_{\text{Td}}(\sigma, \sigma') = w \sum_i \tilde{d}_{\text{Td}}(\Delta_i)$, where $\tilde{d}_{\text{Td}}(\Delta_i) = \min(4, 4 - B_{62}(\Delta_i))$ if the i^{th} edit step is an amino-acid substitution, and $\tilde{d}_{\text{Td}}(\Delta_i) = c_{\text{indel}}$ if the i^{th} edit step is an insertion/deletion. Here, B_{62} denotes the BLOSUM62 matrix. For CDR3 loops, $w = 3$ and $c_{\text{indel}} = 8$, while $w = 1$ and $c_{\text{indel}} = 4$ for CDR1 and CDR2 (see Fig. S1A). In the remainder of this section, we use TCRdist as a baseline for comparisons.

B. Learning an amino-acid substitution matrix

To test whether an amino-acid substitution matrix directly learned from TCR data would outperform the BLOSUM-derived TCRdist score, we used our framework to train the following simple metric

$$d_A(\sigma, \sigma') = \sum_i A(\Delta_i), \quad (12)$$

where A is a matrix of amino-acid substitution weights (Fig. S1B). We included a blank ('-') in the amino-acid alphabet to treat insertion/deletion as a substitution involving '-'.

To evaluate the performance of d_A , we generated pairs of TCR CDR3 β sequences from the MIRA database that differed by a single edit step and belonged to a specificity group not included in the training data. The performance of distance metrics was quantified using a co-specific pair identification test, in which co-specific TCRs were treated as positive pairs, while TCR pairs across different specificity groups were treated as negative pairs as described before. The receiver operating characteristic (ROC) curves for different models shows that d_A outperforms d_{Td} (Fig. 2B). Furthermore, the learned substitution matrix also better classifies co-specific TCR CDR3 β sequence pairs from the VDJdb database (Fig. 2C), as assessed by the area under the receiver operating curve (AUROC). Both tasks involve TCRs specific to unseen pMHCs, which in the case of VDJdb additionally originate from pathogens other than SARS-CoV-2 which was used during training.

FIG. 2. **Learning of a CDR3 β distance metric that generalizes to unseen peptides.** **A)** Distance metrics are defined in terms of the edit steps between two CDR3 β sequences. Each edit step includes the length of sequence ℓ , position of substitution κ , and the identity of substitution Δ . **B)** Receiver Operating Characteristics (ROC) curves for identifying co-specific relative to cross-specific (i.e., $\in \mathcal{C} = \{(\sigma_i, \sigma_j) | \pi_i \neq \pi_j, \forall i, j\}$) TCR CDR3 β pairs from the MIRA test set that differ by a single edit using different TCR similarity metrics. The metrics include TCRdist (d_{TD} , black) as a baseline, as well as a series of metrics optimized using the mathematical framework proposed in this study. These metrics involve substitution type (which amino acids are substituted) and/or substitution site (which position along the CDR3 sequence is substituted). Specifically, the curves show metrics using only type (d_A , blue), only site (d_S , green), or using both jointly (d_{AS} , red). Curves are averaged over 15 subsampled test sets, each equally balanced across pMHC groups. **C)** Areas under the ROC (AUROC) for the MIRA test set and an external validation set (VDJdb). Error bars indicate the standard error over resampled testing batches. Note that due to cross-reactivity some cross-specific pairs also exhibit co-specificity, which bounds achievable AUROCs below one.

C. Substitution position influences TCR co-specificity

We next investigated whether the position of substitution (independently of the identity of the substituted amino acids) determines the likelihood of TCR co-specificity, as suggested by structures [4, 24]. To address this question, we trained a distance metric that considers only the position of substitution:

$$d_S(\sigma, \sigma') = \sum_i S(k_i, \ell), \quad (13)$$

where S represents a matrix of site weights dependent on k_i , the position of substitution, and $\ell(\sigma, \sigma') = \max(|\sigma|, |\sigma'|)$, the aligned length of the TCR pair (Fig. S2A).

Results on the testing task shows that d_S has some predictive power on unseen pMHCs (Fig. 2B), and even outperforms d_{TD} on the validation task (Fig. 2C). These findings confirm that location matters for the impact of a substitution on TCR specificity.

D. Joint inference of site and identity-dependent substitution weights

Having established that both the identity of substituted amino acids and the position of substitution influence the probability of co-specificity in a pair of TCRs, we next inferred a model accounting for both factors jointly.

Incorporating multiple factors into phenomenological distance metrics is challenging, as it requires ad hoc choices for setting the relative weight given to each factor. However, in our framework, different parameters are jointly optimized during the training process to disentangle their relative influence.

We defined a distance metric, d_{AS} based on a functional form inspired by biophysical receptor-ligand interaction models [17, 44]. This model depends on $P_S(k, \ell)$, the probability that a residue at site k on a TCR of length ℓ determines pMHC specificity, and $P_A(\Delta)$, the probability that co-specificity is maintained at a given site following a substitution Δ . Most simply, $P_S(k, \ell)$ can be viewed as a contact probability, although it may also account for the indirect effects of non-contact residues on binding specificity. For simplicity, we assume that P_S and P_A are independent, and that substitution penalties are only incurred at sites important to binding. Under these assumptions, co-selection factors can be expressed as:

$$Q_{AS}(\sigma, \sigma') = \sum_i [1 - P_S(k_i, \ell) (1 - P_A(\Delta_i))]. \quad (14)$$

We further set $Q_{AS}(\sigma, \sigma') \propto e^{-d_{AS}(\sigma, \sigma')}$ and parameterize the probabilities using substitution weights similar to those used in the previous single-factor optimization: $P_S(k_i, \ell) = 1 - e^{-\mathcal{S}(k_i, \ell)}$, and $P_A(\Delta_i) = e^{-\mathcal{A}(\Delta_i)}$, where \mathcal{S} and \mathcal{A} are, respectively, the co-optimized substitution weights that depend on the the position of substitution, and the identity of the substitution. Using these definitions, it follows that Eq. 14 is equivalent to a choice of

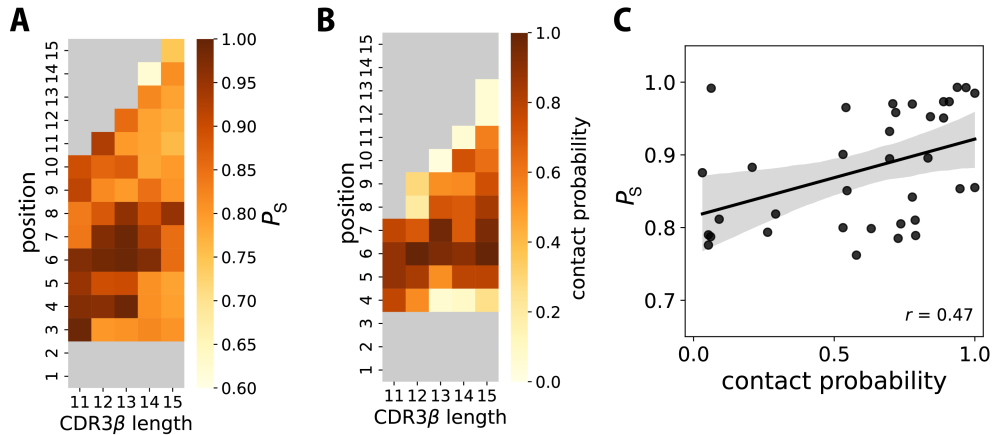

FIG. 3. **Comparison of site-dependent weights with TCR-pMHC contact probabilities reveals the importance of non-contact sites.** **A)** Site weights, P_S , learned from learned from joint optimization of substitution type-dependent and site-dependent weights (d_{AS}). Sites that lack sufficient substitution statistics are shown in gray. **B)** Average contact probability in TCR-pMHC crystal structures (see Methods). Sites along the CDR3 β sequence that never contact the peptide in known structures are shown in gray. **C)** Scatter plot showing the correlation of both quantities across sites.

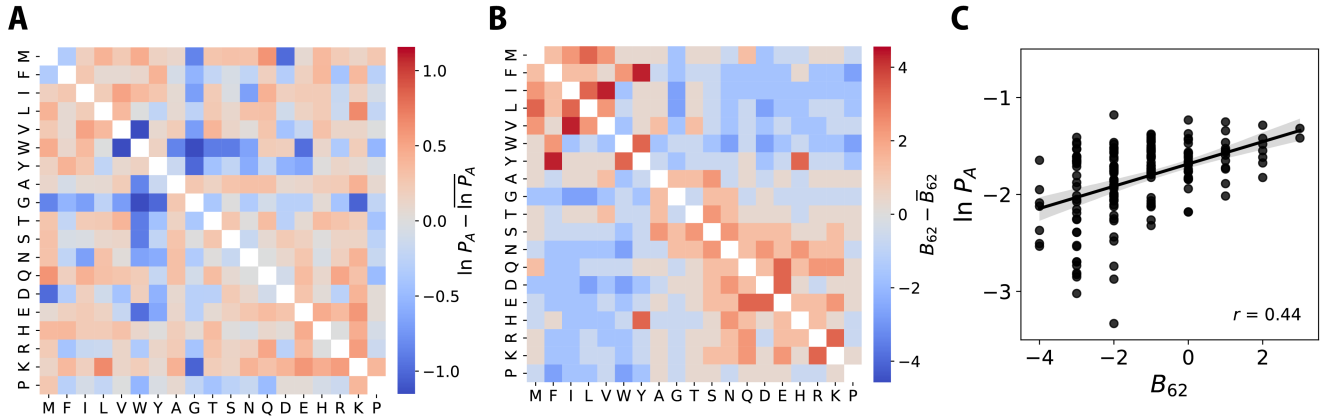

FIG. 4. **Optimized amino-acid substitution matrix differs from BLOSUM.** **A)** Probability of maintaining co-specificity, P_A , learned from joint optimization of substitution type-dependent and site-dependent weights (d_{AS}). Note that cysteine was removed from the optimization due to lack of substitution statistics in CDR3 β sequences. **B)** BLOSUM62 amino-acid substitution matrix. **C)** Comparison of learned P_A and the BLOSUM62 matrix.

distance metric given by

$$d_{AS}(\sigma, \sigma') = - \sum_i \log \left[1 - \left(1 - e^{-S(k_i, \ell)} \right) \left(1 - e^{-\mathcal{A}(\Delta_i)} \right) \right]. \quad (15)$$

We found that by simultaneously accounting for both the position and identity of substitutions, d_{AS} outperforms all other distance metrics (Fig. 2B). Furthermore, this improved performance extends to the external validation on data from VDJdb (Fig. 2C).

V. BIOPHYSICAL INTERPRETATION OF INFERRED PARAMETERS

What physical properties govern TCR specificity? Having established that the position and identity of substitutions determine the likelihood of TCR co-specificity, we turned our attention to the biophysical interpretation of the optimized parameters of the jointly optimized d_{AS} (Eq. 15).

To judge how reliably parameters could be inferred from the available training data, we calculated their coefficients of variation across resampled training sets. We found them to be modest (Fig. S3A,B and Fig. S4A,B), particularly for more commonly observed substitutions

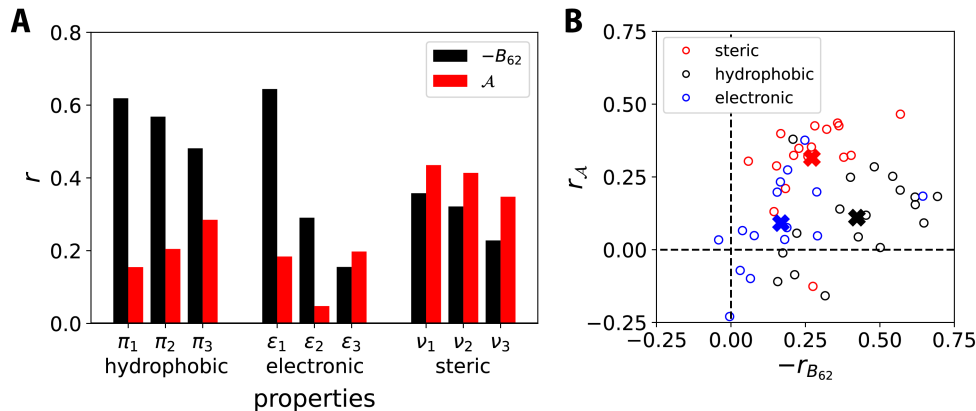

FIG. 5. **Physical correlates of the optimized amino-acid substitution matrix highlight the contribution of shape to TCR specificity.** **A**) Spearman’s rank correlation coefficient (r) of substitution matrices with matrices constructed from pairwise absolute difference in physical properties of amino acids. Selected hydrophobic, electronic, and steric properties were compared. Hydrophobic properties: partition coefficient in octanol/water (π_1), solvation free energy (π_2), and dG of transfer from organic solvent to water (π_3). Electronic properties: polarity (ϵ_1), pK of COOH on C_α (ϵ_2), and pK of NH_2 on C_α (ϵ_3). Steric properties: average volume of buried residue (ν_1), normalized van der Waals volume (ν_2), and STERIMOL maximum width of the side chain (ν_3). **B**) Comparison of the correlation coefficients of both substitution matrices with those obtained from a panel of 50 amino-acid properties (for the complete list, see SI). Centroids for each property class are shown as “x”.

(Fig. S3C and Fig. S4C). We expect this variability to further decrease as more data becomes available. This would potentially boost the correlation coefficients between fitted site- and substitution-weights and biophysical parameters, but some broad insights already emerge from the analysis of the available data.

To test whether site weights P_S are in line with their intuitive role as a proxy for contact probabilities, we calculated contact probabilities from TCR-pMHC complexes deposited in the Structural T Cell Receptor Database [45] (Fig. 3B; see Methods for details). We found that P_S is moderately correlated with these contact probabilities, with a Spearman’s rank correlation of $r = 0.47$ (Fig. 3C). Weights S learned by single-factor optimization (Fig. S2A) show a marginally weaker correlation of $r = 0.45$ (Fig. S2B), while S and \mathcal{S} were strongly correlated overall (Fig. S2C). In contrast to contact probabilities, however, the optimal metric still heavily weights the edges of the CDR3 loop. This implies that substitutions of residues that do not make direct with the peptide still substantially impact TCR specificity and should be taken into account when clustering TCRs for their specificity.

We next compared the learned amino-acid substitution matrix $P_A(\Delta)$ with prior expectations. Our results show that as expected TCR pairs differing by insertions or deletions are much less likely to be co-specific compared to those differing by amino-acid substitutions (Fig. S1C). We further compared $\log P_A$ (Fig. 4A) and the widely used BLOSUM62 matrix B_{62} (Fig. 4B). Both matrices are moderately correlated with a Spearman’s rank correlation coefficient of $r = 0.44$ (Fig. 4C). The jointly optimized amino-acid substitution matrix \mathcal{A} was also correlated with the truncated BLOSUM62 variant used by TCRdist (Fig. S1E), and the matrix \mathcal{A} obtained by single-

factor optimization (Fig. S1F). Single-factor optimization led to marginally weaker correlations with BLOSUM-based scores (Fig. S1A).

What factors drive observed differences between \mathcal{A} and B_{62} ? To answer this question, we identified the physical properties of amino acids that predict most closely the substitution matrices. For a given property $h(n)$ of amino acid n , we quantified the contribution of h to the substitution matrices by calculating the matrix of absolute differences in h , defined as $\mathcal{H}(n, m) = |h(n) - h(m)|$. We then calculated Spearman’s rank correlation coefficient between the entries of \mathcal{H} and the entries of \mathcal{A} and B_{62} for 9 amino-acid properties. As shown in Fig. 5A, we find that B_{62} is strongly dependent on a number of hydrophobic and electronic properties of amino acids. In contrast, these properties are less correlated with the learned substitution matrix \mathcal{A} . Instead, \mathcal{A} correlates most with the steric similarity of substituted amino acids. For instance, many of the most strongly penalized substitutions involve replacing glycine, the amino acid with the smallest and most conformationally flexible side chain. The importance of steric properties in determining the specificity of TCRs, was also found when analyzing a larger panel of 50 amino-acid properties [46] (listed in Table S1). These results are compatible with prior findings using different amino-acid properties to determine optimal reduced alphabets [27] and they provide further biophysical insights into the determinants of TCR-pMHC specificity.

VI. EXTRAPOLATION OF LEARNED RULES

Having learned biophysically interpretable local rules based on pairs of single-edit TCR β sequences, we asked

FIG. 6. **Learned metrics generalize to pairs of TCRs with a range of sequence similarities.** AUROC of baseline method TCRdist (d_{Td} , black) and inferred site-specific metric (d_S , green), amino-acid substitution metric (d_A , blue), and jointly learned metric (d_{AS} , red) for edit distance 1-6 TCR pairs from different datasets. **A)** MIRA test set. **B)** VDJdb CDR3 β validation set. **C)** VDJdb CDR3 α validation set. Error bars show the standard error over resampled test batches.

whether these rules can be extrapolated to more dissimilar TCR pairs and the TCR α chain. To quantify this, we tested ability of trained metrics to identify co-specific sequence pairs among TCRs with an increasing number of edits on the β chain (Fig. 6A & B) and the α chain (Fig. 6C). This approach allowed us to evaluate the robustness and applicability of the metric across a broader range of sequence variations, providing insights into whether the local substitution rules remain effective when sequence dissimilarity increases.

We find that d_{AS} and d_S consistently outperform d_{Td} across all distances (Fig. 6A,B). These metrics optimized to take into account amino-acid substitution type (d_A and d_{AS}) retain strong predictive power for TCR pairs with edit distances up to 3-4 edit steps. When applied to VDJdb, classification performance for certain metrics even increases for sequences that differ by two or three edits (Fig. 6B), as might be expected within the range of applicability of an independent substitution model. However, this relatively high predictability needs to be interpreted in the context of the lower overall prevalence of co-specific sequences at higher edit distances. Beyond this range, performance declines, likely due to the increasing importance of higher-order features, such as motifs, that are not captured by the simple independent substitution model. These findings demonstrate the strength of basic distance metrics for refining notions of similarity for TCRs, while also highlighting their limitations when comparing receptors that are highly dissimilar.

We furthermore tested the generalization of the metrics to the α chain using data from VDJdb. We find that the learned amino-acid substitution matrix improves upon TCRdist scoring across a range of edit distances (Fig. 6C). These results indicate that some of the local co-specificity rules are common to both α and β chains.

VII. DISCUSSION

Despite rapid growth in TCR-pMHC data, only a tiny fraction of the vast diversity of pairings have been measured. This sparsity complicates the discovery of generalizable rules. In this study, we addressed this problem by developing a pseudolikelihood maximization framework for optimizing notions of TCR sequence similarity. We demonstrate that it is possible to use this framework to learn rules that robustly generalize to pMHCs not used during training. Our findings highlight that, while TCR-pMHC interactions are globally complex, local sequence-based rules effectively predict co-specificity, offering a practical advance for deorphanizing TCRs of unknown specificity.

Our results challenge the use of the BLOSUM62 amino-acid substitution matrix for TCR sequence analysis. These insights align with the independent findings of Postovskaya et al. [47] using alternative approaches and data, further underscoring the need for tailored distance matrices. Our results revealed steric similarity as a key predictor for the impact of amino-acids substitutions within the flexible hypervariable loops that make up the TCR binding interface. This finding aligns with the long-standing concept of an immunological shape space [48] in which shape complementarity governs receptor-ligand binding. Comparison of position-specific terms in more complex models with structural data further highlighted the importance of non-peptide-contact sites within the CDR3 to binding specificity, compatible with the presumptive role of all residues in determining overall loop geometry.

The application of our optimization framework was limited by the available sequence data. In order to make robust inferences possible, we decided to simplify the problem setting and restrict the family of metrics used for inference. We trained on CDR3 β sequences of restricted lengths and only considered sequence pairs with

matching V genes. Moreover, we only considered simple metrics with a limited number of free parameters. We assumed, for example, a factorization of site-dependent and substitution-dependent terms. With increasing data availability, including more diverse data on paired chain TCR $\alpha\beta$ sequences and their pMHC ligands, our framework can be applied to learn more sophisticated distance metrics.

Ultimately, we envisage that it will be possible to derive a machine-learning optimized mlTCRdist metric, which can act as a drop-in replacement for TCRdist. Additionally, we hope that the biophysical insights, robust learning framework, and data curation strategy introduced in this study can also be used to overcome current bottlenecks in the supervised contrastive training of TCR representations using deep learning architectures [18, 49]. Better TCR representations could significantly enhance TCR clustering for biomarker and metaclonotype discovery [42]. Improved understanding of the biophysical determinants of TCR specificity could also advance rational TCR design for therapeutic applications [50].

METHODS

Training procedure

Parameters were optimized by gradient descent, using the Adam algorithm as implemented in PyTorch [51]. To reduce sampling bias, the summed loss over 15 batches with equal representation of different pMHCs was simultaneously minimized, i.e., $\varepsilon(d) = \sum_{i=1}^{15} \varepsilon(d|\mathcal{P}_i, \mathcal{U}_i)$. All

distance metrics were trained with a learning rate of 10^{-3} , where 3000 steps were taken to train d_S , 5000 steps for d_A , and 12000 steps for d_{AS} .

Calculation of contact probabilities

To obtain TCR-peptide contact information, we utilized 179 publicly available TCR-pMHC complexes from the Structural T Cell Receptor Database [45]. The pairwise distances between each residue in the TCR CDR3 β loop and each peptide residue were calculated as the minimum distance between non-hydrogen atoms, as previously described [24]. Residues were defined as being in contact if their pairwise distance was less than or equal to 5 Å.
