Abstract

Titan's abundant atmospheric N₂ and CH₄ gases are notable characteristics of the moon that may help constrain its origins and evolution. Previous work suggests that atmospheric CH₄ is lost on geologically short timescales and may be replenished from an interior source. Isotopic and noble gas constraints indicate that N₂ may derive from a mixture of NH₃ ice and heating of organic matter. Here, we report experimental results from hydrothermal alteration of insoluble organic matter from the Murchison meteorite and analog insoluble organic matter at temperatures and pressures that are relevant to Titan's interior. Our results indicate both CH₄ and CO₂ are formed, with the ratio between the two depending on a multitude of factors, particularly temperature and, to a lesser degree, the dielectric constant of water and carbonyl abundance in the starting material. Sufficient CH₄ is produced to source Titan's atmospheric reservoir if temperatures are greater than 250 °C. Nitrogen is volatilized, primarily in the form of NH₃, in sufficient abundances to source at least 50 % of Titan's atmospheric N₂. The isotopic characteristics of volatilized material relative to the starting organics are consistent with current constraints for the nature of the accreted complex organics and Titan's evolved atmosphere.

Keywords: organics, ocean worlds, volatiles, Titan

1 Introduction

The origin of Titan's thick atmosphere may provide key clues not only to the formation and evolution of Titan but also to the formation conditions of the Saturnian system. The presentday atmosphere of Titan has a base pressure of approximately 1.5 bar and is dominated by N_2 gas. The presence of between 1.5 mole% and 5.7 mole% CH₄ is, however, critical to the maintenance of the relatively warm temperatures required for N_2 to remain in the gas phase

2

(Charnay et al. 2014; Lorenz et al., 1997). Measurements by the Cassini Huygens probe indicate that there are trace quantities of ³⁶Ar and ⁴⁰Ar in Titan's atmosphere, while Xe and Kr were below detection with upper limit mole fractions of 1×10^{-8} (Niemann et al., 2010). Measurement of the ¹⁴N/¹⁵N ratio in N₂ (~168; Niemann et al., 2010), and the ¹²C/¹³C (91.4±1.5; Niemann et al., 2005, 2010) and D/H ([1.35±0.3]×10⁻⁴; Niemann et al., 2010) ratios in CH₄ are also recognized as key constraints in the current understanding of the formation of Titan's atmosphere (Mandt et al., 2009, 2012; Nixon et al., 2012).

The primary accretion of N₂ at Titan as a volatile ice was initially ruled out by the limit set on the abundance of Ne relative to N₂ from the Voyager UV, IRIS, and radio experiments (Strobel and Shemansky, 1982). These measurements indicated strongly subsolar Ne relative to N. This could be explained by accretion of N₂ as a clathrate, to the exclusion of Ne (Owen, 1982); but if true, then a solar Ar/N₂ ratio would be expected. Measurements by the Huygens probe GC-MS experiment, however, showed that ³⁶Ar/N₂ is subsolar by a factor of approximately 10⁵ (Niemann et al., 2010), ruling out accretion of N₂ ices as the primary source for Titan's atmospheric N₂. Secondary production of N₂ from N-bearing precursors must therefore be a significant process at Titan.

One possible precursor form is gaseous NH₃, which is the thermodynamically favored volatile form of N in disk environments. Kinetic inhibition of the formation of NH₃ from N₂ (Lewis and Prinn, 1980) may be overcome in a warm, well-mixed Saturnian subnebula (Prinn and Fegley, 1981). However, orbital evolution of giant planet-satellite systems may instead point towards formation in a gas-starved disk (e.g. Canup and Ward, 2006). Under such conditions, conversion of gaseous N₂ to NH₃ is kinetically inhibited at Titan's distance from Saturn (Alibert and Mousis, 2007), favoring NH₃ ice as the N source.

3

High ¹⁵N/¹⁴N ratios in cometary NH₃ ice were predicted on the basis of Titan's atmospheric composition (Sekine et al., 2011). Later measurements of ¹⁵NH₂/¹⁴NH₂ in comets (Rousselot et al., 2013; Shinnaka et al., 2014, 2016) confirmed this prediction. Modeling of atmospheric loss processes at Titan indicate that the evolution of the ¹⁵N/¹⁴N ratio of the atmosphere over the lifetime of the solar system points towards cometary NH₃ ice as a significant source of N for Titan's atmosphere (Erkaev et al., 2021; Mandt et al., 2009, 2014). Hydrodynamic escape and sputtering were found to be inefficient at N isotopic fractionation, while Jeans escape would act too slowly to isotopically fractionate N within the lifetime of the solar system (Mandt et al., 2014). When the effects of the evolution of the extreme ultraviolet (EUV) flux from the young sun on photochemical loss processes are taken into account, Titan's initial ¹⁵N/¹⁴N ratio is estimated to have been (5.8-6.0)×10⁻³ (Erkaev et al., 2021), where the cometary value for NH₂ is ¹⁵N/¹⁴N = (7.1-7.7)×10⁻³ independent of cometary dynamic family (Shinnaka et al., 2016).

Accreted NH₃ ices may be converted to N₂ via photolytic processes and may yield up to 10 bars of N₂ in 30 Myr in an NH₃ - CH₄ primary atmosphere (Atreya et al., 1978, 2010). However, such processes are only effective between 150 K and 250 K, which would require greenhouse warming from a 0.45 bar CH₄ - H₂ atmosphere prior to the transformation of NH₃ to N₂ (Atreya et al., 1978). For comparison, the present-day partial pressure of CH₄ in Titan's bulk atmosphere is less than 0.1 bar (Niemann et al., 2010), but significant CH₄ loss over the lifetime of the atmosphere is expected (Yung et al., 1984). As an alternative to photolytic conversion, NH₃ may be oxidized to N₂ via impact processes. Experimental work has demonstrated the production of N₂ under relevant impact conditions (McKay et al., 1988; Sekine et al., 2011).

However, the impact erosion of Titan's atmosphere is highly effective (Marounina et al., 2015) and may limit the formation of an N₂ atmosphere by this process.

Interior processing provides a third possible mechanism for the formation of secondary N₂ from NH₃ or other accreted forms. Episodic outgassing from Titan's interior has been posited as a mechanism for replenishing CH₄ in Titan's atmosphere (Tobie et al., 2006), which is consumed by photochemical processes on timescales of 10 Myr at present rates (Wilson and Atreya, 2004; Yung et al., 1984). Geothermal modeling of Titan's interior suggests that temperatures exceed 400 K within 100 km of the water-rock interface (Castillo-Rogez and Lunine, 2010; Reynard and Sotin, 2023). Endogenic formation of CH₄ from C grains or CO₂ (Atreya et al., 2006) and of N₂ from NH₃ (Glein et al., 2009) may occur in a warm interior. Outgassing may also contribute noble gases to Titan's atmosphere. Assumptions about the outgassing efficiency of noble gases, N₂, and CH₄, based on geochemical behavior including their saturation vapor pressures, suggest that the bulk of Titan's atmosphere may form via outgassing (Glein, 2015).

Assuming chondritic abundances of insoluble organic matter (IOM; up to 4 wt.% in chondrites, e.g. Alexander et al. 2007) in Titan's building blocks, organic contributions to Titan's volatile reservoir from heating in the interior are probable, but likely insufficient to serve as the dominant source (Tobie et al., 2012). Measurements from comet Halley and comet 67P/Churyumov-Gerasimenko suggest that IOM-like material may be a dominant component of outer solar system bodies, though, with abundances on the order of 45 wt.% of the refractory material (Bardyn et al., 2017; Greenberg, 1986; Kissel et al., 1986; Kissel and Krueger, 1987; McDonnell et al., 1986). In this case, the potential for production of atmospheric N₂ from IOM-like source material increases significantly, such that production of 50 % of Titan's N

5

atmosphere from hydrothermally degraded IOM is theoretically consistent with both the abundance of N available in such a source and the likely isotopic and noble gas composition of such a source (Miller et al., 2019). The model of Miller et al. (2019) draws on previously published anhydrous pyrolysis experiments on isolated IOM at ambient pressures to estimate outgassing abundances. Additional experimental work on whole rock samples confirms the production of CH₄, CO, and CO₂ from carbonaceous chondrites at high temperatures and ambient pressures (Thompson et al., 2022). Titan's present-day water-rock interface is at a pressure of approximately 8 kbar (Sotin et al., 2021), and pressure and temperature may both influence volatilization of complex organic matter (Mi et al. 2014). Here, we examine the role of temperature and pressure on the composition and abundance of volatile material derived from complex organic matter, including C-bearing gases as well as production of NH₃, and consider the implications for the origins of Titan's volatiles.

2 Materials and Methods

2.1 Synthesis of syn-IOM

Analog IOM ("syn-IOM") was synthesized in batches following established protocols (Foustoukos et al., 2021). These organic residues have been shown to exhibit similar chemical and molecular compositions and structures to chondritic IOM (Foustoukos et al., 2021). Briefly, approximately 170 mg of dextrose ($\delta^{13}C = -9.6 \%$) and 1 mL of ~ 1 M NH₄Cl_(aq) ($\delta^{15}N = 0.33$ ‰, $\delta D = -77 \%$) in aqueous solution ($\delta D = -250 \%$ or -100 %) were added to a borosilicate glass tube. The tube was flame sealed under atmosphere, and then heated to a temperature of 150 °C to 250 °C, where it was held for over 100 hours. The dextrose polymerizes, and the C/N ratio of the final product is controlled by the concentration of NH₄⁺ in solution. Upon quenching, the

vials are transferred to a freezer overnight. The vials are broken open while frozen, and the residue is retrieved and dried under N₂. The syn-IOM is rinsed multiple times with deionized water, followed by a final ethanol rinse. The initial composition of syn-IOM and IOM materials used is summarized in Table 1.

2.2 Extracted Murchison IOM

Murchison IOM used was a combination of material extracted from the bulk aliquots (A&B) of Murchison using the CsF-HF protocol as described in Cody et al. (2024). Briefly, powdered meteorite samples were first digested with 2 N HCl, before rinsing with Milli-Q water and dioxane. The resulting residue was treated with a combination of aqueous CsF-HF solution and dioxane, which leads to two immiscible layers. Iterative agitation and centrifuging of the sample leads to accumulation of the separated IOM at the boundary between the two layers. The IOM is removed by pipette, rinsed successively with 2N HCl, Milli-Q water, and dioxane, and then dried at 30-50 °C.

2.3 Heating experiments

Experiments at 1 kbar and 3 kbar were conducted using cold seal pressure vessels at the Carnegie Institution for Science's Earth and Planets Laboratory, while experiments at 10 kbar were performed using a piston cylinder apparatus. The adopted protocols followed those described in Foustoukos (2012) and Foustoukos and Mysen (2015). Briefly, the experiments were performed in Au capsules that were pre-treated with an acid wash to remove contaminants. For each syn-IOM experiment, approximately 20 mg of syn-IOM was loaded into a ~10 mm Au tube that had been sealed at one end. For the Murchison IOM experiments, approximately 10 mg of IOM were used for each aliquot. A mass of water that was approximately equal in mass to the IOM/syn-IOM aliquot was added to the Au tube, which was then welded closed using a PUK 3s professional plus arc welder. The tubes were weighed before and after sealing to ensure that the welding did not cause loss of water. Water was not specifically degassed to remove O₂ prior to sealing, and we estimate based on atmospheric composition that at most $\sim 4 \times 10^{-7}$ moles of O₂ may have been included in the experimental charges, equivalent to $\sim 2 \times 10^{-5}$ mmole O₂/mg organics. The initial presence of atmospheric O₂ in the experimental charges may have resulted in consumption of product H₂ to form water, or in oxidation of C to form CO₂. However, the abundance of atmospheric O₂ initially present in the experimental charges is negligible compared to the abundance of CO_2 produced.

For all experiments, the reaction times at the targeted temperature and pressure conditions (Table 2) were 48 hours. After quenching, the capsules were recovered and placed in glass vials with a blue butyl rubber stopper and sealed with an aluminum crimped cap. The vials were subsequently evacuated and backfilled to atmospheric pressure with Ar. To each vial was added 1 mL of 0.1 N HCl to maintain acidic conditions with the aim of converting all dissolved C and N to $CO_{2(g)}$ and NH_4^+ , respectively. The Au capsules were then punctured with a steel needle to release the contents.

2.4 Gas Analysis

Volatile samples from the headspace were analyzed by a Shimadzu GC-8A gas chromatograph (GC) equipped with a thermal conductivity detector (TCD) and a Carboxen-1010 Plot/Silica Gel column. Calibration was performed via replicate injections of a mixture of 1% CO_2 , CO, H_2 , O_2 , and CH_4 with N_2 for the balance (Matheson Gas, Item No. GMT10403TC, Lot No. 109-56-13398). The detection limit for these volatiles is 1–5 µmol/kg (Foustoukos et al., 2011). For each measurement, 1 mL of gas at atmospheric pressure was injected into the chromatograph. The measurements were made at a constant temperature of 120 °C, with a TCD current of 60 mA and Ar as the carrier gas.

To verify that headspace gas was representative and dissolution of gas in the sample vial fluid was not significant, we estimated the total pressure in the vial with the product gas (up to 100 bar) and examined the solubility of CO_2 (Diamond and Akinfiev, 2003) and CH_4 (Duan and Mao, 2006) at 25°C up to that pressure. We find that dissolved CO_2 may add at most 9% to the reported abundances, and dissolved CH_4 may add at most 0.6%. While product gases dissolved in the fluid are not directly accounted for, their amount is negligible.

2.5 Bulk Analyses of Solids

The elemental and isotopic analyses of the organic residues were made with (i) a Thermo Scientific Delta V^{plus} mass spectrometer connected to a Carlo Erba (NA 2500) elemental analyzer (CE/EA) via a Conflo III interface for C and N analyses, (ii) a Thermo Finnigan Delta

Plus XL mass spectrometer connected to a Thermo Finnigan Thermal Conversion elemental analyzer (TC/EA) via a Conflo III interface for H analyses, and an iii) Thermo Scientific Delta Q mass spectrometer connected to an EA - Isolink via a Conflo IV interface for H and O analyses. The Conflo III/IV interfaces facilitate the introduction of the H₂, N₂, CO₂, and CO reference gases. In the Delta Plus XL, a dual inlet system facilitates the introduction of the H₂ reference gas. An H₃⁺correction was determined and applied to the H measurements (Sessions, 2001). We used in-house standards to normalize and correct the data at regular intervals to monitor the accuracy and precision of the measured isotopic ratios and elemental compositions throughout the runs. These in-house standards, which included both gases and solid materials, have been calibrated against international and other certified standards (Standard Mean Ocean Water or SMOW, National Bureau of Standards-22, IAEA-601, Pee Dee Belemnite, and air) from the Isoanalytical Laboratory, the U.S. Geological Survey, the National Bureau of Standards, and the Oztech Trading Company. The reported uncertainties for the elemental and isotopic analyses correspond to the highest 1σ deviations attained from either the replicate analyses of distinct subsamples or the internal standards.

The experimental solid products were washed several times with milliQ water and ethanol, before being dried down at < 50 °C under vacuum. The solid residues were weighed into foil capsules (Ag for H and O, Sn for C and N). Before H analysis, the solid samples were transferred to a zero-blank autosampler and flushed with dry He for at least one hour. Typical sample sizes were 0.3 mg. For the H analyses, replicate samples were analyzed sequentially to check for both sample heterogeneity and small memory effects that occur. Blanks were run before and after samples, again to reduce any memory effects. For example, the H abundances of the duplicate samples generally differed by \leq 5 % of their absolute values, and the δ D values

11

differed by a median of 4 ‰ (the δ notation stands for the deviation of a sample ratio from a standard ratio in parts per thousand, δ (‰) = (R_{smp}/R_{std} -1) x 1000, and in this case R = D/H). The isotopic ratios are reported in ‰ relative to VSMOW (O, H), Pee Dee Belemnite (C) and standard air (N). There is no memory effect for C, N and O analyses.

2.6 NH_4^+ Analysis

Ammonium concentrations were determined with the indophenol blue method via spectrophotometry (Tecan Inifinite M200 spectrophotometer) at 570 nm (Pérez-Rodríguez et al., 2017). The reagent kit utilized was from Abcam (#102509). Spectrophotometric measurements were performed as duplicates for each sample and reported as average values. The estimated uncertainty (2σ) for the NH₄⁺ analysis is less than 2%.

To extract NH₄⁺ from the sample solutions (3 mL), NH₄⁺ was converted to NH_{3(g)} using a pH-buffered Na₂B₄O₇-NaOH solution (1 mL, pH = 12.7), and then diffused into diffusion packets (e.g. Holmes et al., 1998; Pérez-Rodríguez et al., 2017; Sigman et al., 1997). The diffusion process occurred in pre-evacuated vials to enhance the purity and partial pressure of NH_{3(g)} in the headspace. Diffusion packets were made with 1 cm diameter glass fiber disks grade GF/D filters, pre-acidified with 50 µL of 2 M sulfuric acid (4 N) and sandwiched between 2.5-cm diameter, 10-µm pore size Teflon membranes. Samples were incubated for 7 days at 60 °C. After removing the diffusion packets, the GF/D disks were freeze-dried. Every set of analyses was cross-referenced to standard NH₄⁺ solutions ($\delta^{15}N = 17 \%$) with concentrations ranging from 1.9 mM to 0.019 mM. The minimum NH₄⁺ concentration for $\delta^{15}N$ analysis is 0.019 mM.

12

3 Results

3.1 Headspace gas

The results from GC analyses of the headspace volatiles are summarized in Table 2. The primary constituents identified via GC analysis included CH_4 , CO_2 , H_2 , and CO (Figure 1), as well as small abundances with an elution time consistent with N₂ or air. Overall, the abundances are consistently reproduced across different replicates and syn-IOM starting samples, suggesting that the observed results and trends may be broadly applicable for complex organic matter. We are unable to exclude the possibility that contaminant air was introduced at trace quantities during sample preparation or subsequent work-up, and therefore cannot conclude from these experiments that what is likely N₂ was produced via hydrous pyrolysis of the samples. The levels of N₂ determined by GC analysis were significantly smaller (~ 10% by volume) than those expected under 1 atmosphere partial pressure, suggesting that atmospheric contamination was minor.

To assess whether experimental charges reached equilibrium, we compared the logarithms of the reaction quotient O and the equilibrium constant K for the reaction

$$\mathrm{CO}_2(\mathrm{aq}) + 4\mathrm{H}_2(\mathrm{aq}) = \mathrm{CH}_4(\mathrm{aq}) + 2\mathrm{H}_2\mathrm{O}$$

The activities of CH₄, CO₂, and H₂ are taken from the experimental results to calculate log(Q). We used the CHNOSZ package (Dick, 2019) with the Deep Earth Water model (Sverjensky et al., 2014) implemented for water to calculate log(K) at our experimental conditions (250 °C, 350 °C, 500 °C; 1 kbar, 3 kbar, 10 kbar). With the possible exception of experiment 350-1-1, our results (Table 2) suggest that the experiments did not achieve equilibrium.

Figure 1. Production of COH volatiles for all experimental charges: (a) H_2 , (b) CO, (c) CH₄, and (d) CO₂. The temperature at which experiments were conducted is given on the x-axis, and the color of the symbol gives the pressure. The shape of the symbol corresponds to the syn-IOM or IOM used as described in Table 1; "Murch" denotes IOM extracted from Murchison. Results are the average of multiple analyses on a single experimental charge, where the error bars give one standard deviation. Error bars for CO are larger than the measured values, and CO data should be interpreted as a qualitative detection.

Some pressure dependencies for the measured gas compositions were observed. The magnitudes of the trends are summarized in Table 3. Overall, pressure most strongly affects H_2 yields at temperatures below 500 °C, with increasing production at increasing pressures and some sample dependency. CH_4 and CO_2 exhibit minor pressure effects, and yields tend to decrease with increasing pressure at temperatures above 250 °C.

Production of H₂ at 250 °C increases by a factor of $\sim 2\times$ from 1 kbar to 3 kbar. At 350 °C, increasing production with increasing pressure is also observed, by as much as a factor of 8. This trend is seen in both the syn-IOM and the Murchison IOM samples and extends up to 10 kbar. At 500 °C, the results from HC096 suggest almost a 4× increase from 3 kbar to 10 kbar, and results from HC113 show a $\sim 3\times$ increase from 3 kbar to 10 kbar. However, IOM HC096 shows a slight decrease in H₂ production from 1 kbar to 3 kbar.

CO was infrequently observed, and no conclusions can be drawn about the pressure

dependence of its generation at 250 °C or 350 °C. Data from the HC096 sample at 500 °C

suggest that CO production may decrease with increasing pressure. However, we note that the

CO abundances were very low, and these results should be interpreted with caution.

Table 3. Summary of pressure effects. Comparisons are made only between experiments with the same starting syn-IOM or IOM sample (third column). The absolute change in gas production is given in the fifth column, and the relative change gives the ratio of the gas production from the higher pressure to the lower pressure.

Gas	Temperature	Sample(s)	Pressure change,	Change in gas	Relative
			kbar	production, mmole	change
				gas/mg IOM	
H ₂	250 °C	HC113	1 kbar to 3 kbar	7.2×10 ⁻⁷	2.3×
	350 °C	HC096	1 kbar to 3 kbar	1.1×10 ⁻⁵	8.1×
		HC083	1 kbar to 10 kbar	2.4×10 ⁻⁶	1.6×
		Murchison	3 kbar to 10 kbar	2.0×10 ⁻⁵	4.3×
	500 °C	HC096	1 kbar to 3 kbar	-3.5×10 ⁻⁵	0.2×
			3 kbar to 10 kbar	1.8×10 ⁻⁵	3.6×
			1 kbar to 10 kbar	-1.7×10 ⁻⁵	0.6×
		HC113	3 kbar to 10 kbar	2.0×10 ⁻⁵	2.9×
CH ₄	350 °C	HC096	1 kbar to 3 kbar	-3.5×10 ⁻⁵	0.7×
		HC083	1 kbar to 3 kbar	-3.1×10 ⁻⁵	$0.8 \times$
			3 kbar to 10 kbar	-4.3×10 ⁻⁵	0.7×
			1 kbar to 10 kbar	-7.4×10 ⁻⁵	0.6×
		Murchison	3 kbar to 10 kbar	9.9×10 ⁻⁵	1.5×
CO ₂	500 °C	HC096	1 kbar to 3 kbar	-2.3×10 ⁻⁴	0.8×

For CH₄, decreasing abundance with increasing pressure (0.6 to $0.8\times$) is observed at 350 °C, for both the HC096 and HC083 samples. A very slight decrease from 1 kbar to 3 kbar may be present at 250 °C for HC113, but the difference is so small that in the absence of the 350 °C

trend, it would not be notable. No apparent pressure trend is observable for CH_4 at 500 °C. Note also that production of CH_4 from Murchison IOM shows the opposite trend at 350 °C, with CH_4 abundance increasing by 1.5× as pressure increases from 3 kbar to 10 kbar.

The HC096 samples show a slight decrease of $0.8 \times$ for CO₂ production at 500 °C from 1 kbar to 3 kbar, but no apparent change from 3 kbar to 10 kbar. No other pressure trends are observed for CO₂.

While pressure affects gas production with up to nearly an order of magnitude difference for H_2 , temperature is the dominant variable in controlling the abundance of CH_4 and CO_2 production. CH_4 production increases with increasing temperature, while CO_2 displays more complex behavior. The changes in gas production as a function of temperature are summarized in Table 4.

The production of H_2 generally increases with increasing temperature by up to a factor of 9.4×, although a slight decrease (0.6×) in H_2 is seen from 350 °C to 500 °C for the HC096 sample at 3 kbar. This trend is not repeated for the Murchison sample or the HC113 sample over the same pressure and temperature interval and may suggest some sample-dependence.

The HC096 sample exhibits an apparent increase in CO production with increasing temperature from 250 °C to 500 °C at 3 kbar. However, no CO production was observed for the HC096 sample at 350 °C and 3 kbar, and CO abundances have large uncertainties that make the reported detections more qualitative than quantitative.

The abundance of CH₄ increases with increasing temperature. This is best typified by the HC096 sample at 3 kbar from 250 °C to 350 °C (78.2×), and again from 350 °C to 500 °C (37.8×). A more modest increase in CH₄ is also observed in the Murchison sample at 3 kbar from 350 °C to 500 °C (8.5×), and in the HC113 sample at 10 kbar from 350 °C to 500 °C (4.6×).

18

While the abundances of most gases generally increase with increasing temperature, CO₂ production is seen to peak at 350 °C in these experiments. Again, this is most easily observed with the HC096 sample at 3 kbar, which shows an increase in CO₂ production from 250 °C to $350 \text{ °C} (11.7\times)$, and then a decrease from $350 \text{ °C} to 500 \text{ °C} (0.4\times)$. In contrast, both the Murchison IOM sample at 3 kbar and the HC113 sample at 10 kbar show a very slight increase in CO₂ production from $350 \text{ °C} to 500 \text{ °C} (1.1\times)$, but this increase is significantly less than the CH₄ increase over the same temperature range. The net result is an increase in the CH₄/CO₂ ratio in the product gas from 350 °C to 500 °C.

The molar CH_4/CO_2 ratios in the experimental products are plotted in Figure 2. For these experiments, CO₂ was the dominant product below 500 °C, including both syn-IOM and Murchison IOM. The syn-IOM samples show a decrease in CH_4/CO_2 with increasing pressure at 250 °C and 350 °C. The Murchison IOM shows the opposite trend at 350 °C, with increasing pressure resulting in increasing CH₄/CO₂. Comparison of Murchison IOM production rates for each gas to syn-IOM HC083 suggests that the increasing CH_4/CO_2 results from a slight increase from Murchison IOM relative to the syn-IOM in CH₄ production and a slight decrease in CO₂ production. That is, whatever structural differences there are between the syn-IOM and the Murchison IOM that controls their hydrous pyrolysis behavior affects the production of both gases. At 500 °C, CH₄ abundances become similar to those of CO₂, although which gas ultimately dominates the composition is sample-dependent. While HC096 has a higher H/C ratio (0.96) than Murchison (0.70) or HC091 (0.91), the highest H/C ratio is for HC113 (1.13). The CH₄/CO₂ ratios of the different samples at 500 °C (HC096>HC113>HC091>Murchison) may be influenced by the H/C ratios of the starting materials (HC113>HC096>HC091>Murchison), but the HC113 and HC096 samples suggest additional factors may also come into play. The

production of CO₂ is low for HC096, which further suggests that the CH₄/CO₂ ratio at 500°C is

affected by both O and H in the IOM.

Table 4. Summary of the observed temperature effects. Comparisons are made only between experiments with the same starting syn-IOM or IOM sample (third column). The absolute change in gas production is given in the fifth column, and the relative change gives the ratio of the gas production from the higher temperature to the lower temperature.

Gas	Pressure, kbar	Sample(s)	Temperature change, °C	Change in gas production, mmole gas/mg IOM	Relative change

3.2 Residue composition

Subsequent to the heating experiments, the solid residues remaining in each experimental charge were analyzed for their bulk elemental (Table 5) compositions. Normalized elemental compositional changes are calculated as:

$$R_{X/C} = \frac{\left(\frac{X}{C}\right)_{final}}{\left(\frac{X}{C}\right)_{initial}}$$

where X/C is the atomic ratio of H, N, or O to C, "initial" refers to the starting materials, and "final" refers to the solids after reaction. The relative changes are graphically displayed in Figure 3, and trends with pressure and temperature are summarized in Table 6.

Experiment	T, °C	P, kbar	(syn)- IOM sample	H/C (at.)	R _{H/C} *	N/C (at.)	R _{N/C} *	O/C (at.)	Ro/c*	C, wt.%	H, wt.%	N, wt.%	O, wt.%

Table 5. Elemental composition of bulk solid residues after reaction. Changes listed are relative to starting compositions for the syn-IOM and IOM samples listed in Table 1. "Murch." represents IOM extracted from Murchison.

Symbols are as described in Figure 1.

The $R_{H/C}$ values generally drop as temperature increases, consistent with the loss of H from the organic matter at a greater rate than the loss of C. The $R_{H/C}$ values at a given temperature may increase very slightly with increasing pressure (e.g., $R_{H/C}$ at 350 °C and 500 °C for HC096 samples), but the averaged values are within one standard deviation. The increase in $R_{H/C}$ with increasing pressure is consistent with the stronger pressure dependence of H₂ compared to CO₂ or CH₄ (Figure 1). The decrease in H/C of complex organic matter following heating is very well established across a broad range of samples (e.g. van Krevelen, 1982). Our

analyses overall follow the expected trend of increasingly C-enriched composition at higher

temperatures (e.g. Figure 4).

Table 6. Trends in evolution of elemental composition of solids. Values reported are averages of all syn-IOM samples; Murchison IOM is excluded. Cited uncertainties correspond to one standard deviation.

Temp, °C	Pressure, kbar	R _{H/C}	R _{N/C}	R _{O/C}
250 °C	1	0.71±0.05	0.48±0.27	0.53±0.01
	3	0.83±0.15	0.52±0.34	0.51±0.03
350 °C	1	0.69±0.01	0.65 ± 0.08	0.23
	3	0.68±0.01	0.85±0.25	0.23
	10	0.81±0.33	0.43±0.29	0.15±0.04
500 °C	1	0.35±0.15	0.67±0.42	
	3	0.42±0.10	0.43±0.43	0.08 ± 0.00
	10	0.35±0.17	0.36±0.34	0.09

The $R_{N/C}$ values display a stronger dependence on the starting material than $R_{H/C}$, even with the normalization to the initial N/C ratio. The HC113 sample shows the greatest reduction in N/C, while the HC096 sample shows very little change in N/C. Critically, the $R_{N/C}$ value of the Murchison sample is intermediate to HC113 and HC096, even though the N loss from Murchison is substantially lower than either HC113 or HC096. For each given sample, $R_{N/C}$ generally decreases with increasing temperature, although the HC096 sample shows greater loss of C than N for the 350 °C and 3 kbar experiment. A very slight decrease in $R_{N/C}$ with increasing pressure is seen, most notably for the HC083 samples at 350 °C, but also for HC096 at 500 °C and HC113 at 250 °C. This may reflect the slight reduction in production of CO₂ and CH₄ observed with increasing pressure (Figure 1).

For the HC113 syn-IOM sample, the $R_{O/C}$ values decrease with increasing temperature, especially from 250 °C to 350 °C. Some leveling off is apparent at 500 °C. Some pressure dependence from 3 kbar to 10 kbar may be evident in the HC083 syn-IOM sample, but no pressure dependence is seen in the HC113 syn-IOM, suggesting that this effect is either marginal or sample-dependent. No significant trend in $R_{O/C}$ is apparent for the Murchison samples. This may be consistent with the observations above (Figure 2) of evidence for structural differences between the syn-IOM and the Murchison IOM that affect production of CO₂; however, since there are no data for Murchison IOM at 250°C it is possible that the lack of a trend from 350°C to 500 °C mirrors the leveling off observed in the syn-IOM samples over this temperature range.

The isotopic characterization of the solid residue material is reported in Table 7. Changes are expressed as:

$$\Delta_I = \delta I_{final} - \delta I_{initial}$$

Where *I* refers to the δD , $\delta^{15}N$, $\delta^{18}O$, and $\delta^{13}C$ values. The relative isotopic changes are displayed in Figure 5, and trends with pressure and temperature are summarized in Table 8.

Table 7. Isotopic composition of bulk solid residues after reaction. Changes listed are relative to starting compositions for the IOM samples listed in Table 1.

*Rubber contamination observed in vial; δD may be affected

^{**} $\Delta_I = I_f - I_i$, where subscripts f and i denote final and initial values and I denotes $\delta^{13}C$, δD , $\delta^{15}N$, or $\delta^{18}O$.

In general, the δ^{13} C value for the final residue is lower than for the starting materials, suggesting that ¹³C may be preferentially lost during reaction. However, in most experiments the Δ_{13C} value is within error of zero, and changes in δ^{13} C are overall small. With increasing temperature and pressures of 1 kbar or 10 kbar, the loss of ¹³C may increase slightly; however, no trend with temperature is apparent in the 3 kbar data. CO₂ production is stable from 350 °C to 500 °C at 3 kbar but decreases from 350 °C to 500 °C at 1 kbar and 10 kbar (Figure 1). This may suggest that the loss of ¹³C is more strongly tied to production of CO₂ rather than CH₄. This is consistent with previous studies of IOM, which found that δ^{13} C is higher in carbonyl groups that

may yield CO_2 during decomposition, as compared to aliphatic and aromatic carbon (Oba and Naraoka, 2009). The behavior of Δ_{13C} appears to be similar between the syn-IOM and the Murchison IOM samples.

Evolution of δD is more dramatic than $\delta^{13}C$, consistent with previous studies at ambient pressure (Oba and Naraoka, 2009), but also displays a sample dependence, especially for Murchison IOM. Notably, no sample dependence was observed in the R_{H/C} values, which may point to multiple different H reservoirs in the starting material with different isotopic characteristics. While values for Δ_D suggest the preferential volatilization of D, no trends with pressure or temperature are apparent. The Δ_{180} values also suggest preferential volatilization of ¹⁸O relative to ¹⁶O, with Δ_{180} becoming more negative with increasing temperature for 3 kbar and 10 kbar.

While the C, H, and O isotopic systems all display a counter-intuitive tendency to preferentially volatilize the heavier isotopes from the IOM, leading to more depleted residues, the evolution of the N isotopic system is more variable. The 1 kbar data show an increase in Δ_{15N} as temperature increases, as do the 10 kbar data. Scatter amongst data points at 3 kbar make trends difficult to identify. The HC113 samples at 3 kbar show equally depleted residues at both 250 °C and 500 °C. This is fairly consistent with the HC096 data points at 3 kbar, and this sample displays greater depletion at 350 °C relative to either 250 °C or 500 °C. Examination of the HC083 data points at 350 °C and the HC096 data points at 500 °C suggests a slightly increased depletion in the heavy isotopes of the residues with increasing pressure. While the Murchison samples at 350 °C and 10 kbar, and 500 °C at 3 kbar are generally consistent with the syn-IOM samples, the Murchison 350 °C and 3 kbar experiment shows preferential volatilization of ¹⁴N, to a much greater extent than any of the other experiments.

31

Table 8. Trends in the evolution of the isotopic compositions of solids. Values reported are averages of all syn-IOM samples. Murchison IOM is excluded from these averages since its behavior differs; see Table 7 for individual values. Cited uncertainties correspond to one standard deviation.

3.3 NH₄⁺

Data related to ΣNH_3 in the final solutions are presented in Table 9. The ΣNH_3 abundances are representative of NH₃ and NH₄⁺, due to the acidification of the solution during sample preparation. Hereafter, we refer to the two interchangeably. Results are summarized in Figure 6. In general, a significant percentage of the N present in the starting material was extracted in the form of NH₃, and the efficiency of extraction is noticeably different between the syn-IOM and the Murchison IOM, with less N extracted from Murchison. Extraction of N increases from 250 °C to 500 °C. In the syn-IOM, no additional extraction is observed from 350 °C to 500 °C, potentially because very little N remains in the solid form by 350 °C. For the Murchison IOM, a more modest increase in N extraction is seen from 350 °C to 500 °C. The total abundance of extracted N is on the order of μ moles per mg of IOM. There is some evidence for isotopic depletion of the NH₃ with increasing pressure, but these effects are slight for the syn-IOM. NH₃ from the Murchison IOM is much more enriched compared to the starting material at 3 kbar pressures, and the enrichment is more notable at 350°C than at 500°C.

Experiment	T, °C	P, kbar	IOM sample	N in NH4 ⁺ , μmoles/mg sample	δ ¹⁵ N of NH4 ⁺ , ‰**	$\Delta_{15N,NH4}^{*}$	% of IOM nitrogen in NH4 ⁺

Table 9. Abundance and isotopic characterization of product NH_4^+ . $\Delta_{15N,NH4}$ is reported relative to the isotopic composition of the starting solid material. b.d. is below the detection limits.

*NH₄⁺ δ^{15} N minus the δ^{15} N value for the bulk starting IOM

**errors estimated as same %error for other $\delta^{15}N$ measurements

The significant difference in the degree of ΣNH_3 extraction from the syn-IOM and Murchison residues indicates potential differences in the speciation of N in the organic solids. Previous studies have suggested the predominant presence of amines in the molecular structure of chondritic IOM (Alexander et al. 2017); however, the presence of N-bearing heterocycle moieties has also been hypothesized (Derenne and Robert, 2010; Remusat et al., 2005; Vollmer et al., 2024). It is highly likely, therefore, that the N-functional groups in the Murchison IOM are significantly more attached to aromatic structures, resulting in an enhanced refractory behavior relative to the N in the syn-IOM.

The high $\delta^{15}N$ compositions of dissolved NH₃ from Murchison IOM in the reactant solutions (68-105 ‰) are in close agreement with previous results ($\delta^{15}N = 39-53$ ‰) involving

hydrothermal alteration of Murchison IOM at 250 °C to 450 °C but lower pressure conditions (500 bars; Foustoukos et al., 2021) as well as at 300°C and 1 kbar with reported δ^{15} N of 18 ‰ (Pizzarello and Williams, 2012). Similar δ^{15} N values (δ^{15} N = 69-70 ‰) have also been measured in NH₄⁺ extracted via hot water (110 °C, 24 h; Pizzarello et al., 1994) and MgO-distillation at ambient temperatures (Kung and Clayton, 1978) of bulk Murchison samples. The ammonia released from the bulk samples is associated with NH4⁺-bearing salts and/or with highly labile Nbearing IOM species (Pizzarello et al., 1994; Pizzarello and Williams, 2012). It seems, therefore, that the N-H bearing functional groups released during hydrothermal treatment of IOM at elevated temperatures could be directly linked to the sources of inorganic N in the bulk meteorite with a potential δ^{15} N signature of 50 ‰ to 100 ‰. These values are consistent with the estimated δ^{15} N composition of the free NH₃ in the bulk samples returned from the Ryugu asteroid (~ 56 ‰; Hashizume et al., 2024). Recent remote-sensing studies have suggested that comets and carbonaceous bodies from the outer Solar System have large inventories of solid nitrogen compounds, such as ammonium salts (Altwegg et al., 2020; De Sanctis et al., 2015; Poch et al., 2020). Future studies on samples returned from asteroids (e.g., Bennu, Ryugu) would be instrumental in establishing these δ^{15} N values as signatures of inorganic N in chondritic parent bodies. This could have profound implications for understanding the source and evolution of N

in chondritic material, and especially for constraining N cycling between pre- and proto-solar material (Pizzarello and Williams, 2012).

Figure 6. Percentage of N extracted from IOM as ammonium (a), measured abundance of extracted ammonium per mg of reacted syn-IOM or IOM (b), and isotopic characterization of ammonium extracted from syn-IOM experiments (c) and IOM experiments (d). $\Delta_{15N,NH4}$ describes the difference between the $\delta^{15}N$ of NH_4^+ and of the starting IOM or syn-IOM. Symbols are as described in Figure 1. "Murch" denotes IOM extracted from Murchison.

4 Discussion

4.1 Impact of the dielectric constant and kinetics on gas production

The abundance trends observed for different gases as a function of pressure and temperature may be related in part to changes in the dielectric constant, ɛ, of water (Figure 7). The dielectric constant was calculated using the Deep Earth Water (DEW)

model (Sverjensky et al., 2014). Briefly, this model provides an analytical formulation of ε at high pressures via extrapolation of the observed linear relationship between ln(ε) and ln(ρ), where ρ is the density of water. The formula fits experimental data ranging up to 12 kbar and 600 °C (Fernandez et al., 1997; Heger et al., 1980), and provides estimates for pressure and temperature conditions where experimental data are lacking, especially at higher pressures. Higher values for ε correspond to increased polarity. For a given temperature, as the pressure increases ε also increases. At lower temperatures, the change in ε with pressure is smaller. As temperature increases, the dependence of ε on pressure also increases. At 350 °C where an increase in CO₂ is observed with increasing pressure, the higher polarity of water may lead to

more effective solvation and removal of C-O or C=O groups in the Murchison IOM and syn-IOM structures. Pyrolysis experiments on coal samples suggest that product CO_2 may derive from such functional groups rather than the incorporation of O from water (Cramer, 2004).

Gas production as a function of ε is shown in Figure 8. A clear trend of decreasing H₂ production with increasing ε , and increasing polarity, is visible. This may indicate that H₂ production is associated with nonpolar functional groups in the organic solids. The trend with ε becomes flatter at higher pressures, where the ε contours begin to flatten in Figure 7. CO production may also trend with ε , although caution is warranted in using our determinations of CO abundances (see Section 3.1). The behavior of CH₄ is similar to that of H₂, which may be expected given the relatively nonpolar nature of alkyl groups compared to C-O or C=O groups.

The behavior of CO₂ relative to ε is more complex and suggests that multiple factors may be at play. CO₂ initially increases with increasing ε , which may correspond to enhanced solvation of the more polar C-O or C=O groups with increasing polarity of the solvent. However, at ε ~25, the CO₂ abundance stops increasing. In Figure 7, this corresponds to the salmon-colored contour from approximately 235 °C to 310 °C at 0.1 kbar. This may reflect depletion of extractable C-O at ε ~ 25 or could reflect more complex chemical effects. A similar reduction in the abundances of CO₂ at higher temperatures and increases in the CH₄/CO₂ ratios have been reported for anthracite coal in anhydrous experiments, with CO₂ peaking at 400 °C at 5 kbar and the peak extending to 600 °C at 2 kbar (Mastalerz et al., 1993), suggesting that at higher temperatures CO₂ production from complex organic matter may decrease independent of the presence of water. Future characterization of the functionality of experimental residues compared to starting materials may help resolve which answer is more likely.

Consistent with the complex behavior of gas production, kinetic modeling of the O/C and H/C ratios of residues from terrestrial kerogen samples suggests a range of activation energies for precursor functional groups that yield H₂O, CO₂, CH_n, and CH₄ gases during thermal maturation on geologic timescales (Burnham and Sweeney, 1989; Burnham 2017). This canonical "Vitrimat" model indicates lower activation energies for CO₂ production, and higher energies for CH₄ production. Figure 9a shows the O/C and H/C ratios of experimental residues from this work overlaid with variations of the Vitrimat model of Burnham and Sweeney (1989). The original model is shown by the line labeled as "BS89 model." The color of the line shows progressive evolution as temperature increases from 20°C to greater than 600°C at a rate of 10°C/Ma,

Figure 9. Kinetic models of the O/C and H/C ratio of solid residues are shown as lines, and the changing color corresponds to temperature as shown by the colorbar. (a) Models are based on the original Vitrimat model of Burnham and Sweeney (1989), shown by the "BS89 model" line. Data from residues generated in this work are overlaid as points, with symbol shapes corresponding to the starting syn-IOM or IOM material. The symbol color shows the temperature for the corresponding experiment. Data include all pressures. The HC083 model and Murch model utilize identical kinetic parameters to the BS89 model, except for the O/C and H/C of the starting material which reflects the corresponding syn-IOM (HC083) or IOM (Murchison) sample. The HC113 model has been additionally tuned to better match the data, with higher activation energies for CO₂ precursors as summarized in Table 10. (b) Same as panel (a), but the activation energy distributions are all shifted 22 kcal/mol higher.

taken from Burnham and Sweeney (1989). The HC083 model and Murch model utilize identical parameters, except for the starting compositions that have been changed to match the HC083 syn-IOM and Murchison IOM, respectively. The shapes of these curves reasonably reproduces the corresponding datapoints, shown by the left-pointing triangle (HC083) and star (Murchison) symbols. The color of the symbols corresponds to the experimental temperatures; data at all pressures are shown but not differentiated, since pressure is the weaker variable. While the overall evolutionary trend is a reasonable match for the data, the experimental

temperatures are noticeably higher than the model temperatures. The strongest model parameter controlling the temperature is the activation energy for the gas precursors, and this difference may indicate that the model underestimates the activation energies, which are distributed here from 38 to 74 kcal/mol. Burnham and Sweeney (1989) note the same mismatch in their comparison to laboratory data, with higher temperatures required in laboratory settings compared to geologic settings, and cite pressure as one important variable, especially for materials with higher starting O/C. A second version of this figure with the same distribution of activation energies uniformly shifted 22 kcal/mol higher is shown in Figure 9b to demonstrate the effect of activation energy on the modeled temperature. The HC113 model in both panels is further tuned to better fit data from the HC113 experiments (downward-pointing triangles); here, the distribution of activation energies for the CO₂ precursors are shifted higher with respect to the H₂O, CH_n, and CH₄ precursors to change the shape of the curve (Table 10).

Fable 10. Activation energies used for Vitrimat modeling of CO ₂ in the original model (middle	
column) and for HC113 in this work (right column).	

Activation energy E in Figure	Percent of CO ₂ precursors,	Percent of CO ₂ precursors,

52	10	15
54	5	25
56		25
58		15
60		10
62		5

This may suggest that CO_2 precursors in the HC113 sample differ from the other samples. This is consistent with the different productivity of CO_2 at 250°C from this sample compared to the others (Figure 1); however, generally speaking, the model is under-constrained and additional work is needed to confirm the nature of these potential differences.

4.2 Equilibrium speciation in Titan's interior

The predominance fields were calculated for aqueous species in the COH system between 1 kbar and 10 kbar for the COH system using the DEW model (Sverjensky et al., 2014), which has been validated for pressures up to 60 kbar. The calculations utilized values from Zhang and Duan (2005) to calculate the density of water. For pressures above 5 kbar, Sverjensky et al. (2014) was used to calculate the dielectric constant, while the SUPCRT equation formulated in Johnson and Norton (1991) was used for lower pressures.

With increasing temperature, the stability field for CO_2 increases (Figure 10), while that of CH₄ decreases. The pH at which CO₂ transitions to HCO_3^{-1} increases relative to neutral pH with increasing temperature. The transition from CH₄ to HCO_3^{-1} and CO_3^{-2-1} occurs at conditions that are more oxidizing with increasing temperature. The transition from CO_2 to CH₄ is relatively insensitive to pressure (Figure 10a), while speciation between HCO_3^{-1} and CO_3^{-2-1} ionic species and CH₄ varies somewhat with increasing pressure. As pressure increases, the range over which CH₄ dominates decreases. CH₄ stability under equilibrium conditions is favored overall by lower temperatures and lower pressures. The equilibrium speciation of aqueous compounds with one C in Figure 11 provides another visualization of this trend. Figure 11a shows the speciation at 8 kbar, the pressure at Titan's water-rock interface, while Figure 11b shows the speciation at 2 kbar, a pressure that is equivalent to several 10s of km below Titan's icy crust and within the ocean layer (Sotin et al., 2021). For outgassing from the rocky interior, fluid parcels would travel from 8 kbar through 2 kbar. At low temperatures, C speciation drives towards CH₄ as the stable phase, especially for the lower pressures. Here, we assume slightly oxidizing conditions (fayalite-magnetite-quartz buffer, f_{O2} = FMQ, +1) and basic conditions (3 units above neutral pH).

Figure 10. Predominance plots for major compounds in the COH system. Regions in redox-pH space where each compound is most abundant at equilibrium are marked, and the lines show the redox-pH condition at which the chemical activities of the two compounds on either side of the line are equal. The identity of the two compounds is given by the line color. (a) Trends as pressure increases at a constant temperature of 250°C. Pressure increases from 1 kbar (solid line) to 3 kbar (dashed line) to 8 kbar (dotted line) to 10 kbar (dash dot line). The red arrow shows the direction that each boundary in the predominance plot moves with increasing pressure. Panel (b) holds pressure constant at 8 kbar, and shows the effect of increasing temperature: 100 °C (solid line), 250 °C (dashed line), 350°C (dotted line), and 500 °C (dash dot line). Line colors in panel (b) are the same as in panel (a).

Given the relatively short (~ 48 hour) timescale that these experiments were run, C-O-H

equilibrium was not achieved except for experiments at 500 °C and 10 kbar. Our experimental results indicate that CH₄ is favored by higher temperatures. At 3 kbar for the HC096 sample, the molar ratio of CH₄/CO₂ increases from 5×10^{-3} at 250 °C to 2.7 at 500 °C. A previous hydrothermal experiment on IOM from the Murray CM2 chondrite identified the loss after heating of carbonyl groups in solid residues via NMR (Yabuta et al., 2007). It is possible that decarboxylation of IOM side chains is the dominant source of volatile C, and at higher

temperatures, the kinetics and extent of CO₂ reduction to CH₄ is higher (Foustoukos, 2012). In this case, the results do not reflect equilibrium speciation, but constrain overall production of volatile C. The ultimate fate of volatile C depends on the specific environmental context in which it is produced and equilibrated. Volatilization itself is an instantaneous process, geologically speaking, and the quantities produced are well within the solubility limits for relevant pressures and temperatures. Therefore, the volatiles are likely to be entrained in the fluid phase, and to mobilize (or not) as the fluid does. While trapped fluids may eventually reach equilibrium conditions, kinetics are likely to play the more important role in the absence of confining phases.

Figure 11. Calculation of the equilibrium speciation in the COH system at 8 kbar (a), representative of the water-rock interface of Titan; and at 2 kbar (b), representative of the ocean near the ice shell interface. The same line colors apply to both panels. CH₃OH and HCOOH were included in calculations, but the maximum fractional abundance was below 0.01 in both cases.

CO was infrequently observed in the hydrous pyrolysis experiments conducted here. This is consistent with equilibrium calculations, which indicate that CO should not be the dominant equilibrium species. Comparisons of measured C speciation in hydrothermal vent fluids to equilibrium models for fluid cooling indicate that equilibration in the C-O-H system is very rapid for temperatures in excess of ~200 °C (Foustoukos et al., 2009). Since CO does not begin to

appear in equilibrium speciation plots until approximately 700 °C at f_{O2} = FMQ-2 and 1 pH unit above neutral, and this region of stability is relatively insensitive to pH and f_{O2} , CO is unlikely to be a major hydrothermal product of IOM in Titan's interior so long as IOM reaction occurs in the presence of water.

4.3 Implications for Titan's atmosphere

At present, Titan's atmosphere includes approximately 9×10^{18} kg of N₂ and on the order of 2×10^{17} kg of CH₄ and organic matter that may be photolytically derived from CH₄ (Tobie et al., 2012). These values are likely lower limits since they do not consider atmospheric escape over the lifetime of Titan's atmosphere. In order for IOM in Titan's interior to significantly contribute to atmospheric N₂ or CH₄, production of these components in the interior must be comparable to or in excess of their total atmospheric abundances. Furthermore, outgassing from Titan's interior is likely to be incomplete, with efficiencies on the order of 1 to 6% cited on the basis of ⁴⁰Ar abundances in Titan's atmosphere (Miller et al., 2019; Waite et al., 2005). Here, we scale our results to values that are reasonable for Titan's interior and consider whether the isotopic behavior observed in our experiments is consistent with existing constraints.

In Table 11, we summarize a calculation of the total CH_4 and CO_2 production that might be expected from Titan's interior, in comparison to an existing estimate of the surface C reservoir (Tobie et al., 2012) of approximately 1.3×10^{19} moles of C. We use calculations of the total mass of Titan's rocky core with a convecting or a conducting upper ice shell to set the range of interior masses (Sotin et al., 2021). Based on density data, Reynard and Sotin (2023) suggest that the present-day interior of Titan may contain between 17 wt.% and 30 wt.% organic matter, which we use as additional constraints. Note that our premise assumes mass loss from interior

44

organics to generate Titan's atmosphere; this suggests that the present-day value for the interior organic mass is lower than Titan's accreted organic mass. Since temperature is generally the strongest control on production of CH_4 and CO_2 in our experiments, we use the minimum and maximum abundances for each temperature bin for all pressures and samples, including both Murchison IOM and syn-IOM. Our estimates show that at 250 °C, CH_4 production from all organic matter in Titan's interior may be of order 1× to 10× the abundance of the surface reservoir. Since the surface reservoir is a lower limit on the total amount of material, these production rates are barely sufficient or insufficient. A few scenarios are possible as a result.

Table 11. Summary of volatile carbon production in the interior compared to surface carbon reservoir. Values for CH₄ and CO₂ production show the minimum and maximum for temperature sets that include both syn-IOM and Murchison IOM.

Mass	Wt.%	Mass		CH ₄			CO ₂		Surface

^aSotin et al. (2021) ^bReynard and Sotin (2023) ^cTobie et al. (2012)

Some or most of Titan's CH₄ may be derived from accreted ices. Methane ice and/or methane clathrate has been detected remotely at more than ten different comets (Bockelée-Morvan and Biver, 2017) and may be a common component of cometary ices. However, rapid

photolytic processing of CH₄ at Titan's surface (Yung et al., 1984) suggests an interior source may be important. Alternatively, Titan's atmospheric CH₄ might be reconciled with our experimental data at 250°C if the outgassing efficiency from Titan's interior is closer to 10 % to 100 %, at least for CH₄. However, this seems unlikely, given the low abundance of Kr in Titan's atmosphere, the potential role of Kr-rich Phase Q in Titan's interior chemistry (Miller et al., 2019), and the assumed similarity between Kr and CH₄ outgassing rates (Glein, 2015). Another alternative is that some CO₂ produced in the interior may have reacted to yield CH₄ over geologically long timescales, as discussed above. Our estimate for the total interior reservoir of volatile C at 250 °C is 6.3×10^{20} to 3.7×10^{22} moles, or 50 to 2000 times the surface reservoir. If the original IOM abundance in the interior was higher than 30 wt.%, this may be reconciled with present-day constraints for the organic mass in the interior given mass loss via volatilization. Volatilization losses are likely to be on the order of 10s of percent, and such a mechanism does not provide a much larger margin for derivation of the surface reservoir. Finally, higher temperatures may be more representative of the interior environment in which IOM produced CH₄. At 350 °C, the minimum production of CH₄ is nearly 100 times greater than at 250 °C, and 1 % outgassing efficiency is consistent with the estimated surface reservoir.

Very little O is observed at Titan's surface (Hörst et al., 2008) and outgassing of volatilized CO₂ from Titan's interior would contravene the observed surface chemistry. However, CO₂ that does not equilibrate in Titan's interior to CH₄ may be sequestered as precipitated carbonate minerals. Aragonite (CaCO₃) is a common high-pressure carbonate phase that may precipitate from the carbonate system in the presence of Ca²⁺ in aqueous solution in Titan's ocean. As a rough estimate for the activity of Ca²⁺ (a_{Ca}), we utilize a value of 10^{-2} drawn from the range from >10⁻² to >10⁻¹ calculated for Europa (Melwani Daswani et al., 2021). They

46

utilize a hydrosphere mass for Europa that is only ~40% of Titan's hydrosphere mass and a_{Ca} may be diluted at Titan compared to Europa. However, Mg^{2+} and Fe^{2+} are also common carbonate-forming cations, and Mg^{2+} may be more abundant than Ca^{2+} (Melwani Daswani et al., 2021); the use of a_{Ca} from Europa therefore provides a reasonable estimate for Titan's ocean. We utilize a thermodynamic database from PyGeochemCalc (Awolayo and Tutolo, 2022) for

 $log(a_{CO2})$ exceeds -1.4; this corresponds to an a_{CO2} value of approximately 0.04. From Table 11, the minimum predicted abundance of CO₂ is 6.2×10^{20} moles. Titan's ocean may have a presentday mass of $(1.92-4.04) \times 10^{22}$ kg (Sotin et al., 2021). This suggests a molality on the order of 0.02-0.03 mol/kg. The minimum predicted CO₂ abundance is therefore very close to the stability limit for aragonite, and CO₂ in excess of this amount may form carbonate precipitates that would sink to Titan's ocean floor. Alternatively, CO₂ clathrates may form (Safi et al., 2017) and sink or float depending on the density of Titan's ocean (Idini and Nimmo, 2024; Leitner and Lunine, 2019; Mitri et al., 2014). Like CH₄ clathrate, the presence of such a layer may have implications for the thermal evolution of Titan's interior and for surface-interior exchange (Kalousová and Sotin, 2020), though thermal properties of clathrates may vary as a function of composition (Sloan and Koh, 2007).

Our results suggest that there is little isotopic fractionation between IOM and the labile C species derived from it. The Huygens probe measured δ^{13} C for Titan's atmospheric CH₄ between -8 ‰ to -38 ‰ (Niemann et al., 2010), and this value may have evolved from lower initial atmospheric values (Nixon et al., 2012). This range of values brackets the δ^{13} C of the Murchison IOM sample used here (-18.5 ‰), suggesting that our experimental results for C isotopic evolution are consistent with IOM as a major source for atmospheric CH₄, at least if Murchison IOM is isotopically representative. More broadly, the δ^{13} C of IOM in chondrites, including Ryugu, generally ranges from -5 ‰ to -35 ‰ (Alexander et al., 2007; Yabuta et al., 2023). CI chondrites and Ryugu may represent primitive samples of the solar system outside of Saturn's orbit (Hopp et al., 2022), and we therefore conclude that this range for δ^{13} C is a reasonable representation for IOM accreted by Titan.

Table 12. Summary of volatile N production in the interior compared to surface nitrogen reservoir. Values for NH₃ production are for Murchison IOM.

Mass of Titan's Wt.% IOM in core, 10 ²² kg ^a core ^b		Mass of IOM in Titan's core, 10^{22} kg	NH ₃ production,	Surface reservoir, moles of N ^c

^cTobie et al. (2012)

Production of N in Titan's interior may result in a volatile N reservoir that is comparable in abundance to the atmospheric reservoir, if 350 °C is a representative temperature (Table 12). This reservoir may, therefore, be abundant enough to reasonably contribute to Titan's atmospheric N (Miller et al., 2019) if interior processes can transform NH₃ to N₂ (Glein, 2015), or if NH₃ outgasses efficiently enough and surface processes alter it to N₂ (Atreya et al., 1978).

Any experimentally produced N₂ would be indistinguishable from contaminant air in our GC measurements. However, we can use the abundance of air as an upper limit on N₂ production for comparison to the NH₃ abundances. Our Murchison experiment "500-3-M" has an air abundance on the order of 1×10^{-4} mmole/mg IOM, or 0.1 µmole/mg IOM, comparable to the NH₃ measured for that sample (0.72 µmole/mg IOM). However, in general, the abundance of NH₃ exceeds the upper limit for N₂ by closer to a factor of 100, suggesting that NH₃ is the dominant form of volatilized N in our experiments.

Our isotopic results suggest that NH₃ derived from chondritic IOM is significantly enriched in ¹⁵N. However, this enrichment may have a relatively small effect on the allowable contribution of N from Titan's interior IOM. Figure 13a shows the nominal mixing model for organic-derived N and NH₃ from Miller et al. (2019), which assumes that there is no isotopic fractionation between extracted N and bulk IOM. This model compares reported values for the N-isotopic composition of N₂ and NH₃ ices as well as IOM to Titan's atmosphere as one constraint on atmospheric origins. The ³⁶Ar/¹⁴N ratio measured in Titan's atmosphere provides an additional constraint. The ratio for N₂ is taken from cometary ices based on the observed correlation of ³⁶Ar and N₂ (Balsiger et al., 2015). NH₃ ice is assumed to have a near-zero ³⁶Ar/¹⁴N because of temperature fractionation (Mousis et al., 2009). The ratio for organics is

49

linked to the Phase Q noble gas component that is associated with carbonaceous phases in chondrites (Ott et al., 1981; Busemann et al. 2000). Titan's atmosphere intersects the mixing line at roughly 50 % organics and 50 % NH₃ ice. In Figure 13b, the model is shown using isotopic values consistent with the maximum observed fractionation. Here, Titan's atmosphere intersects the mixing line at closer to 60 % NH₃ and 40% organics. The difference between these two scenarios is close to negligible with current uncertainties.

4.1 Implications for other Ocean Worlds

While our experiments focused on temperatures and pressures relevant to Titan, our results are relevant for other Ocean Worlds. Geophysical constraints suggest that Ceres and Enceladus may have higher abundances of complex organic matter in their interiors than Titan, while Ganymede and especially Europa may have lower abundances (Reynard and Sotin, 2023). Volatilization of such material may be a potential source for CO₂ ices observed at the surfaces of

Ocean Worlds such as Europa (Trumbo and Brown, 2023; Villanueva et al., 2023) and the Uranian satellites (Cartwright et al., 2015, 2022; Grundy et al., 2003, 2006). To date, such observations have not identified features associated with organic materials at Europa or the Uranian satellites; however, data from Juno's Jovian Infrared Auroral Mapper (JIRAM) instrument suggest the presence of organic and ammoniated compounds at Ganymede's surface (Tosi et al., 2024). Pressures at the water (or high-pressure ice) interface with the rocky interior are generally lower for other Ocean Worlds compared to Titan. For example, the water-rock interface at Europa may be at a pressure of approximately 1.8 kbar (Schubert et al., 2009), while the ocean floor of Enceladus may be only 74 bar (Glein et al., 2018). Relevant interior conditions for these smaller bodies may correspond more closely to our lower pressure experiments. Since ϵ remains lower at low pressures over the relevant temperature range, we may expect somewhat more efficient extraction of volatiles like H₂ and CH₄ from nonpolar regions of the IOM, even at lower temperatures. Volatile production from IOM on other Ocean Worlds may therefore include the production of CH₄, even at lower interior temperatures. Future missions such as Europa Clipper and Juice should search for such features in the Jovian system to better understand the origin of CO₂ at the surface.

5 Conclusions

Heating of complex organic matter similar to chondritic IOM in the presence of water may be an important source of CH₄ and NH₃ for Titan's atmosphere. Sufficient abundances of both compounds are produced to meet existing constraints on total abundance, outgassing efficiency, and isotopic composition. Volatile production varies as a function of pressure, temperature, and starting composition of the organic matter. Equilibration of carbon-bearing products subsequent to heating and prior to outgassing favors production of CH₄. Nitrogen is

51

likely volatilized in the form of NH_3 , and if IOM is a significant source than subsequent alteration to N_2 either in the interior or at Titan's surface is likely required.
