THz Channels for Short-Range Mobile Networks: Multipath Clusters and Human Body Shadowing

Minseok Kim, Jun-ichi Takada, Minghe Mao, Che Chia Kang, Xin Du, and Anirban Ghosh

Abstract—The THz band (0.1-10 THz) is emerging as a crucial enabler for sixth-generation (6G) mobile communication systems, overcoming the limitations of current technologies and unlocking new opportunities for low-latency and ultra-high-speed communications by utilizing several tens of GHz transmission bandwidths. However, extremely high spreading losses and other interaction losses pose significant challenges to establishing widearea communication coverage, while human body shadowing further complicates maintaining stable communication links. Although point-to-point (P2P) fixed wireless access in the THz band has been successfully demonstrated, realizing fully mobile and reliable wireless access remains a challenge due to numerous issues to be solved for highly directional communication. To provide insights into the design of THz communication systems, this article addresses the challenges associated with THz shortrange mobile access networks. It offers an overview of recent findings on the environment-dependence of multipath cluster channel properties and the impact of human body shadowing, based on measurements at 300 GHz using a double-directional high-resolution channel sounder and a motion capture-integrated channel sounder.

Index Terms—Terahertz (THz), short-range, multipath clusters, human body shadowing, channel sounding, motion capture.

I. INTRODUCTION

While the deployment of fifth-generation (5G) mobile networks at Frequency Range 1 (FR1) (sub-6 GHz) and FR2 (24.25–52.6 GHz) is accelerating globally, the research and development focus is already shifting towards beyond 5G (B5G) and sixth-generation (6G) mobile networks. Future mobile networks are expected to demand low-latency of less than 1 ms and ultra-high data rates exceeding 100 Gbps, more than ten times faster than 5G. Recently, utilizing FR3 (midband, 7.1–24.25 GHz) has gained attention, but developing terahertz (THz) bands above 100 GHz (100 GHz–10 THz), which still can leverage large channel bandwidths of several tens of GHz, remains crucial.

As a result of the World Radiocommunication Conference 2019 (WRC-19), a part of the THz spectrum, 137 GHz within the 275-450 GHz band, has been identified for land mobile and fixed services, enabling ultra-high-speed communications at the 100 Gbps level. Further, at the WRC-23 in Dubai, a proposal to allocate the frequency bands of 102-109.5 GHz, 151.5-164 GHz, 167-174.8 GHz, 209-226 GHz, and 252-275 GHz for the future development of International Mobile Telecommunications (IMT) was approved as a preliminary agenda item for WRC-31. This increases expectations for the utilization of low-THz or sub-THz bands (100-300 GHz) beyond 2030. To effectively use THz waves in mobile networks, it is crucial to develop highly directional transmission methods that can overcome the significant spreading losses. Until now, THz waves have primarily been explored for pointto-point (P2P) fixed and backhaul communications, but various applications, including short-range mobile access, are being considered [1].

1

Fig. 1 shows a potential application of THz mobile networks. The pronounced line-of-sight (LoS) propagation and significantly large propagation losses in THz waves make it difficult to establish wide-area communication coverage, especially in non-line-of-sight (NLoS) regions. To achieve fully mobile and reliable wireless access, highly directional communication that leverages multipath propagation is essential. However, significant reflection losses, including the impact of rough surface scattering, greatly reduce the chances of obtaining viable multipath signals as the distance between antennas and reflectors increases. Consequently, securing multipaths suitable for multi-stream data transmission and diversity combining becomes challenging. Expanding coverage by densely deploying access points or base stations is a straightforward solution, but actively leveraging multipath propagation is essential to reduce installation and maintenance costs. Thus, a transmission approach that dynamically manages multiple beams along both direct and reflected paths to increase channel capacity and maintain communication continuity despite human body blockage is highly desirable.

A site-specific deployment that incorporates passive or intelligent reflecting surfaces (PRS/IRS) is essential to maximize the effective utilization of multipath propagation. While IRS technology holds significant promise for enhancing propagation environments, substantial technical challenges remain. Achieving precise, real-time control over reflected waves poses a considerable challenge, and the effective placement of IRS within complex environments requires meticulous planning. Additionally, the development of cost-effective, robust, and reliable IRS hardware capable of effective operation in the THz

Fig. 1. A potential application of THz mobile networks.

frequency bands remains a formidable obstacle. Accordingly, as an essential step prior to the consideration of such advanced technology, this article provides an overview of recent findings on multipath clusters and human body shadowing (HBS) to offer insights into the intrinsic capacity of THz multipath channels.

The remainder of this article is organized as follows. Following a brief review of recent progress, it presents multipath cluster channel characteristics obtained from doubledirectional high-resolution channel sounding at 300 GHz across diverse indoor and outdoor mobile access scenarios, covering distances of approximately 5 to 50 meters, which is crucial for estimating the intrinsic capacity of a propagation environment. Then, it presents HBS properties accurately captured through the simultaneous acquisition of channel responses and human motion. Furthermore, it discusses the challenges in THz short-range mobile access networks. Finally, conclusions are drawn.

II. RECENT PROGRESS

The modeling of the disparate properties of the THz band compared to the other well-studied lower-frequency spectrum may need a fresh approach. In this context, accurate channel modeling is essential for the reproducibility of radio wave propagation, validation of novel algorithms, and development of new systems. In this section, recent progress in channel measurement and modeling of multipath cluster channels at THz frequencies and human body shadowing at millimeterwave (mm-wave) frequencies is overviewed.

A. Multipath Cluster Channels

Channel measurements followed by modeling and characterization using various approaches have been reported in the literature for the THz band. In indoor settings, the environment that has been in focus includes data centers [2], offices [3], conference rooms [4], and corridors [5]. In [2], a modified Saleh-Valenzuela (S-V) model, where the modification lies in defining the cluster power as a function of delay, is used for channel modeling. In comparison, [3] uses an extended S-V model, which is dependent on the frequency of operation and stochastic properties of the position of transmitter (Tx) and receiver (Rx).

The channel modeling can be broadly classified into stochastic, deterministic, and hybrid models. Hybrid channel modeling combines either the strengths of both deterministic and stochastic approaches or different deterministic approaches to balance accuracy and computational efficiency. In the quasi-deterministic (QD) model, a widely accepted approach as a hybrid model, the dominant multipath components (MPCs) are identified from environmental geometry, whereas the complex scatterers are stochastically modeled to characterize the intra-cluster parameters for greater accuracy. This approach has been successfully applied to THz propagation in various indoor and outdoor scenarios, providing an optimal trade-off between accuracy and complexity [4], [5].

In non-indoor settings such as train to infrastructure (T2I) [6] and urban microcell (UMi) [7], multipath clustering has been used for modeling signal propagation in the THz band. While a third-generation partnership project (3GPP)-like QD model is used in [6], [7] presents a spatial autocorrelation function that can be used to develop a spatially consistent channel model. Individual and concerted efforts across the globe have led to measurement campaigns in the low THz band (below approximately 300 GHz) in different environments. Extensive measurement campaigns for parameterization remain insufficient, and a standardized channel model capable of accurately capturing cluster channel characteristics in the THz bands across diverse application scenarios has yet to be established.

B. Human Body Shadowing

To the best of the authors' knowledge, no relevant literature on HBS measurements in the THz band currently exists. Consequently, this subsection introduces related studies conducted in the mm-wave bands to highlight the challenges associated with the THz band. The measurements for the propagation channel affected by a pedestrian have been conducted [9], [10] using continuous wave (CW) signals. HBS properties, including shadowing loss and shadowing duration, were empirically parameterized from measurements of a fixed propagation channel shadowed by a human body moving at a constant speed. Given the short wavelength of mm-wave and THz bands, these HBS properties can vary significantly with instantaneous human motion. Therefore, further investigation and measurement of the relationship between the dynamic channel and corresponding human motion are required.

Various human models for deterministic simulations have been proposed and reviewed in [9]. In these simulations, human blockers can be represented by rectangular screens, spheres, cylinders, and polygons. However, in the THz band, ray tracing (RT)-based simulations often suffer from limited accuracy, while electromagnetics (EM)-based simulations incur prohibitively high computational costs. Consequently, a balanced approach that incorporates a detailed human body model with RT-based simulation is essential.

III. MULTIPATH CLUSTER CHANNEL MEASUREMENT AND MODELING

Integrating multiple-input-multiple-output (MIMO) antennas into THz systems enables ultra-narrow directional beamforming to mitigate severe path loss, and multi-stream transmission via multi-beam MIMO can significantly enhance data rates. Consequently, understanding multipath cluster channel characteristics at THz frequencies is essential for accurately assessing the intrinsic channel capacity of an environment and expanding coverage with PRS/IRS. This section introduces an in-house developed channel sounder and presents the environment-dependent multipath cluster channel properties measured at 300 GHz across various indoor and outdoor scenarios.

A. Double-Directional Channel Sounder

Channel sounding captures samples of the transfer function in time, frequency, and space domains to characterize the dispersive properties of a multipath propagation channel in terms of Doppler frequency, delay, and angles. These sampling domains are interchangeable due to the Fourier transform duality relationships, linking Doppler frequency with time, delay time with frequency, and angle with space.

Regarding angle domain channel acquisition, there are three widely recognized approaches: a full array, a virtual array, and angle scanning with directive antennas. In a full-array setup, simultaneous transmission from multiple antennas using orthogonal waveforms enables fast acquisition in the space domain. However, this approach typically involves greater complexity and higher development costs. On the other hand, a virtual array can capture channel responses in the space domain using a single antenna element, which is physically moved to various positions to form a synthetic array. While this method requires more time for measurement, it is generally more cost-effective. Both of these approaches rely on array signal processing, such as beamforming, to obtain channel responses in the angle domain, which is equivalent to performing a Fourier transform on the samples in the space domain. Angle scanning, a preferred method for channel measurements for mm-wave and THz bands, can relax post-processing requirements. This is beneficial because virtual arrays often experience phase drift over long measurement periods due to the relatively high phase noise of local oscillators. However, prolonged measurement time limits the ability to capture Doppler characteristics in dynamic scenarios. Thus, both the virtual array and angle scanning methods should maintain a static channel condition during measurement.

Several studies have developed channel sounders for THz bands. In [11], an instrument-based development was proposed. On the Tx side, an intermediate frequency (IF) signal with an 8 GHz bandwidth is generated by an arbitrary waveform generator and upconverted to 300 GHz. On the Rx side, the downconverted IF signals are sampled using an ultra-highspeed digitizer with a rate of 32 GSa/s. Angular characteristics are obtained by panning and tilting 26 dBi rectangular horn antennas on both the Tx and Rx sides. Due to the limited output power, the equivalent isotropically radiated power (EIRP) is around 16 dBm, which restricts the measurable distance. In a static environment, however, the signal-to-noise ratio (SNR) can be enhanced by averaging multiple sounding symbols, resulting in a gain of $10 \log_{10} M$ dB, where M is the number of averages. A dynamic range of approximately 60 dB is achieved when 100 snapshots are averaged, with a minimum separation distance of 1 meter; thus, multipaths can be measured at Tx-Rx separation extending to several hundred meters.

B. Environment-Dependent Cluster Channel Characteristics

To investigate the environment-dependent trends, both indoor scenarios, such as two different-scale conference rooms [11] and a corridor [5], and an outdoor scenario, an open square hotspot [12], were selected as typical environments, as shown in Fig. 2(a). These results were derived from cluster extraction and power spectrum synthesis, utilizing doubledirectional channel impulse responses obtained through angle scanning measurements. The key findings from the analysis of the 300 GHz band measurement data are summarized as follows.

The primary propagation mechanism observed, aside from the direct wave, is single-bounce reflection. The power delay spread characteristics obtained through omnidirectional antenna pattern synthesis are highly dependent on the environment and generally less than 10 ns, as shown in Fig. 2(b). The maximum excess delay is less than 100 ns in indoor environments and 160 ns in the open square environment. As the scale of the environment increases, the distance between the antenna and scatterers grows, causing a decrease in the number of multiple reflected waves with substantial power.

Fig. 3(a) illustrates the cumulative distribution of the number of clusters, which increases from left to right in the order of open square, large conference room, medium conference room, and corridor. In terms of average values, corridors, and medium conference rooms have eight clusters, large conference rooms have six, and open squares have four, indicating a tendency for the number of clusters to decrease as the environment size increases. Regarding the power of multipath clusters, Fig. 3(b) shows the cumulative distribution of relative power compared to the LoS path. That increases in the order of medium conference room, corridor, large conference room, and open square. The proportion of multipath clusters with a relative power greater than -10 dB, which could be advantageous for multi-stream transmission, is approximately 40 % in indoor environments. However, in open square environments, this proportion drops below 10 %, making multipath utilization less feasible in an open square.

Propagation loss characteristics improved by 2–5 dB compared to free-space path loss (FSPL) due to the presence of multipaths, as illustrated in Fig. 3(c). The distance between the antenna and the scatterer becomes larger, so the number of observable multipath clusters becomes even smaller. In particular, in the open square environment [12], single-bounce

Fig. 2. Measurement campaigns.

Fig. 3. Environment dependent cluster characteristics.

reflected waves from glass walls and windows were prominent. In NLoS conditions, diffracted waves other than reflected waves cannot be observed, making it difficult to receive signals. An obstruction by tree leaves caused a loss of larger than 10 dB.

deterministic components as $h_c^{\rm d}(\tau, \phi_{\rm T}, \phi_{\rm R}) = \gamma_{\rm los} \delta(\tau_{\rm los}, \phi_{\rm T, los}, \phi_{\rm R, los}) +$

direct path and specular reflection by walls are treated as

$$\sum_{n=1}^{N_b} \sum_{l=1}^{2} \chi_{n,l} \gamma_{n,l}^{\rm d} \delta(\tau_{n,l}^{\rm d}, \phi_{{\rm T},n,l}^{\rm d}, \phi_{{\rm R},n,l}^{\rm d}), \quad (2)$$

where $\delta(\cdot)$ is the Dirac delta function, γ and N_b denotes the amplitude and the maximum number of bounces. Herein, dominant MPCs up to quadruple bounces were counted ($N_b = 4$). $\chi_{n,l}$ denotes a random variable that captures the randomness related to the presence or absence of a path generated by a Markov chain. It is observed that, in general, two mirror-image paths are present for any Rx position due to quasi-symmetric reflections from opposite walls. On the other hand, the random components are expressed as

$$h_c^{\rm r}(\tau,\phi_{\rm T},\phi_{\rm R}) = \sum \gamma_l^{\rm r} \delta(\tau_l^{\rm r},\phi_{{\rm T},l}^{\rm r},\phi_{{\rm R},l}^{\rm r})$$
(3)

where $\delta(\tau_l, \phi_{\mathrm{T},l}, \phi_{\mathrm{R},l}) \equiv \delta(\tau - \tau_l)\delta(\phi_{\mathrm{T}} - \phi_{\mathrm{T},l})\delta(\phi_{\mathrm{R}} - \phi_{\mathrm{R},l})$ in both (2) and (3).

Furthermore, due to the irregularities and surface roughness, diffuse scattering can be viewed as a cluster of MPCs with delays and angles close to those of the specular component. By treating surface roughness as a spatially stationary stochastic

C. Cluster Channel Modeling

Since the wavelength of THz waves is much shorter than the size of typical interacting objects, the dominant propagation mechanism is specular reflection, which can be effectively predicted using deterministic prediction methods like RT. However, the shape and surface roughness of interacting objects cannot be ignored compared to the wavelength. Therefore, a QD model appears to be more effective.

For example, the impulse response of the QD model for a corridor environment developed in [5] is expressed as

$$h_c(\tau, \phi_{\rm T}, \phi_{\rm R}) = h_c^{\rm d}(\tau, \phi_{\rm T}, \phi_{\rm R}) + h_c^{\rm r}(\tau, \phi_{\rm T}, \phi_{\rm R}),$$
 (1)

where τ , $\phi_{\rm T}$, and $\phi_{\rm R}$ represent the delay time and azimuth angles of departure and arrival of an MPC, respectively. The

Fig. 4. Synchronized HBS channel and human motion measurement.

process, stochastic modeling can represent the small-scale fading of the specular reflection component caused by interference from diffuse scattering.

IV. HUMAN BODY SHADOWING MEASUREMENT AND MODELING

THz signal propagation is highly vulnerable to blockages caused by moving humans, building walls, and furniture. In particular, a thorough investigation into the relationship between human motion and the dynamic channel in THz bands is essential. This section introduces an in-house integrated system developed for the simultaneous acquisition of channel responses and human motion and proposes an RT-based HBS prediction model. Additionally, experimental validation is presented.

A. Motion Capture-Integrated Channel Sounder

An integrated system for simultaneous acquisition of THz channel responses and human motion has been developed [13]. The detailed human motion can be captured as point clouds using a motion capture (MoCap) system. The MoCap system and channel sounder are synchronized using an external trigger, as shown in Fig. 4. A continuous wave (CW) signal at 300 GHz was used for measurement. The received signal, influenced by human motion, was down-converted to 6 GHz and sampled by the signal analyzer at a rate of 30 kHz to capture the small-scale fading fluctuation caused by HBS. Multipath components from the surrounding environment were minimized by using 26 dBi rectangular horn antennas on both the Tx and Rx ends. Due to limited output power, the EIRP was approximately 16 dBm, providing a dynamic range of 54 dB with an antenna separation of 3.5 m.

B. Accurate RT-based Model for HBS Propagation Channel

The uniform geometrical theory of diffraction (UTD) for an edge has been commonly used in RT-based models to predict the shadowing effect, but its applicability to curved objects was in question. Through a unified analysis of the formulas for diffraction at edges and curved surfaces, it was shown that creeping diffraction or reflection occurs on the curved

(a) HBS calculation method considering reflection, edge diffraction, and creeping diffraction.

(b) Diffraction points extracted from human body.

Fig. 5. Accurate RT-based HBS calculation model.

surface [14]. Fig. 5(a) shows the spatial distributions of the receiving power normalized by the LoS power at 300 GHz CW for parallel polarization when a circular cylinder with the radius of 0.2 m obstructs the uniform plane wave. Here, the relative complex permittivity is set to 5.6 - j7.1 for modeling the human body. The simulation involves four methods: "UTD circle", "UTD screen", "proposal", and "exact solution". The "UTD circle" represents the results of the Uniform Theory of Diffraction (UTD) applied to curved surfaces. The "UTD screen" corresponds to the UTD results for edges. The "proposed" method is a superposition approach combining edge diffraction with an additional term accounting for reflection or creeping diffraction on curved surfaces. Finally, the "exact" solution as a reference is derived using eigen-function expansions. The results demonstrate that the proposed method exhibits good agreement with the exact solution.

In addition, the work in [14] demonstrates that an additional term can be neglected at high frequency near a shadow boundary. Consequently, the dynamic HBS channel can be modeled as diffraction paths from a human-shaped screen, suitable for RT-based simulation, as illustrated in Fig. 5(b). This human-shaped screen is created by projecting the human body's point cloud onto a projection plane. The projection plane is perpendicular to the LoS. Here, the distances between the human-shaped screen and the antennas are identical to those between a human blockage and the antennas. Since the phase of the diffraction paths is stationary, the criterion for identifying stationary phase points [15] can be applied to

the fading pattern in the lit region. The diffraction paths from the human-shape screen improve the bias error by a factor of five.

Fig. 6. The measurement environment for an office scenario and the CDF of the prediction error in the lit region.

determine the diffraction points.

C. Validation in an Office Scenario

The diffraction paths of the human-shaped screen were validated by observing the interference caused by Doppler frequencies in the lit region for an office scenario. The setup diagram of the HBS channel measurement in the office environment is shown in Fig. 6(a). In the measurement, the human specimen sat on the seat between the antennas, as one of the typical motions observed in the office. From the viewpoint of the Tx antenna, the human obstacle walked to the seat on the right-hand side, as depicted in Fig. 6(a). The human-shaped screen is compared with the rectangular screen by observing linear error predicting the envelope of dynamic HBS channel gain in the lit region. The cumulative distribution of ten measurements is displayed in Fig. 6(b). From the results, the human-shaped screen achieves better accuracy in bias error than the rectangular screen. Therefore, the efficient RT-based simulation can be an accurate alternative to EM-based HBS channel simulation when the diffraction paths are extracted from a human-shaped screen.

V. FUTURE RESEARCH CHALLENGES

The exploration of dynamic channel properties in indoor and outdoor environments, crucial for short-range mobile access in future communication systems, is necessary to understand the potential performance of the THz systems but remains limited due to the absence of extensive measurement campaigns. In addition, the current measurement campaigns have primarily focused on frequencies below 500 GHz, leaving large portions of the spectrum uninvestigated. Furthermore, the dynamic behavior of channels, such as human body blocking, reflections, and scattering from mobile objects, needs further study.

As discussed earlier, integrating IRS into THz communication systems is essential, offering a promising low-cost approach to addressing the short-range limitations and achieving reliable wireless connectivity. Moreover, IRS-assisted multibeamforming can significantly enhance spectrum and energy efficiency while providing alternative propagation paths to mitigate the impact of human blockages. Importantly, due to extremely small wavelengths, the THz communications in short-range mobile scenarios will often have to operate in the near-field. In this scenario, the IRS can focus energy precisely on a specific mobile user, significantly enhancing communication efficiency. However, achieving this requires accurate near-field channel estimation and precise phase control of IRS unit cells, which remain critical challenges to be addressed. As THz communication matures, integrating advanced technologies like IRS, holographic MIMO, and heterogeneous 3D networks into dynamic short-distance scenarios will necessitate comprehensive studies to optimize frequency planning, communication range, and network capacity.

VI. CONCLUDING REMARKS

While THz frequency bands offer the potential for ultrahigh-speed data transmission at rates of hundreds of gigabits per second, enabled by their large channel bandwidth, concrete applications, and usage scenarios have yet to be fully articulated. This is mainly due to the inherent challenges associated with THz frequencies, including limited coverage, significant path losses, and human blockages. In this regard, to understand the potential of THz multipath channels, this article presented an overview of recent findings on multipath clusters and the effects of HBS. Advanced system design that leverages intrinsic multipath links and virtual links facilitated by IRS is anticipated to enhance both coverage and reliability in THz communication networks significantly.
