Abstract

Recent advances in autoregressive (AR) models with continuous tokens for image generation show promising results by eliminating the need for discrete tokenization. However, these models face efficiency challenges due to their sequential token generation nature and reliance on computationally intensive diffusion-based sampling. We present E-CAR (Efficient Continuous Auto-regressive Image Generation via Multistage Modeling), an approach that addresses these limitations through two intertwined innovations: **1** a stage-wise continuous token generation strategy that reduces computational complexity and provides progressively refined token maps as hierarchical conditions, and **2** a multistage flow-based distribution modeling method that transforms only partial-denoised distributions at each stage comparing to complete denoising in normal diffusion models. Holistically, E-CAR operates by generating tokens at increasing resolutions while simultaneously denoising the image at each stage. This design not only reduces token-to-image transformation cost by a factor of the stage number but also enables parallel processing at the token level. Our approach enhances computational efficiency and aligns naturally with image generation principles by operating in continuous token space and following a hierarchical generation process from coarse to fine details. Experimental results demonstrate that E-CAR achieves comparable image quality to DiT [Peebles & Xie, 2023] while requiring $10 \times$ FLOPs reduction and $5 \times$ speedup to generate a 256×256 image.

1 Introduction

Autoregressive (AR) Large Language Models (LLMs) [Vaswani, 2017, Achiam et al., 2023, Touvron et al., 2023a,b, Jiang et al., 2023] have demonstrated remarkable capabilities in natural language generation, driven by scaling laws [Kaplan et al., 2020, Hoffmann et al., 2022]. Inspired by these advancements, the computer vision community has been striving to develop large autoregressive and world models [Zhou et al., 2024, Team, 2024, Liu et al., 2024a] for visual generation. This effort is initiated by VQ-GAN [Esser et al., 2021] and further advanced by its successors [Lee et al., 2022, Sun et al., 2024, Tian et al., 2024, Team, 2024], showcasing the potential of AR models in visual generation.

Traditional AR image generation models employ a visual tokenizer to discretize continuous images into grids of 2D tokens, which are then flattened into a 1D sequence for AR learning (see Fig. 2.b). However, recent research [Li et al., 2024, Tschannen et al., 2023, Zhou et al., 2024, Fan et al., 2024] demonstrates that discrete tokenization is not only unnecessary but potentially detrimental to AR models' generation capabilities. These works show that AR image generation can be formulated continuously, modeling per-token probability distributions on continuous-valued domains. For

^{*}Equal Contribution.

instance, several approaches [Li et al., 2024, Zhou et al., 2024, Fan et al., 2024] leverage diffusion models for representing arbitrary probability distributions, where the model autoregressively predicts a continuous vector for each token as conditioning for a denoising network (see Fig. 2.c). We refer to this paradigm as *continuous AR* models.

Despite their advantages, continuous AR models, such as MAR [Li et al., 2024], face significant efficiency challenges. Generating a 256×256 image with MAR using one NVIDIA A5000 GPU requires more than 30 seconds, making these models impractical for real-time applications. We identify two main efficiency bottlenecks: **①** Token-by-token generation: Similar to text generation in LLMs, the sequential token-by-token nature of generation limits efficiency [Yuan et al., 2024]. **②** Diffusion-based sampling: The sampling process inherits the inefficiencies of diffusion models [Song et al., 2020a,b], requiring hundreds of denoising network inferences for token-to-image sampling. Beyond the direct computational costs, these issues significantly constrain parallelization potential, as the token generation process must proceed sequentially.

In this work, we propose Efficient Continuous Autoregressive Image Generation via Multistage Modeling (E-CAR) to address these limitations while maintaining generative capability. As shown in Fig. 1, E-CAR progressively generate tokens at increasing resolutions while simultaneously transport towards the image distribution via a multistage flow at each stage. Our approach features two intervened innovations targeting the efficiency bottleneck: ① Stagewise Progressive Token Map Generation: A hierarchical AR transformer architecture that generates continuous tokens at stage-wisely increasing resolutions (i.e., continuous token map), reducing token generation computation by enabling parallel processing within each stage. **2** Multistage Flow-based Distribution Modeling: A flow-based method that transforms continuous token distributions at multiple

Figure 1: **High-level Idea of** E-CAR. The model progressively generates tokens at increasing resolutions, while correspondingly denoising the image at each stage. By combining stage-by-stage continuous token generation with multistage flow-based image synthesis, E-CAR achieves efficient continuous autoregressive image generation while maintaining high visual quality.

stages, requiring only partial transport at each resolution level instead of complete denoising processes. This design reduces continuous detokenization computation proportionally to the number of stages. The stage-wise design of our approach enables parallel token sampling, as tokens are generated in resolution-specific stacks. From a flow matching perspective [Ma et al., 2024, Lipman et al., 2022, Liu et al., 2022, Liu, 2022], our multistage approach can be viewed as using the AR model to guide the flow model's visual generation process, creating a complementary relationship between continuous token generation and flow-based image synthesis.

Importantly, E-CAR's multistage continuous AR solution aligns naturally with image generation's pyramidal principles [Pernias et al., 2023, Saharia et al., 2022]. By operating in a continuous token space, it better reflects the inherent structure of images—a widely accepted inductive bias in computer vision [Li et al., 2024]. The increasing resolution generation mirrors the hierarchical nature of visual information, progressing from coarse structures to fine details, enabling effective multi-scale image generation while maintaining high quality [Jin et al., 2024]. To the best of our knowledge, this is the first work that integrates continuous AR and flow-based method in a multistage manner, offering a novel approach to efficient, high-quality visual generation.

2 Related Work

Autoregressive Visual Generation models initially operated on sequences of pixels [Gregor et al., 2014, Van Den Oord et al., 2016, Chen et al., 2018a, 2020]. While early implementations primarily utilized RNNs and CNNs as base models, Transformers [Vaswani, 2017] have recently become the dominant architecture for these tasks [Esser et al., 2021]. VQGAN [Esser et al., 2021] pioneered the use of Transformers for autoregressive image generation. Specifically, it employs a GPT-2 decoder-only Transformer [Radford, 2018] to generate tokens in a raster-scan order, similar to how ViT [Dosovitskiy, 2020] serializes 2D images into 1D patches. Building upon this paradigm, [Razavi et al., 2019, Lee et al., 2022] extend the approach by incorporating multiple scales or stacked codes. More recently, LlamaGen [Sun et al., 2024], based on the popular open-source

LLM architecture Llama [Touvron et al., 2023a,b], scales the Transformer to 3B parameters and demonstrated impressive results in text-to-image synthesis. In parallel, recent advancements have focused on continuous-valued tokens in AR models. GIVT [Tschannen et al., 2023] represents token distributions using Gaussian mixture models with a pre-defined number of mixtures. MAR [Li et al., 2024] leverages the effectiveness of the diffusion process for modeling arbitrary distributions. We categorize these AR methods that do not use discrete tokenizers as *continuous AR* methods.

Our work focuses on improving the efficiency of continuous AR models. To achieve this, we propose using a multistage AR Transformer to generate continuous tokens stage-by-stage, coupled with a multistage flow-based method to model the token distributions.

Diffusion Models and Flow Matching Models. Diffusion models [Sohl-Dickstein et al., 2015, Ho et al., 2020, Song et al., 2020b] have demonstrated remarkable success across various generative modeling tasks, such as the generation of images, videos, and audio [Croitoru et al., 2023]. Predominantly, these models utilize stochastic differential equations (SDEs) to model the diffusion and denoising processes. [Song et al., 2020b,a] also converted these SDEs into ordinary differential equations (ODEs) that preserve the marginal probability distributions, thereby accelerating the denoising process. Recent research [Liu et al., 2022, Liu, 2022, Lipman et al., 2022] has introduced novel methods for directly learning probability flow ODEs, employing both linear and nonlinear interpolation techniques between distributions. These ODE-based approaches rival the performance of conventional diffusion models while substantially reducing the number of inference steps required. The practical applications of flow matching have expanded beyond theoretical frameworks, with recent investigations applying these methods to larger datasets and more complex tasks. For example, [Liu et al., 2024b] showcased the Rectified Flow pipeline's capability to produce high-fidelity, one-step generation in large-scale text-to-image (T2I) diffusion models. This advancement has paved the way for extremely rapid T2I foundation models trained exclusively through supervised learning. The influence of these developments is evident in cutting-edge T2I systems, such as Stable Diffusion 3 [Esser et al., 2024], which incorporates reflow as a fundamental component of its generation process.

Our work focuses on continuous AR, but we formulate the distribution estimation under the framework of multistage flow matching, offering a more efficient method for continuous distribution matching.

3 E-CAR: Efficient Continuous Auto-regressive Image Generation via Multistage Modeling

We first review the basic pipeline of continuous autoregressive (AR) visual generation models (Sec.3.1). Next, we introduce our Efficient Continuous AR (E-CAR) image generation model. The development and optimization of E-CAR include three key advancements: (1) a stage-by-stage continuous token generation AR module (Sec.3.2); (2) an multistage flow model for fast continuous token recovery (Sec. 3.3); and (3) the multistage loss that enhances training stability (Sec.3.4). Finally, we provide a straightforward explanation of why E-CAR can be both efficient and effective (Sec.4.3).

3.1 Preliminaries: Continuous Autoregressive Visual Generation

The review of continuous AR visual generation models focuses on their main components and training procedures. In this review, we highlight the inefficiencies associated with existing continuous AR models.

Image Tokenization and Detokenization. Images are inherently 2D continuous signals. Pioneering AR studies [Esser et al., 2021, Sun et al., 2024, Tian et al., 2024, Yu et al., 2023a,b] apply AR modeling to images via next-token prediction, mimicking AR in language models [Vaswani, 2017]. This approach requires two key steps: (1) tokenizing an image into discrete tokens, and (2) modeling the tokens' unidirectional generation process.

For tokenization, a quantized autoencoder such as VQGAN [Esser et al., 2021] is often used to convert the image feature map $\mathbf{f} \in \mathbb{R}^{(h \cdot w) \times C}$ to discrete tokens $\mathbf{z} \in [V]^{(h \cdot w)}$:

$$\mathbf{f} = \mathcal{E}(\mathbf{x}), \quad \mathbf{z} = Q(\mathbf{f}), \tag{3.1}$$

where $\mathbf{x} \in \mathbb{R}^{h' \times w' \times 3}$ denotes the raw image, $\mathcal{E}(\cdot)$ is an encoder, and $Q(\cdot)$ is a quantizer. The quantizer typically includes a learnable Codebook $\in \mathbb{R}^{V \times C}$ containing V vectors with C dimensions.

The quantization process $\mathbf{z} = Q(\mathbf{f})$ maps each feature vector \mathbf{f}^i to the code index \mathbf{z}^i of its nearest code w.r.t. the Euclidean distance:

$$\mathbf{z}_j = \arg\min_{v \in [V]} \|\text{lookup}(\text{Codebook}, v) - \mathbf{f}_j\|_2,$$
(3.2)

where lookup(Codebook, v) means taking the v-th vector in codebook, \mathbf{z}_j and \mathbf{f}_j means j-th discrete token and feature map, respectively.

Quantized autoencoder training involves reconstructing the image and minimizing a compound loss:

$$\mathbf{f} = \text{lookup}(\mathbf{Z}, \mathbf{z}), \quad \hat{\mathbf{x}} = \mathcal{D}(\mathbf{f}),$$
(3.3)

$$\mathcal{L} = \|\mathbf{x} - \hat{\mathbf{x}}\|_2 + \|\mathbf{f} - \mathbf{f}\|_2 + \lambda_P \mathcal{L}_P(\hat{\mathbf{x}}) + \lambda_G \mathcal{L}_G(\hat{\mathbf{x}}),$$

where $\mathcal{D}(\cdot)$ is the decoder, $\mathcal{L}_P(\cdot)$ is a perceptual loss, and $\mathcal{L}_G(\cdot)$ is a discriminative loss. Using this tokenizer, a continuous image x can be discretized into a sequence of categorical tokens $\mathbf{z} = (z_1, \ldots, z_I)$. Conversely, generated tokens can be detokenized and then decoded back into a continuous image (i.e., realizing image generation).

Autoregressive Token Generation model predicts tokens sequentially, by factorizing the likelihood of a sequence $\mathbf{z} = (z_1, \dots, z_I)$ as:

$$p(z_1, z_2, \dots, z_I) = \prod_{t=1}^T p(z_i | z_1, z_2, \dots, z_{i-1}).$$
(3.4)

In the traditional AR image generation models [Esser et al., 2021, Sun et al., 2024, Tian et al., 2024, Yu et al., 2023a,b] (see Fig.2), $\{z_i\}_{t=1}^T$ are discrete tokens. However, the discrete tokens $\{z_i\}_{t=1}^T$ are not directly generated by the AR model. In fact, the autoregressive model produces a continuous-valued *C*-dim vector $\mathbf{z}_i \in \mathbb{R}^C$, which is then projected by a *V*-way classifier matrix $\mathbf{W} \in \mathbb{R}^{C \times V}$ to $z_i \in [V]$. In other words, one can use Eq.3.4 and an additional projector to generate a sequence of categorical tokens, and then use Eq.3.3 to decoder back to the image space.

Continuous AR. Recent work [Li et al., 2024, Tschannen et al., 2023] formulate the probability distribution $p(\mathbf{f}_i | \mathbf{z}_i)$ to model the detokenization for continuous tokens, where $\mathbf{f}_i \in \mathbb{R}^C$ is the *t*-th image patch's feature map and $\mathbf{z}_i \in \mathbb{R}^D$ is the corresponding AR model's output *continuous token*. MAR [Li et al., 2024] uses diffusion models to define the loss function and sampler, as shown in Fig.2 (c). MAR and its follow-up work [Fan et al., 2024] achieve state-of-the-art performance in image generation, showing the promising potential of continuous AR in the visual generation.

Efficiency Bottlenecks of Continuous AR Models. Continuous AR models face two main efficiency challenges: ① Token-by-token generation: Similar to LLMs, the sequential nature of generation limits efficiency [Yuan et al., 2024]. In these models, each token is produced based on all the previously generated tokens, which means that the process cannot be easily parallelized. This sequential dependency results in longer computation times, especially for generating lengthy tokens (corresponding to high-resolution images or videos). ② Diffusion sampling: [Song et al., 2020a] diffusion models require a large number of iterative denoising steps to generate a single sample, each of which must be executed sequentially [Song et al., 2020a].

We propose a hierarchical framework for addressing these issues, in which continuous token generation and continuous detokenization are realized in a hierarchical manner. By doing so, we are able to improve the efficiency of the continuous AR model as well as maintain its effectiveness.

3.2 Multistage Autoregressive Token Generation

Targeting the **①** efficiency challenge, we introduce a stage-by-stage continuous tokens AR generation model to enhance the efficiency of token generation. Our method reimagines autoregressive image modeling by transitioning from a "next-token prediction" paradigm to a "next-stage prediction" strategy, as illustrated in Figs.1 and 2. In this framework, the autoregressive unit evolves from a single token to an *entire token map*. The process begins by encoding a feature map $\mathbf{M} = [\mathbf{z}_i, \dots, \mathbf{z}_{(h \cdot w)}] \in \mathbb{R}^{(h \cdot w) \times C}$ into a sequence of S-stage token maps $(\mathbf{M}_1, \mathbf{M}_2, \dots, \mathbf{M}_S)$. Each successive map increases in resolution from $h_1 \times w_1$ to $h_S \times w_S$, with the final map m_S matching the original feature map's dimensions $(h \cdot w)$. The autoregressive likelihood can be formulated as:

$$p(\mathbf{M}_1, \mathbf{M}_2, \dots, \mathbf{M}_S) = \prod_{s=1}^S p(\mathbf{M}_s \mid \mathbf{M}_1, \mathbf{M}_2, \dots, \mathbf{M}_{s-1}).$$
(3.5)

Figure 2: (a) Diffusion/Flow-matching model: Generates images through multiple iterations of denoising/velocity network inference. (b) Traditional AR Transformer: Sequentially generates discrete tokens, followed by codebook-based detokenization. (c) Continuous Masked AR [Li et al., 2024]: Sequentially produces continuous tokens, which are transformed into image patches via a diffusion model. (d) E-CAR: Introduces two key innovations: multi-stage continuous token generation and (Sec.3.3) multi-stage flow for efficient continuous token generation and token-to-image detokenization, respectively. Using the upsample and renoise technique [Jin et al., 2024], we can correspondingly reduce the number of steps for flow matching at each stage, enhancing the efficiency of the continuous token detokenization process.

Here, each autoregressive unit $\mathbf{M}_s \in \mathbb{R}^{(h_s \cdot w_s) \times C}$ represents the token map at stage s, encompassing $h_s \cdot w_s$ continuous tokens. The preceding sequence $(\mathbf{M}_1, \mathbf{M}_2, \dots, \mathbf{M}_{s-1})$ functions as a "pre-fix" [Yuan et al., 2024] for m_s . During the *s*-th autoregressive step, our model generates distributions for all $h_s \cdot w_s$ tokens in m_s concurrently. This parallel generation is conditioned on both the prefix and the stage-specific positional embedding map. We term this "next-stage prediction" approach Multi-stage Continuous Autoregressive, as depicted in Fig. 2.

Efficiency Benefit. The designed multi-stage continuous token generation offers significant computational advantages over the vanilla continuous AR. Theoretically, our method achieves a time complexity of $\mathcal{O}(n^2)$, where *n* is the number of tokens representing an image. In contrast, the vanilla continuous AR method has a time complexity of $\mathcal{O}(n^3)$. This improvement results in our approach being *n* times faster than the vanilla method. More details can be found in the Supplementary Materials. We would like to highlight that this efficiency gain becomes increasingly significant as we move towards long-sequence token generation (*e.g.*, higher-resolution images or video generation).

3.3 Multistage Flow Matching for Fast Sampling from Continuous Token

After we get the set of continuous tokens $\{\mathbf{M}_s\}_{s=1}^S$, we hope to get a sampler that can draw samples from the distribution $\mathbf{F}_S \sim p(\mathbf{F}_S | \mathbf{M}_S)$ at inference time, *i.e.*, generate image patches' embeddings

based on the output tokens. Targeting the **2** efficiency challenge, we model this sampler under the framework using multistage flow [Liu et al., 2022, Lipman et al., 2022, Liu et al., 2024b, Xie et al., 2024] to improve the continuous detokenization efficiency.

Problem Formulation. Consider the continuous-valued token map at *S*-th stage $\mathbf{M}_{S} \in \mathbb{R}^{(h_{S} \cdot w_{S}) \times D}$, and the ground-truth image patch embeddings $\mathbf{F}^{(S)} \in \mathbb{R}^{(h_{S} \cdot w_{S}) \times C}$ to be predicted at the this stage. Our goal is to model a probability distribution of \mathbf{F}_{S} conditioned on \mathbf{M}_{S} , that is, $p(\mathbf{F}^{(S)}|\mathbf{M}_{S})$. In the context of optimal transport, we hope to find a velocity model, optimal transport from $\mathbf{n}|\mathbf{M}_{S} \sim \pi_{0}$ to $\mathbf{F}^{(S)}|\mathbf{M}_{S} \sim \pi_{1}$. For simple sampling, π_{0} commonly be set as a normal distribution.

Flow Matching [Liu, 2022, Liu et al., 2022, Ma et al., 2024, Jin et al., 2024] is a unified ODE-based framework for generative modeling and domain transfer. It provides an approach for learning a transport mapping T between two distributions π_0 and π_1 . Specifically, flow Matching learns to transfer π_0 to π_1 via an ordinary differential equation (ODE), or flow model

$$\frac{d\mathbf{F}_{t}^{(S)}}{dt} = v_{\theta}((\mathbf{F}^{(S)}), t \mid \text{cond} = \mathbf{M}_{S}), \text{ initialized from } \mathbf{F}_{0}^{(S)} \sim \pi_{0} = \mathcal{N}(\mathbf{0}, \mathbf{I}), \text{s.t.} \mathbf{F}_{1}^{(S)} \sim \pi_{1},$$
(3.6)

where cond is the condition variable, it can be a class or a text embedding, and $v_{\theta} : \mathbb{R}^d \times [0, 1] \times \mathbb{R}^D \to \mathbb{R}^d$ is a velocity field, learned by minimizing a mean square objective:

$$\min_{v_{\theta}} \mathbb{E}_{((F_S)_0, (F_S)_1) \sim \gamma, z \sim \mathcal{D}_{\text{cond}}} \left[\int_0^1 \left\| \frac{d}{dt} \mathbf{F}_t^{(S)} - v_{\theta}(\mathbf{F}_t^{(S)}, t \mid \mathbf{M}_S) \right\|^2 dt \right],$$
(3.7)

with $\mathbf{F}_t^{(S)} = \phi(\mathbf{F}_0^{(S)}, \mathbf{F}_1^{(S)}, t)$ where \mathcal{D}_{cond} is the collection of conditions, $\mathbf{F}_t^{(S)} = \phi(\mathbf{F}_0^{(S)}, \mathbf{F}_1^{(S)}, t)$ is any time-differentiable interpolation between $\mathbf{F}_0^{(S)}$ and $\mathbf{F}_1^{(S)}$, with $\frac{d}{dt}\mathbf{F}_t^{(S)} = \partial_t\phi(\mathbf{F}_0^{(S)}, \mathbf{F}_1^{(S)}, t)$. The γ is any coupling of (π_0, π_1) . A simple example of γ is the independent coupling $\gamma = \pi_0 \times \pi_1$, which can be sampled empirically from unpaired observed data from π_0 and π_1 . Usually, v_{θ} is parameterized as a deep neural network and Eq.3.7 is solved approximately with stochastic gradient methods. Different specific choices of the interpolation process $\mathbf{F}_1^{(S)}$ result in different algorithms. As shown in [Liu, 2022], the commonly used denoising diffusion implicit model (DDIM) [Song et al., 2020a] and the probability flow ODEs of [Song et al., 2020b] correspond to $\mathbf{F}_t^{(S)} = \alpha_t \mathbf{F}_0^{(S)} + \beta_t \mathbf{F}_1^{(S)}$, with specific choices of time-differentiable sequences α_t , β_t (see [Liu, 2022, Liu et al., 2024b] for details). In rectified flow [Liu, 2022], the authors suggested a simpler choice of

$$\mathbf{F}_{t}^{(S)} = (1-t)\mathbf{F}_{0}^{(S)} + t\mathbf{F}_{1}^{(S)} \implies \frac{\mathrm{d}}{\mathrm{d}t}\mathbf{F}_{t}^{(S)} = \mathbf{F}_{1}^{(S)} - \mathbf{F}_{0}^{(S)}.$$
(3.8)

Simple Flow Sampler. Once we obtain a well-trained velocity model v_{θ} through optimization of Eq. 3.7, we can sample image patches's embedding \mathbf{F}_S) conditioned on the continuous token map \mathbf{M}_S). The sampling process involves approximating the ODE in Eq. 3.6 using numerical methods. The most common approach for this approximation is the forward Euler method, which discretizes the continuous ODE into finite steps:

$$\mathbf{F}_{t+\Delta t}^{(S)} = \mathbf{F}_{t}^{(S)} + \Delta t \cdot v_{\theta}(\mathbf{F}_{t}^{(S)}, t \mid \text{cond} = \mathbf{M}_{S}),$$
(3.9)

where $t \in \{0, \frac{1}{N}, \frac{2}{N}, \dots, \frac{N-1}{N}\}$ and $\Delta t = \frac{1}{N}$ is the step size, N is the total number of simulation steps, $\mathbf{F}_t^{(S)}$ represents the state at time t, and $v(\mathbf{F}_t^{(S)}, t)$ is the velocity predicted by our trained model. The sampling process starts at t = 0 and iteratively applies this update equation N times until reaching t = 1, thereby transforming the initial noise distribution into the desired sample distribution.

However, directly using full-size token map \mathbf{M}_S to generate full-size feature map $\mathbf{F}^{(S)}$ in the final stage is not optimal for efficiency, specifically in our stage-wise token generation case. We hope to fully leverage the low-resolution token maps. Therefore, to leverage our multi-stage token generation framework and accelerate sampling, we propose a multi-stage sampling strategy that aligns with the hierarchical nature of our token generation process.

Multi-stage Flow. To reduce redundant computation in early steps, we propose a multistage flow approach that operates at multiple resolutions. We interpolate the flow between the feature map and compressed low-resolution noise, progressively increasing the resolution at each stage, as shown in Fig.2.d.

Figure 3: **Training of** E-CAR. Our model combines multistage autoregressive token generation with progressive flow matching. The AR transformer (left) generates continuous token maps using a multistage causal attention mask, which are then transformed to spatial conditions for each stage. Each stage's token map conditions its corresponding flow model, enabling progressive reconstruction of image latents at different resolutions. The flow matching loss is computed between the predicted velocity and the ground truth trajectory at each stage, with back-propagation through the entire pipeline for end-to-end training.

Suppose we have S stages, each corresponding to a resolution level, with each stage halving the spatial dimensions of the previous one. We partition the time interval [0, 1] into S segments: Stage s corresponds to the time interval $t \in [t_{s-1}, t_s]$, where $t_s = \frac{s}{S}$ for $s = 1, 2, \ldots, S$. At each stage s, we define the rescaled time within the stage: $\tau = \frac{t-t_{s-1}}{t_s-t_{s-1}} \in [0, 1]$. The target feature map at the current resolution:

$$\mathbf{F}_{1}^{(s)} = \operatorname{Down}\left(\mathbf{F}_{1}, 2^{S-s}\right),\tag{3.10}$$

where \mathbf{F}_1 is the ground-truth feature map $\mathbf{F}^{(S)}$, $\text{Down}(\cdot, k)$ denote downsampling by a factor of k.

The initial noise feature map at the current resolution $\mathbf{F}_{0}^{(s)}$:

$$\mathbf{F}_{0}^{(s)} = \begin{cases} \operatorname{Down}\left(\mathbf{F}_{0}, 2^{S-1}\right), & \text{if } s = 1, \\ \operatorname{Up}\left(\mathbf{F}_{0}^{(s-1)}\right), & \text{if } s > 1, \end{cases}$$
(3.11)

where \mathbf{F}_0 is the initial noise sample (e.g., Gaussian noise), and $Up(\cdot)$ denotes upsampling by a factor of 2. Within stage *s*, we interpolate between $\mathbf{F}_0^{(s)}$ and $\mathbf{F}_1^{(s)}$ using the rescaled time τ :

$$\hat{\mathbf{F}}_{t}^{(S)} = (1 - \tau), \mathbf{F}_{0}^{(s)} + \tau \mathbf{F}_{1}^{(s)}.$$
(3.12)

This interpolation ensures that feature maps at each stage have matching dimensions, allowing us to perform computations efficiently at each resolution level. Only the final stage (s = S) operates at full resolution, where no downsampling is applied: $\mathbf{F}_1^{(S)} = \mathbf{F}_1$. More details about the multistage flow can be found in [Jin et al., 2024] and our Appendix.

Efficiency Benefits. By performing computations at progressively higher resolutions, we can reduce the computational burden. Early stages operate on downsampled feature maps, which are much smaller in size, thus requiring fewer computations. Only the final stage processes the full-resolution feature map. This multistage approach effectively reduces the overall computational cost by a factor of approximately 1/S, assuming uniform time partitioning and resolution scaling.

Latent Space Technique. Even though the whole story is on how to model between continuous token map \mathbf{M}_s and image feature map $\mathbf{F}^{(s)}$, the latent space technique for high-resolution image synthesis [Rombach et al., 2022] can also be easily removed out of our pipeline (*i.e.*, directly used in the image domain $\mathbf{X}^{(s)}$ without latent space).

3.4 Training Loss

The training of E-CAR involves optimizing both the multistage autoregressive token generation model and the multistage flow matching model. At each stage, our goal is to reconstruct the image's

latent representations at varying resolutions, ensuring that the model learns to generate accurate representations progressively. Specifically, for each stage *s*: **Continuous Token Generation**: We generate the continuous token map \mathbf{M}_s using the multistage autoregressive (AR) model, as described in Sec. 3.2. This token map serves as the conditioning information for the flow model at stage *s*. **Image Latent Reconstruction**: We reconstruct the image's latent representation \mathbf{F}_s at resolution level *s* using the multistage flow model. The reconstruction is conditioned on the continuous token map \mathbf{M}_s . Specifically, we sample $\hat{\mathbf{F}}^{(s)}$ by solving the ODE defined in Eq. (3.9) using the velocity model v_{θ} :

$$\hat{\mathbf{F}}^{(s)} = \text{ODE}[v_{\theta}](\mathbf{F}_{0}^{(s)} \mid \mathbf{M}_{s}), \qquad (3.13)$$

where $\mathbf{F}_0^{(s)}$ is the initial noise sample at stage *s*, typically a downsampled noisy image. Flow Matching Loss Computation: We compute the flow matching loss l_{flow}^s at stage *s* using the time-dependent interpolated latent representations $\hat{\mathbf{F}}_t$ and their derivatives:

$$l_{\text{flow}}^{s} = \mathbb{E}_{(\mathbf{F}_{0}^{(s)}, \mathbf{F}_{1}^{(s)}), t \in [t_{s-1}, t_{s}]} \left[\left| \frac{d\hat{\mathbf{F}}_{t}^{(s)}}{dt} - v_{\theta} \left(\hat{\mathbf{F}}_{t}^{(s)}, t \mid \mathbf{M}_{s} \right) \right|^{2} \right],$$
(3.14)

where $\mathbf{F}_{1}^{(s)}$ is the ground-truth image latent at stage s, and $\frac{d\hat{\mathbf{F}}_{t}^{(s)}}{dt} = \mathbf{F}_{1}^{(s)} - \mathbf{F}_{0}^{(s)}$ due to linear interpolation (see Fig.3).

This multi-stage loss encourages the model to generate accurate representations at various resolutions, ultimately leading to high-quality final outputs. To dynamically balance the contributions of different stages to the overall loss, we employ the GradNorm technique [Chen et al., 2018b]. This adaptive weighting method automatically adjusts the stage-specific weights w_s during training.

4 Experiments

We detail the experimental setup and model configurations in Sec. 4.1, followed by an analysis of the quantitative and qualitative performance of our approach in Sec. 4.2 and Sec. 4.4. Finally, we demonstrate the effectiveness of each component in our model in Sec.4.5.

4.1 Experimental Setup

We train the image generation models on ImageNet [Deng et al., 2009] train dataset at 256×256 resolution. The image tokenizer is from SDXL [Podell et al.], which is a VAE that transform the image to the latent space with 8x reduction. The latent resolution is 32×32 when the image resolution is 256×256 . All models are trained with the settings: AdamW optimizer with learning rate of 1e-4, no weight decay, and the batch size of 256. We use 8 NVIDIA A100 GPUs to train each model and the TF32 dataformat to accelerate the training process.

	Table 1: Model configurations.						
		E-CAR-S	E-CAR-B	E-CAR-L			
	Layers	10	20	24			
AR	Hidden size	768	1024	1152			
	Heads	6	16	16			

Model. To demonstrate the scalability of E-CAR, we trained different size of models, E-CAR-{S,B,L}. The model configurations are shown in Table 1. The auto-regressive model (AR) takes ViT backbone [Dosovitskiy, 2020]. There are three auto-regressive stages to generate image at latent space, and the latent resolutions of these stages are {8,16,32}. For each stage, we use a diffusion model with much smaller number of Transformer layers than the auto-regressive model. Therefore, the diffusion model is efficient to iteratively denoise on the latent space. We use the adaptive layer normalization (adaLN) [Peebles & Xie, 2023] to incorporate the conditional information into the diffusion process. Unlike DiT [Peebles & Xie, 2023] takes the class condition as a global information, the condition from AR model is spatially variant in E-CAR. That is, the condition is different at each spatial location in diffusion model.

Model	Params	FLOPs	FID↓	IS↑	P↑	R↑

Metric. We use the same evaluation metrics as Guided Diffusion, FID [Heusel et al., 2017], Inception Score (IS) [Salimans et al., 2016], Improved Precision and Recall [Kynkäänniemi et al., 2019]. In general, Frechet Inception Distance (FID) and Inception Score can measure the quality of the generated images, and recall score can measure the diversity of generated images. We generate 50K images with 250 total denoising steps. Each stage takes 1/3 of the total denoising steps.

4.2 Quantitative Results

To quantitatively evaluate the performance of E-CAR image generation, we trained the E-CAR S,B,L models for 400K iterations. We choose two widely used model series to compare, including DiT [Peebles & Xie, 2023] and MAR [Li et al., 2024].

The results are shown in Table 2. The E-CAR-L model achieves a computational performance of 5.8 TFLOPs for generating 256×256 images with classifier-free guidance (CFG), which is a mere 9.7% of the capabilities seen in both the MAR-H and DiT-XL/2 models. E-CAR-L achieve highest inception score and precision among three types of model. Though E-CAR-L has a higher FID compared with MAR-H and DiT-XL/2, it's important to highlight that due to time constraints, our E-CAR models have only undergone 400K training iterations, significantly fewer than the 7 million iterations typical for DiT and MAR models. As shown in fig 6, at 400K iterations, the model loss is continuously decreasing, suggesting that further training could potentially result in a lower FID. Our findings demonstrate that E-CAR-L significantly diminishes computational expenses while maintaining a high standard of image generation quality.

4.3 Inference Efficiency Analysis

To evaluate the inference efficiency of E-CAR, we deploy the model on different devices including NVIDIA 4090 24G GPU, Intel i9-13900K CPU with 32G memory, and Apple M2 16G on Macbook Air. The batchsize of inference is set to 1. The result is shown in Table 3. The generation time of E-CAR-L model on 4090 GPU is less than 1 second. In comparison to MAR models, E-CAR models achieve a substantial speedup from $63 \times$ to $107 \times$ on NVIDIA 4090 GPUs, and $25 \times$ to $37 \times$ on Intel

Figure 4: Samples from different models with the same noise.

i9-13900K CPUs. MAR results for the Apple M2 are not listed, as the platform is not supported and encountered errors during testing. When compared with DiT models, despite having a slightly higher number of model parameters than DiT models, our models still deliver considerable acceleration on all test devices. E-CAR models achieve $3.6 \times -4.0 \times$ speedup on 4090 GPUs, $4.1 \times -5.5 \times$ speedup on i9-13900K CPU, and $4.1 \times -4.9 \times$ speedup on Apple M2 chips.

Efficiency of E-CAR. Here, we provide a straightforward explanation of why E-CAR is both more efficient and effective than traditional AR image generation models. The efficiency of E-CAR stems from three key factors: (1) Hierarchical Continuous Token Generation: As described in Sec. 3.2, our stage-wise approach reduces the computational complexity from $O(n^3)$ to $O(n^2)$, where *n* is the number of tokens. (2) Efficient Detokenization: The multistage flow in Sec.3.3 offers a more efficient alternative to diffusion-based approaches for transforming tokens into images. Diffusion-based detokenizer needs (3) Parallel Processing: Unlike token-by-token generation, E-CAR can generate the entire stack of tokens for an image simultaneously. This enables parallel processing during token recovery, further enhancing efficiency.

Effectiveness in Image Generation. The effectiveness of E-CAR in image generation is rooted in two principles: (1) Continuous Representation: Images are inherently continuous signals. By operating in a continuous token space, E-CAR aligns more closely with the natural structure of images, a widely accepted inductive bias in computer vision. It echoes the finding in [Yu et al., 2024] that representation space is important for generative models' training. (2) Hierarchical Architecture: The stage-wise generation process of E-CAR mirrors the hierarchical nature of visual information, from coarse structures to fine details. This approach allows the model to generate images at multiple scales effectively.

4.4 Qualitative Results

We show the generated images of E-CAR models with three different model size in Figure 4. We can observe that our method is able to generate high quality images with 400K training rounds. Among three models, images generated by E-CAR-L has highest visual fidelity, demonstrating our method has scaling behavior.

4.5 Ablation Study

To show the effective of the E-CAR architecture, we replace the layers in auto-regressive model with layers in denoising model, that is, only the low resolution image is sent to the next stage.

The results are shown in Figure 5. It shows that by using the auto-regressive model, the loss can decease significantly quickly. This indicate that the auto-regressive can plan the generation process in high-level, and the denoising model is only focused on low-level denoising process.

5 Conclusion

We introduce E-CAR, a method enhancing continuous AR image generation efficiency with two innovations: 1) stage-wise progressive token map generation that reduces computation by generating tokens at increasing resolutions in parallel, and 2) multistage flow-based distribution modeling that transforms only partial-denoised distributions at each stage comparing to complete denoising in normal diffusion models. Experiments show that E-CAR achieves comparable image quality to prior work while requiring $10 \times$ fewer FLOPs and providing a $5 \times$ speedup for 256×256 image generation.

Acknowledgment: We would like to express our gratitude to Xuefei Ning for her invaluable guidance and support throughout this research endeavor. We are also grateful to the NICS-efc Lab and Infinigence AI for their substantial support.

A Appendix

A.1 Training More Iterations

We have extended the training of E-CAR-L to 800,000 iterations, resulting in a Fréchet Inception Distance (FID) of 4.9. This represents a significant improvement compared to the 400,000 iterations, which achieved an FID of 6.5. However, we have observed that the loss has not yet converged and continues to decrease steadily. Therefore, we are continuing the training of this model for more iterations, as we believe the results will improve further.

A.2 Token Generation Efficiency Analysis

For a standard self-attention transformer, the time complexity of AR generation is $O(n^3)$, where n is the total number of image tokens.

In AR generation, tokens are generated one at a time. For the *i*-th token $(1 \le i \le n)$, the model computes attention scores between the new token and all previously generated i - 1 tokens. The attention computation scales quadratically with the sequence length, so the time complexity for generating the *i*-th token is $O(i^2)$.

The total time complexity is the sum over all n tokens:

$$T_{\text{AR}} = \sum_{i=1}^{n} O(i^2)$$
$$= O\left(\sum_{i=1}^{n} i^2\right)$$
$$= O\left(\frac{n(n+1)(2n+1)}{6}\right)$$
$$= O(n^3).$$

For a standard self-attention transformer using the multistage method with a resolution schedule, the time complexity is $O(n^2)$.

In Multistage AR generation, tokens are generated in stages with increasing resolutions. Define a sequence of stages (n_1, n_2, \ldots, n_K) , where n_k is the number of tokens at stage k, and K is the total number of stages.

Assume that the number of tokens doubles at each stage (for simplicity), starting from $n_1 = 1$:

$$n_k = 2^{k-1}, \quad \text{for } 1 \le k \le K.$$

The cumulative number of tokens up to stage k is:

$$S_k = \sum_{i=1}^k n_i = 2^k - 1.$$

Since the total number of tokens is n, we have:

$$n = S_K = 2^K - 1 \implies K = \log_2(n+1).$$

At each stage k, the time complexity is proportional to S_k^2 (due to the quadratic scaling of attention computation):

$$T_{\text{MultiAR}} = \sum_{k=1}^{K} O(S_k^2)$$

Substitute $S_k = 2^k - 1$:

$$T_{\text{MultiAR}} = O\left(\sum_{k=1}^{K} (2^{k} - 1)^{2}\right)$$
$$= O\left(\sum_{k=1}^{K} (2^{2k} - 2^{k+1} + 1)\right)$$
$$= O\left(\sum_{k=1}^{K} 4^{k} - 2^{k+1} + 1\right).$$

Compute each term separately and combine the sums:

$$T_{\text{MultiAR}} = O\left(\frac{4^{K+1} - 4}{3} - 2^{K+2} + 4 + K\right)$$
$$= O\left(\frac{4^{K+1}}{3} - 2^{K+2} + K + \text{constants}\right).$$

Since $K = \log_2(n+1)$, we have:

$$4^{K+1} = 2^{2(K+1)} = 2^{2(\log_2(n+1)+1)} = 4(n+1)^2.$$

Similarly:

$$2^{K+2} = 2^{\log_2(n+1)+2} = 4(n+1).$$

Therefore, the dominant terms in T_{MultiAR} are:

$$T_{\text{MultiAR}} = O\left(\frac{4(n+1)^2}{3} - 4(n+1) + \log_2(n+1)\right)$$

= $O(n^2)$.

Comparing the time complexities:

$$\frac{T_{\rm AR}}{T_{\rm MultiAR}} = \frac{O(n^3)}{O(n^2)} = O(n)$$

Thus, the multistage AR method is faster than the AR method by a factor of O(n) when generating an image with n tokens. The modeling and proof are inspired by VAR [Tian et al., 2024].

A.3 Upsample-Renoise in Multi-stage Flow

In the inference phase, because the interpolation of $\hat{\mathbf{F}}_t$ involves feature maps of varying dimensions across different stages, we employ an Upsampling and Re-noising module inspired by Pyramidal Flow Matching [Jin et al., 2024]. This module ensures that the Gaussian distributions are matched at each transition point by applying a linear transformation to the upsampled results. Specifically, when moving from a lower-resolution stage to a higher-resolution one, we upsample the feature map and add Gaussian noise to match the statistical properties required for flow matching. This process facilitates smooth transitions between stages and maintains consistency in the multistage flow framework.
