# 4, and 5 colors Thomas DeGrand<sup>1</sup> <sup>1</sup>Department of Physics, University of Colorado, Boulder, CO 80309, USA[∗](#page-0-0) (Dated: December 19, 2024) Abstract

I show comparisons of the pseudoscalar meson vector form factor from simulations of QCD with  $N_c = 3$ , 4 and 5 colors and  $N_f = 2$  flavors of degenerate mass fermions at a common (matched) fermion mass, lattice spacing, and simulation volume. The dependence of the form factor on the momentum transfer is nearly independent of the number of colors, and is consistent with the expectations of vector meson dominance.

Comparison of a pseudoscalar meson form factor in QCD with 3,

<span id="page-0-0"></span><sup>∗</sup>Electronic address: [thomas.degrand@colorado.edu](mailto:thomas.degrand@colorado.edu)

#### I. INTRODUCTION

It is generally expected  $[1-3]$  that as the number of colors  $N_c$  becomes very large, the mesonic sector of QCD is described by planar amplitudes, interacting open strings with quarks and antiquarks on their perimeters [\[4](#page-17-2), [5\]](#page-17-3). This says further that properties of mesons are independent of  $N_c$  up to overall (process dependent)  $N_c$  scaling factors, at least to leading order in  $N_c$ . The parameter which connects results with different numbers of colors is the 't Hooft coupling  $\lambda = g^2 N_c$ .

Lattice simulations have tested much of this paradigm. (For reviews, see Refs. [\[6](#page-18-0)[–8](#page-18-1)].) The bare 't Hooft coupling sets the lattice spacing. The overall scaling  $N_c$  has been seen many times, in (for example) decay constants of pseudoscalar and vector mesons or the kaon B parameter. The underlying independence of observables after the  $N_c$  dependence is removed has many indirect tests: one is how a quantity scales with fermion mass, such as any hadron mass versus quark mass  $m_q$ . In quark models, decay constants are proportional to a color factor (typically a power of  $N_c$ ) times the squared quark wave function at zero separation  $|\psi(0)|^2$  (see for example Ref. [\[9](#page-18-2)]), and seeing the appropriate overall  $N_c$  scaling is a statement that  $|\psi(0)|^2$  is independent of  $N_c$ .

It would be nice to have a more direct comparison of the underlying independence of mesonic matrix elements across  $N_c$ . This little note makes that comparison in the vector form factor  $F(q^2)$  of a pseudoscalar meson as a function of (spacelike) momentum transfer q. The form factor is defined as

<span id="page-1-0"></span>
$$
\langle \pi(p') | J_{\mu}(q) | \pi(p) \rangle = (p'_{\mu} + p_{\mu}) F(q^2)
$$
 (1)

where  $J_{\mu}$  is the vector (electromagnetic) current. Current conservation requires that  $F(0) =$ 1 so the shape is the interesting quantity. In a quark model, again, the form factor is the Fourier transform of the charge density of the meson and the goal is to see whether the shape of  $F(q^2)$  varies with N<sub>c</sub>. I did an absolutely minimalist calculation: I looked at N<sub>c</sub> = 3, 4, and 5 systems at a single lattice spacing, a single volume (chosen to avoid finite volume artifacts) and a single quark mass, matched across  $N_c$ . In physical units, the lattice spacing is roughly 0.1 fm, the lattices have a spatial size of 1.6 fm, and the pseudoscalar and vector meson masses are about 650 and 1050 MeV, respectively. (Lattice numbers will be given below, in Table [I.](#page-17-4)) The result is easy to state: over the range of momenta where I had a signal, the shape of the form factor is independent of  $N_c$ .

There are two technical issues in the calculation. The first is that it is necessary to have good interpolating fields to produce particles at nonzero three momentum. The second problem is that lattice calculations produce the form factor along with other nuisance quantities, which must be separated in the analysis. People have been computing the form factor of the pseudoscalar meson since at least 1987 (see Ref. [\[10\]](#page-19-0)) and by now there are probably hundreds of papers about hadronic form factors in the literature with many methods to deal with these problems. One only has to search the literature and adapt something already there. I chose to use the interpolating field techniques of Refs. [\[11](#page-19-1)] and [\[12\]](#page-19-2) and the fitting procedure of Ref. [\[13](#page-19-3)].

And a remark before we continue: the goal of a little study like this is to ask whether versions of QCD with different numbers of colors (but everything else fixed) produce different values for an observable. The overall  $N_c$  counting and dependence of the quark mass is what is important. High precision, chiral extrapolations, or a continuum limit can come later (if ever).

<span id="page-2-1"></span>FIG. 1: Diagram for the pion form factor, labelling the momenta and initial and final states.

So let us proceed. Sec. [II](#page-2-0) goes through all the technical aspects of the lattice calculation. Results are found in Sec. [III.](#page-7-0) Sec. [IV](#page-15-0) summarizes and concludes.

## <span id="page-2-0"></span>II. METHODOLOGY

#### A. Generating the data sets

All my publications about large  $N_c$  QCD used the same lattice action and methodology. A long description of techniques can be found in Ref. [\[14\]](#page-19-4). Here is a short summary:

The gauge action is the Wilson plaquette action. Two flavors of degenerate mass Wilsonclover fermions are simulated. Configurations are generated using the Hybrid Monte Carlo (HMC) algorithm [\[15](#page-19-5)[–17\]](#page-19-6) with a multi-level Omelyan integrator [\[18](#page-19-7)] and multiple integration time steps [\[19](#page-19-8)] with one level of mass preconditioning for the fermions [\[20](#page-19-9)].

The fermion action uses normalized hypercubic smeared links [\[21](#page-19-10)[–23\]](#page-19-11) as gauge connections. The method of updating these gauge links is described in Ref. [\[24](#page-19-12)]. The action is written in terms of  $\beta = 2N_c/g_0^2$  and the hopping parameter  $\kappa = (2m_0^q a + 8)^{-1}$  rather than the bare gauge coupling  $g_0$ , the bare quark mass  $m_0^q$  and the lattice spacing a. The clover coefficient is fixed to its tree level value,  $c_{SW} = 1$ . The gauge fields obey periodic boundary conditions; the fermions are periodic in space and antiperiodic in time. The lattices have  $L^3 \times N_t = 16^3 \times 48$  sites. The lattice size and bare quark mass were chosen to minimize finite volume effects; the product of pseudoscalar mass and spatial size  $m_{PS}L$  is greater than 5.

The vector current in Eq. [1](#page-1-0) is the local current,  $J_{\mu} = \bar{\psi}\gamma_{\mu}\psi$ . The continuum form factor is related to the lattice one by  $F(q^2) = 2\kappa Z_V F(q^2)_{latt}$  where  $Z_V$  is a scheme matching factor, computed in the "regularization independent" or RI scheme [\[25](#page-19-13)]. The calculation is identical to the one carried out for the axial vector current in Ref. [\[14](#page-19-4)].

When needed, the lattice spacing is set via the flow parameter  $t_0$  [\[26](#page-19-14), [27\]](#page-19-15). The nominal value of the flow parameter in  $N_c = 3$  QCD with  $N_f = 2$  is  $\sqrt{t_0} = 0.15$  fm according to Ref. [\[28\]](#page-19-16).

#### B. Amplitudes and interpolating fields

Graphical realizations of the necessary amplitudes are shown in Figs. [1](#page-2-1) and [2.](#page-3-0)

The first figure works in a meson basis: a meson in an initial state  $I$  with three momentum  $\vec{k} + \vec{q}$  couples to a current emitting outgoing momentum  $\vec{q}$  to become a meson in a final state F carrying momentum  $\vec{k}$ . The second figure shows the amplitude in terms of the

<span id="page-3-0"></span>FIG. 2: Diagram at the quark level of the pion form factor, labelling the Euclidean times of the vertices.

constituent quarks and antiquarks. As is usually done in the literature, I introduce a source interpolating field at space-time coordinates  $(\vec{x}_0, t_0)$ , a sink or outgoing interpolating field at time coordinate  $t_{sink}$  and space coordinates  $\vec{y}$ , and put the current at space-time coordinates  $(\vec{z}, t)$  in between the source and sink. I sum over  $\vec{y}$  and  $\vec{z}$  weighting by complex exponentials to project out momentum eigenstates, and sew the propagators together to produce a threepoint correlator at all t values between  $t_0$  and  $t_{sink}$ . It is

<span id="page-3-1"></span>
$$
C_{FIJ_{\mu}}(y_0, \vec{k}, x_0, z_0, x_0, \vec{q}) = \sum_{\vec{y}, \vec{z}} e^{-i\vec{k} \cdot \vec{y}} e^{-i\vec{q} \cdot \vec{z}} \langle O_F(\vec{y}, y_0) J_{\mu}(\vec{z}, z_0) O_I(\vec{x} = 0, \vec{x}) \rangle
$$
  

$$
= \frac{Z_F(\vec{k}) Z_I(\vec{k} + \vec{q})}{4E(\vec{k}) E(\vec{k} + \vec{q})} J_{\mu} \exp(-E(\vec{k} + \vec{q})t) \exp(-E(\vec{k})(t_{sink} - t)) (2)
$$

where  $y_0 = t_{sink} + x_0$ ,  $z_0 = t + x_0$ ,

$$
J_{\mu} = \left\langle \pi(\vec{k}) | J_{\mu}(0,0) | \pi(\vec{k} + \vec{q}) \right\rangle \tag{3}
$$

and

$$
Z_J(\vec{k}) = \langle 0|O_J|\pi(\vec{k})\rangle.
$$
 (4)

The passage between the first and second lines of Eq. [2](#page-3-1) comes by inserting complete sets of states of hadrons between the operators and truncating the sum to the lowest-energy state (a single pion); it further assumes that  $t_{sink} \gg t \gg 0$ . The analogous formula for a two point function is

$$
C_{FI}(y_0 = t + x_0, \vec{k}, x_0) = \sum_{\vec{y}} e^{-i\vec{k}\cdot\vec{y}} \langle O_F(\vec{y}, y_0) O_I(\vec{x} = 0, x_0) \rangle
$$

$$
= \frac{Z_F(\vec{k}) Z_I(\vec{k})}{2E(\vec{k})} f(E(\vec{k}), t)
$$
(5)

where

$$
f(E, t) = \exp(-Et) + \exp(-E(N_t - t)).
$$
 (6)

There are two technical issues to face: the first is to find source and sink interpolating fields which couple to meson states with nonzero momentum. The second is how to extract a separate a measurement of  $J_{\mu}$  from fits to a set of three point and two point functions.

At time  $t_{sink}$  I use a simple point sink  $\bar{\psi} \gamma_5 \psi$  projected on momentum  $\vec{k} = 0$ . The fermion world line from  $t_0$  to  $t_{sink}$  to t is computed using the usual "sequential-source" or "exponentiation" method, which is described in most texts about lattice techniques. Being very terse, we need to compute an object like  $M = \text{Tr} Q(x, y)T(y, x)$  where  $Q(x, y)$  is the fermion propagator and  $T(y, x) = Q(y, z)Q(z, x)$ . Then  $D(w, y)T(y, x) = Q(w, x)$ , so the first propagator is the source for the second one.

With that construction,  $C_{FIJ_\mu}$  at many values of  $\vec{q}$  can be found without the need for additional inversions of the Dirac operator.

Now the interpolating field at  $t_0$  must couple to nonzero values of  $\vec{q} + \vec{k}$ . I am accustomed to gauge fixing the link variables to Coulomb gauge and then introducing extended sources which are a product of quark and antiquark sources  $O \sim \Phi_R(\psi) \Phi_R(\psi)$ . A generalization of this construction gives a useful source. I continue to gauge fix to Coulomb gauge.

Maybe it is clearest to introduce the interpolating fields using continuum notation. The convention for Fourier transforms is

$$
\psi(\vec{p}) = \int d^3x e^{i\vec{p}\cdot\vec{x}} \psi(\vec{x}); \qquad \psi(\vec{x}) = \int \frac{d^3p}{(2\pi)^3} e^{-i\vec{p}\cdot\vec{x}} \psi(\vec{p}). \tag{7}
$$

Then a Gaussian source centered at the origin is

$$
\Phi_R(\psi) = \int d^3x S(x) \psi(\vec{x})
$$
  
= 
$$
\int d^3x e^{-x^2/R^2} \psi(\vec{x})
$$
  
= 
$$
C \int \frac{d^3p}{(2\pi)^3} e^{-p^2 R^2/4} \psi(\vec{p})
$$
  
= 
$$
\int d^3p S_R(\vec{p}) \psi(p)
$$
 (8)

and we see that its strength as a creation operator of a particle of momentum  $\vec{p}$  dies as  $\vec{p}$ grows.

The solution of Ref. [\[12](#page-19-2)] is to replace the Gaussian source by something which obviously peaks at  $\vec{p} = \vec{K}$ :

$$
S_{\vec{K}}(\vec{p}) \propto \exp(-\frac{R^2}{4}(\vec{p} - \vec{K})^2)
$$
\n(9)

from which I define

<span id="page-4-0"></span>
$$
S_{\vec{K}}(\vec{x}) = N \int \frac{d^3 p}{(2\pi)^3} e^{-i\vec{p}\cdot\vec{x}} \exp\left(-\frac{R^2}{4}(\vec{p} - \vec{K})^2\right).
$$
 (10)

(The normalization will only be needed when Z factors are quoted below.) The authors of Ref. [\[12\]](#page-19-2) work directly with a meson interpolating field

$$
\Phi_{\vec{K}_{1},\vec{K}_{2}}(x) = \int d^{3}x'' d^{3}x' \bar{\psi}(x'') S_{\vec{K}_{1}}(x'' - x) \Gamma S_{\vec{K}_{2}}(x - x') \psi(x')
$$
\n
$$
= \int \frac{d^{3}q_{1}}{(2\pi)^{3}} \frac{d^{3}q_{2}}{(2\pi)^{3}} \bar{\psi}(q_{1}) \Gamma \psi(q_{2}) \exp[-\frac{R^{2}}{4} ((q_{1} + K_{1})^{2} + (q_{2} - K_{2})^{2})]
$$
\n(11)

which peaks at  $q_1 = -K_1$  and  $q_2 = K_2$ . And

$$
\Phi_{\vec{Q}} = \int d^3x e^{i\vec{Q}\cdot\vec{x}} \Phi_{\vec{K}_1, \vec{K}_2}(x)
$$
\n
$$
= \int \frac{d^3q_1 d^3q_2}{(2\pi)^3} \delta^3(\vec{Q} - \vec{q}_1 - \vec{q}_2)\bar{\psi}(q_1)\Gamma\psi(q_2) \exp[-\frac{R^2}{4}((q_1 + K_1)^2 + (q_2 - K_2)^2)]
$$
\n(12)

projects out a  $\vec{Q}$  momentum eigenstate. Clearly the coupling strength is greatest when  $\vec{Q} = \vec{K}_2 - \vec{K}_1$ , and this suggests taking  $\vec{K}_2 = \vec{Q}/2$ ,  $\vec{K}_1 = -\vec{Q}/2$  as an optimal choice for a source.

The correlator of an extended source and extended sink also factorizes,

$$
C_{SS}(y_0, \vec{p}, \vec{x}) = \sum_{\vec{y}} \exp(-i\vec{p} \cdot \vec{y}) \left\langle \Phi_{-\vec{K}, \vec{K}}(y, y_0) \Phi_{-\vec{K}, \vec{K}}(x, x_0) \right\rangle
$$
  
\n
$$
= \sum_{\vec{y}, \vec{y}', \vec{y}'', \vec{x}', \vec{x}''} \exp(-i\vec{p} \cdot \vec{y}) \times
$$
  
\n
$$
\text{Tr}\left( [S_{-\vec{K}}(x - x'')Q(x'', y'')S_{-\vec{K}}(y'' - y)] \Gamma [S_{\vec{K}}(y - y')Q(y', x')S_{\vec{K}}(x' - x)] \Gamma \right)
$$
\n(13)

(with  $\Gamma = \gamma_5$  here; clearly the procedure generalizes to any meson interpolating field). Of course

$$
D_{zy'}(Q(y',x)S_{\vec{K}}(x-x')) = S_{\vec{K}}(z-x')
$$
\n(14)

that is, one performs the inversion on the smeared source. Then the full correlator is assembled using the "meta-propagators"

$$
\mathcal{Q}_{\vec{K}}(y,x) = \sum_{\vec{y}',\vec{x}'} S_{\vec{K}}(y-y')Q(y',x')S_{\vec{K}}(x'-x). \tag{15}
$$

Notice that a separate inversion must be done for the quark line and the antiquark line because the sources involve  $-K$  and K.

Passage to the lattice involves only a few small changes. The momentum integrals in the formulas above become sums over discrete values defined across the Brillouin zone. The weighting momentum K, however, can take any value. To prevent discontinuities,  $\vec{p} - \vec{k}$  is defined to be the shortest distance between  $\vec{p}$  and  $\vec{K}$  in the Brillouin zone. All convolutions are performed using fast Fourier transforms.

I experimented with various choices for  $\vec{K}$  by looking at spectroscopy on  $16^3 \times 32$  lattices. Pure Gaussian sources ( $\vec{K} = 0$  in the above description) could barely see the lowest nonzero momentum mesons. A choice of  $\vec{K} = (0.2, 0.2, 0.2)$  was able to capture a signal for  $\vec{q} =$  $(1, 0, 0), (1, 1, 0)$  and  $(1, 1, 1)$  times the fundamental scale of  $2\pi/16$ . A q value of  $2\pi/16$  is 0.4 and the optimum K from the analysis above is  $K = q/2$  which is not too different from my choice. The source could see the  $\vec{q} = (2, 0, 0)2\pi/L$  state, though this was very noisy. I could not find a  $\vec{K}$  value which could produce a high quality signal for it: that is a problem with small lattices, even the minimum nonzero momentum is not small. I did not try very hard to do better, however.

I kept  $R = 6$  in the definition of  $S_{\vec{K}}(\vec{p})$  since that worked well for zero momentum spectroscopy with the present set of bare parameters.

So to proceed: I have one final state momentum,  $\vec{k} = 0$ .  $t_{sink}$  is fixed to the value 22, almost halfway across the  $N_t = 48$  lattice. I analyzed the three-point correlator for t between zero and  $t_{sink}$ . I recorded correlators for eleven different values of  $\vec{q}$ : in units of  $2\pi/L$ ,  $\vec{q} = (0, 0, 0), (1, 0, 0), (0, 1, 0), (0, 0, 1),$  then  $(1, 1, 0)$  plus permutations, then  $(2, 0, 0)$  plus permutations, and  $(\vec{q} = 1, 1, 1)$ . I averaged the correlators over all lattice -symmetric points. For matrix elements of  $J_0$ , this is an average over all permutations of positive  $\vec{q}$  values. (Note  $\vec{K}$  in the source is not symmetric under reflection.) Since  $\langle \pi(\vec{k}=0)|J_i(q)|\pi(\vec{q})\rangle = q_i F(q^2),$ I combined measurements of  $J_i$  with corresponding  $q_i$  values which were expected to give a common value of F: for example,  $J_1$  with  $\vec{q} = (1, 0, 0), J_2$  with  $\vec{q} = (0, 1, 0),$  and  $J_3$  with  $\vec{q} = (0, 0, 1)$ . "Odd" combinations, such as the correlator for  $J_1$  computed at  $\vec{q} = (0, 1, 0)$ averaged to zero, noisily.

I should note (and this is explained nicely by Ref. [\[12](#page-19-2)]) – the relevant part of the correlator for matrix elements of the timelike current  $J_0$  is its real part, while the relevant part of the correlator for spacelike  $J_i$  is the imaginary part.

#### C. Fitting strategy

Let me again collect all the fitting functions needed for the actual analysis. There are two three-point correlators,

<span id="page-6-0"></span>
$$
C_{\mu}(t, t_{sink}) = \frac{Z_{SI}(\vec{p}_I) Z_{PF}(\vec{k})}{4E_I E_F} V_{\mu} \exp(-E_I t) \exp(-E_F(t_{sink} - t))
$$
(16)

where  $V_{\mu} = \langle \pi(\vec{p}_F) | J_{\mu} | \pi(\vec{p}_I) \rangle$  and

<span id="page-6-1"></span>
$$
C_F(t, t_{sink}) = \frac{Z_{SI}(\vec{p}_I) Z_{PF}(\vec{k})}{4E_I E_F} (E_I + E_F) F \exp(-E_I t) \exp(-E_F(t_{sink} - t))
$$
(17)

where  $F = F(q^2)_{latt}$ . (I am being a bit redundant with my notation; I and F label the initial and final state meson, and, once more,  $\vec{p}_f = \vec{k}$  and  $\vec{p}_I = \vec{k} + \vec{q}$ .)

For each particle momentum  $(J = I, F)$  there are two kinds of two point functions: a smeared source and a smeared sink,

<span id="page-6-2"></span>
$$
C_{SS}(\vec{p}_J, t) = \frac{Z_S(\vec{p}_J)^2}{2E_J} f(E_J, t);
$$
\n(18)

and a smeared source and a point sink

<span id="page-6-3"></span>
$$
C_{PS}(\vec{p}_J, t) = \frac{Z_S(\vec{p}_J) Z_P(\vec{p}_J)}{2E_J} f(E_J, t).
$$
\n(19)

 $V_i$  and  $F$  are the interesting quantities. The literature describes many ways to extract them. The most common one is to take ratios of three point and two point functions in which the  $Z$ 's cancel. The problem with this, in my opinion, is that many of the methods involve fractional powers of the two point functions (for an example, see Ref. [\[29\]](#page-19-17)), and an issue is that the two point functions can fluctuate to negative values. It seemed to me that it was easier and potentially more transparent to perform correlated fits to a three point functions and a collection of two point functions. So that is what I did. In doing this I was motivated by the analysis in Ref. [\[13\]](#page-19-3).

So a calculation of F or  $V_{\mu}$  requires a simultaneous fit to four two point correlators,  $C_{SS}(\vec{p}_I)$ ,  $C_{PS}(\vec{p}_I)$ ,  $C_{SS}(\vec{p}_F)$  and  $C_{PS}(\vec{p}_F)$  and to one of the three point correlators, Eqs. [16](#page-6-0) or [17.](#page-6-1) The fit has seven free parameters,  $V_{\mu}$  or F plus  $Z_{SS}(\vec{p}_I)$ ,  $Z_{SP}(\vec{p}_I)$ ,  $E_I$ ,  $Z_{SS}(\vec{p}_F)$ ,  $Z_{SP}(\vec{p}_F)$  and  $E_F$ .

The  $\vec{q} = 0$  form factor can be found more simply, with a simultaneous fit to the two point function

<span id="page-7-1"></span>
$$
C_{PS0}(t) = A_0 f(m_{PS}, t) \tag{20}
$$

and the three point function

<span id="page-7-2"></span>
$$
C_0(t, t_{sink}) = \frac{A_0}{2m_{PS}}(2m_{PS})F(0) \exp(-m_{PS}t_{sink}).
$$
\n(21)

(I've kept the redundant factors for comparison with Eq. [17.](#page-6-1)) There are three parameters to be fit,  $A_0$ ,  $m_{PS}$  and  $F(0) = F(q^2 = 0)_{latt}$ .

All results come from a standard full correlated analysis involving fits to a wide range of t's. Best fits are chosen with the "model averaging" ansatz of Jay and Neil [\[30](#page-19-18)]. Recall that this method assigns each particular fit in a suite (with a chi-squared value  $\chi^2$  and  $N_{DOF}$ degrees of freedom) a weight in the average which is proportional to  $\exp(-(\chi^2/2 - N_{DOF}))$ . Typically, I performed a fit for a particular  $\vec{q}$  parameter value as follows: I first did a three parameter combined fit to  $C_{SS}$  and  $C_{SP}$  and model-averaged the result to find a range if t values for the two correlators which had high weights in the model average. I then took sets of these t values and did five-correlator fits whose output was either  $F$  or  $V$  (plus everything else). I first performed "window" fits where I walked across the  $t$  values kept in Eqs. [16](#page-6-0) - [17,](#page-6-1) with  $t_{max} = t_{min} + 4$ . I found a range where the fit values of F or  $V_{\mu}$ appeared flat to the eye. I then resumed doing fits slightly outside this range, varying  $t_{min}$ and  $t_{max}$  independently, and passed the results through the model averaging filter. With model averaging it is possible to do a large number of fits and the averaging will just discard (or give a tiny weight) to fits which have high chi-squared. Therefore, what I did might not be acceptable to the over cautious reader, but I actually wanted to look at the fits myself rather than just take what came out of the model averaging black box.

## <span id="page-7-0"></span>III. RESULTS

I will start with some preliminary pictures. Fig. [3](#page-8-0) shows  $C_{SS}(\vec{q})$  for  $q = (\pm 1, 0, 0)$  from an  $SU(3)$  data set with identical bare parameters to the ones used for the form factor, but lattice volume  $16^3 \times 32$  sites. The source had  $\vec{K} = (0.2, 0.2, 0.2)$  which is a favorable source for  $\vec{q} = (1, 0, 0)$  but an unfavorable source for  $\vec{q} = (-1, 0, 0)$  The correlator for the unfavorable combination of  $\vec{q}$  and  $\vec{K}$  is clearly smaller and noisier. (It even has negative entries, shown as diamonds in the figure.)

As remarked earlier, the lattice to continuum current renormalization factor  $Z_V$  is com-puted in the "regularization independent" or RI scheme [\[25\]](#page-19-13). I used pre-existing  $16^3 \times 32$ (for  $SU(4)$  and  $SU(5)$ ) and  $24<sup>3</sup> \times 32$  (for  $SU(3)$ ) data sets to measure  $Z_V$ . Full details can be found in Ref. [\[14](#page-19-4)].  $Z_V(\mu)$  is expected to be independent of the scale  $a\mu$  where it is evaluated. Because the spatial size of the lattices used is small, lattice artifacts are visible in a plot of  $Z_V$  versus  $a\mu$  where  $(a\mu)^2$  is the squared magnitude of the four momentum at

<span id="page-8-0"></span>FIG. 3: Correlators  $C_{SS}(\vec{q})$  for a favorable combination of  $\vec{q}$  and  $\vec{K}$  (crosses) and an unfavorable combination (squares, and diamonds when the correlator is negative), from an  $SU(3)$  data set at  $\beta = 5.4$ ,  $\kappa = 0.127$  on volume  $16^3 \times 32$ .

which the measurement is performed  $((a\mu)^2 = \sum_j a^2 p_j^2)$  $j^2$ ). Fitting data from small regions of  $\mu$  produces an uncertainty on the order of 0.002 to  $Z_V$  (whose mean value is close to unity) but such fits have poor confidence level due to the lattice artifact scatter. A figure (the  $SU(4)$  case is shown in Fig. [4\)](#page-9-0) shows that the scatter is about a per cent at  $a\mu = 1.0$  or  $\mu \sim 2$  GeV, which is where I choose to evaluate  $Z_V$ . I will take that as an uncertainty for  $Z_V$ . We will shortly see that the uncertainty on  $F(q^2)_{latt}$  is always greater than a few per cent (sometimes much greater) and so this choice is not going to affect the final results. The three values of  $Z_V$  are 0.94(1) for  $SU(3)$ , 0.94(1) for  $SU(4)$ , and 0.95(1) for  $SU(5)$ .

Next comes the dispersion relation  $E(\vec{p})$  versus momentum. When the three momentum gets large, one expects to see a lattice dispersion relation, not a continuum one. Fig. [5](#page-10-0) shows the energy in lattice units,  $E(\vec{p})$  as a function of  $p^2$ , for the different  $N_c$  values and p values. The curve is a plot of  $E(\vec{p}) = \sqrt{m^2 + p^2}$  versus  $p^2$  with  $m = 0.33$ , the common pion mass for all colors. The data seem to be consistent with a continuum dispersion relation. The  $p = (2, 0, 0)$  or  $p^2 = (\pi/4)^2$  energies are quite noisy; more on these data set below.

Now for fits of F or  $V_x$ . The overwhelming impression as one moves from one  $N_c$  value to another is how nearly identical the data sets are.

<span id="page-9-0"></span>FIG. 4:  $Z_V(\mu)$  versus  $a\mu$  from  $16^3 \times 32$   $SU(4)$  data sets at  $\beta = 10.2$ ,  $\kappa = 0.1265$ .

Three figures, one for each  $N_c$ , illustrate this point, plots of fits to  $C_{PS0}(t)$  and  $C_0(t, t_{sink})$ to Eqs. [20](#page-7-1) and [21](#page-7-2) (which give  $F(q^2 = 0)$ ) and to  $C_{SS}(\vec{p})$  and  $C_{PS}(\vec{p})$  (for  $\vec{p} = \vec{k}$  and  $\vec{p} = \vec{k} + \vec{q}$ ) to Eqs. [18](#page-6-2) and [19](#page-6-3) along with  $C_F(t, t_{sink})$  to Eq. [17.](#page-6-1) These are shown in Figs. [6,](#page-11-0) [7](#page-12-0) and [8.](#page-13-0) For completeness I will show one fit to  $V_x$ , for the  $SU(5)$  date set, in Fig. [9.](#page-14-0)

There are many consistency checks of the fits. The final momentum is  $k = 0$  and so the associated Z factors and pseudscalar masses should be identical across all  $\vec{q}$  values.  $A_0$  from Eq. [20](#page-7-1) should match  $Z_P Z_S/(2m_{PS})$  from the nonzero  $\vec{q}$  fits. The initial state Z factors and energies should match between  $F$  and  $V_x$  fits. All these checks produce consistent results. Table [II](#page-17-5) gives results for the Z's and E's. (The overall scale of  $S_{\vec{K}}(x)$  is not physical (in Eq. [10](#page-4-0)  $N = R^3 \pi^{3/2}$  but as long as it is the same for all  $\vec{p}$  values one can use the relative sizes of  $Z_{\mathcal{S}}$ 's to compare how well the source couples to different states.) The  $Z$ 's show rough  $\sqrt{N_c}$  scaling as expected. They also show the efficiency of the coupling of the source to each momentum eigenstate: the largest coupling is to the  $\vec{p} = (1, 1, 1)$  state, as is also expected.

And I can make a few remarks on the data at different q values. The case  $\vec{q} = (2, 0, 0)$ is obviously the noisiest one, with barely a signal to report. One issue is the source, which simply did not couple well to this  $\pi(\vec{q})$  state. I spent a little time experimenting with alternative sources (after all, the choice of  $K$  values for the source was empirical) but I did not find a better choice. I think this is just an issue with using a small spatial lattice:

<span id="page-10-0"></span>FIG. 5: Energy as a function of momentum (all in lattice units) from fits to simulation data. The line is the expected continuum result  $E = \sqrt{p^2 + m^2}$  with  $m = 0.33$ , roughly the common pion mass of all three colors (compare Tab. [I\)](#page-17-4).

 $q = 2(2\pi/16) = 0.79$  is already a large number. This momentum state also has the largest energy in the ensemble and the Parisi [\[31\]](#page-19-19) - Lepage [\[32\]](#page-19-20) argument says that the signal to noise ratio, proportional to  $\exp((m_{PS} - E(\vec{p}))t)$ , is the worst in the data set.

The other  $\vec{q}$  values are better behaved. As an example, the ranges of t values with higher weights in fits to  $C_F(t, t_{sink})$  for  $N_c = 5$  were (5-7) to (13-17) for  $\vec{q} = (1, 0, 0), (8-10)$  to (12-16) for  $\vec{q} = (1, 1, 0), (5-7)$  to  $(12-16)$  for  $\vec{q} = (1, 1, 1),$  but only  $(4-5)$  to  $(7-9)$  for  $\vec{q} = (2, 0, 0)$ .

Finally, the data for the form factor is shown in Fig. [10](#page-15-1) and is recorded in Tables [III](#page-18-3) and [IV.](#page-18-4) The shape of  $F(q^2)$  is independent of the number of colors.

The line in Fig. [10](#page-15-1) is not a fit, it is the simplest possible parameterization from the vector dominance model([\[33\]](#page-20-0); see also [\[34\]](#page-20-1))

<span id="page-10-1"></span>
$$
F(q^2) = \frac{1}{1 + \frac{q^2}{m_V^2}}\tag{22}
$$

where  $am_V = 0.53$ , the common vector meson mass for the data sets as shown in Table [I.](#page-17-4) The model comes from considering diagrams like the ones in Fig. [11.](#page-16-0) Klingl et al [\[34](#page-20-1)] present

<span id="page-11-0"></span>FIG. 6: Examples of fits producing  $F(q^2)$  for the  $SU(3)$  data set. Panels are (a)  $q = (0,0,0)$ ; (b)  $q = (1, 0, 0);$  (c)  $q = (1, 1, 0);$  (d)  $q = (1, 1, 1);$  (e)  $q = (2, 0, 0)$  (all in units otf  $2\pi/L$ ). In all figures, the points used in the fits are marked as octagons. Lines are fits to the individual correlators. In all cases the three point correlator is labelled by a fancy cross. In panel (a), diamonds label the two point function. In the other figures, squares and fancy squares label  $C_{SS}(t)$  and  $C_{SP}(t)$  for the initial momentum  $(\vec{p} = \vec{k} + \vec{q})$  while  $C_{SS}(t)$  and  $C_{SP}(t)$  for the final momentum  $(\vec{p} = \vec{k})$  are labelled by diamonds and fancy diamonds.

<span id="page-12-0"></span>FIG. 7: Examples of fits producing  $F(q^2)$  for the  $SU(4)$  data set. The panels and presentation are the same as for the  $SU(3)$  set, Fig. [6.](#page-11-0)

<span id="page-13-0"></span>FIG. 8: Examples of fits producing  $F(q^2)$  for the  $SU(5)$  data set. The panels and presentation are the same as for the  $SU(3)$  set, Fig. [6.](#page-11-0)

<span id="page-14-0"></span>FIG. 9: Examples of fits producing  $V_x$  for the  $SU(5)$  data set. Panels are (a)  $q = (1, 0, 0)$ ; (b)  $q = (1, 1, 0);$  (c)  $q = (1, 1, 1);$  (d)  $q = (2, 0, 0)$  (in units of  $2\pi/L$ ). The presentation is the same as for the figures showing fits producing  $F(q^2)$ .

several variations on this formula, using the definition of the rho to vector meson coupling as  $\langle \gamma | \rho \rangle = e m_V^2 / g_V$  and the direct coupling of a vector to two pseudoscalars of

$$
\mathcal{L} = \frac{i g_{VPP}}{4} \text{Tr} \left( V_{\mu} [\partial_{\mu} \pi, \pi] \right) \tag{23}
$$

which gives

<span id="page-14-1"></span>
$$
F_{VDM}(q^2) = 1 - \frac{g_{VPP}}{g_V} \frac{q^2}{q^2 + m_V^2 + \Pi(q^2)}
$$
(24)

and  $\Pi(q^2)$  is the vector meson vacuum polarization, a two-pion loop. We already know that  $1/g_V \propto \sqrt{N_c}$  (see, for example, Ref. [\[24\]](#page-19-12)) and the  $N_c$  independence of  $F(q^2)$  tells us that  $g_{VPP}$  should scale as  $1/\sqrt{N_c}$ , or that the hadronic decay width of the vector meson should scale as  $1/N_c$ , which is precisely what large  $N_c$  counting predicts. There will be  $1/N_c$ corrections to the form factor from  $\Pi(q^2)$  which could remain a target for a better study if desired.

<span id="page-15-1"></span>FIG. 10: The form factor of the pseudoscalar meson as a function of squared momentum transfer in lattice units. Squares label  $SU(3)$  points from the  $\mu = 0$  current; fancy squares label points from  $J_x$ . Red octagons and bursts label the corresponding points for  $SU(4)$  and blue diamonds and fancy diamonds repeat the assignment for  $SU(5)$ . The line is the expectation from the vector meson dominance, Eq. [22,](#page-10-1) using a vector meson mass of  $am_V = 0.53$ .

## <span id="page-15-0"></span>IV. SUMMARY

Once again, a low statistics calculation of an observable across  $N_c$  shows agreement with expectations based on large  $N_c$  counting. In the language of the quark model, the charge density of the pseudoscalar meson is independent of the color group. Stepping back a bit, from the point of view of numerical simulation, there seems to be nothing special about QCD;  $SU(N_c)$  gauge theories with a small number of flavors of dynamical fundamental fermions show similar behavior and the differences are well described by large  $N_c$  counting rules.

<span id="page-16-0"></span>FIG. 11: Amplitudes which contribute to the vector dominance formula, Eq. [24.](#page-14-1) The two diagrams correspond to the two terms in the right hand side of this equation.
