ABSTRACT

Gravitational Wave (GW) sources are standard sirens that provide an independent way to map the cosmic expansion history by combining with an independent redshift measurement either from an electromagnetic counterpart for a bright siren or using different statistical techniques for dark sirens. In this analysis, we perform the first Blinded Mock Data Challenge (Blinded-MDC) to test the robustness in inferring the value of Hubble constant H_0 for a dark siren technique which depends on astrophysical mass distribution of Binary Black Holes (BBHs). We have considered different analysis setups for the Blinded-MDC to test both statistical and systematic uncertainties and demonstrate the capabilities in inferring H_0 with detector sensitivity as per the fourth observation run of LIGO-Virgo-KAGRA. We find that when the astrophysical population of BBHs matches with the underlying assumption of the model, a cosmological pipeline can recover the injected parameters using the observed mass distribution. However, when the mock mass distribution of the astrophysical population depends slightly on redshift and one is ignorant about it in analyzing the data, it can cause a systematic discrepancy in the inferred value of H_0 by about 1.5σ , above the statistical fluctuations due to noise and a limited number of events. The discrepancy in H_0 is arising due to astrophysical mis-modeling, and in the future, elaborate studies will be required to mitigate systematic uncertainties due to unknown astrophysical populations of BBHs. This MDC framework sets the road map for inspecting the precision and accuracy of standard siren cosmology and provides the first insight into the robustness of the population-dependent cosmology inference in a blinded analysis setup.

1. INTRODUCTION

The detection of Gravitational Waves (GWs) by the LIGO-Virgo-KAGRA (LVK) Scientific Collaboration has opened a window to the cosmos, making it possible to explore physics from the smallest scale associated with neutron stars to cosmological scales of the Universe and answering several fundamental questions about the Universe (Abbott et al. 2016). One such fundamental question is the expansion history of the Universe as a function of cosmological redshift. Such a measurement will not only shed light on the mismatch in the value of the current expansion rate (called the Hubble constant H_0) but will also discover the constituents that contribute significantly to the energy budget of the Universe such as dark matter and dark energy. Measurement of the expansion history of the Universe using GW sources is feasible using sources having electromagnetic (EM) counterparts such as binary neutron stars (BNSs) and neutron star-black holes (NSBHs), and sources without EM counterparts such as stellar origin binary black holes (BBHs). For the former, measuring the redshift of the host galaxy of the GW sources is possible through spectroscopic follow-ups of the EM counterpart, as shown in the case of GW170817 (Abbott et al. 2017a,b). For the latter, various techniques have been developed and applied to the second (GWTC-2) or third (GWTC-3) GW catalog of the LVK Scientific Collaboration (Abbott et al. 2021; Finke et al. 2021; Abbott et al. 2023a; Mukherjee et al. 2024; Karathanasis et al. 2023a). These techniques include a mass spectrum of BBHs through spectral sirens technique (Farr et al. 2019; Mastrogiovanni et al. 2021; Mukherjee 2021; Leyde et al. 2022; Ezquiaga & Holz 2022; Mastrogiovanni et al. 2024; Leyde et al. 2024; Pierra et al. 2024; Magaña Hernandez & Ray 2024; Farah et al. 2024; Mali & Essick 2024), statistical host identification technique using galaxy catalogs (Schutz 1986; Fishbach et al. 2019; Soares-Santos et al. 2019; Gray et al. 2020; Soares-Santos et al. 2019; Palmese et al. 2021; Gray et al. 2023), and the GW-galaxy cross-correlation technique for LVK (Mukherjee & Wandelt 2018; Mukherjee et al. 2020, 2021b; Bera et al. 2020; Ferri et al. 2024) which will be useful in synergy with the spectroscopic galaxy

surveys such as DESI (Aghamousa et al. 2016), Euclid (Refregier et al. 2010), and SPHEREx(Dore et al. 2018) and upcoming photometric survey Vera Rubin Observatory (LSST Science Collaboration et al. 2009) as demonstrated in (Diaz & Mukherjee 2022; Afroz & Mukherjee 2024).

However, one of the key requirements for an accurate and precise cosmological probe is to understand the impact of astrophysical uncertainty due to various assumptions and the reliability of a technique in providing accurate cosmological results despite these challenges. Such analyses are performed for other cosmological probes to the expansion history such as Cosmic Microwave Background (CMB) (Ade et al. 2016), Barvon Acoustic Oscillation (BAO) (Pérez-Fernández et al. 2024), and lensing time delay measurements (Ding et al. 2018) to understand the impact from possible known sources of systematics. In this work, we explore for the first time a Blinded Mock Data Challenge (Blinded-MDC) on realistically simulated GW sources to understand the interplay between cosmological inference of H_0 and astrophysical population assumptions of BBHs. This Blinded-MDC analysis is focused on the method that uses the mass distribution of the BBHs to infer the expansion history of the Universe and the impact of the underlying assumption on the spectral-sirens technique. In the future, the Blinded-MDC technique will be applied to other astrophysical scenarios for the spectral-siren method, as well as for other techniques to understand the robustness of the standard siren methods in inferring the cosmological parameters, primarily the Hubble parameter H(z). Apart from systematic errors due to astrophysical populations of BBHs, the impact of a few other sources of systematic errors in GW cosmology such as inclination angle (Müller et al. 2024; Salvarese & Chen 2024), inaccurate waveform (Kunert et al. 2024), peculiar velocity of host galaxy (Mukherjee et al. 2021a; Nimonkar & Mukherjee 2023), and photometric redshifts uncertainty of host galaxy (Turski et al. 2023), were explored previously.

The paper is organized as follows: we outline the setup of the Blinded-MDC in section 2. The simulated mock data for different astrophysical cases considered in this analysis are discussed in section 3. The formalism we have used for the analysis is discussed in section 4. The results and the discussion for different cases from the Blinded-MDC are presented in section 5. Finally, the conclusion and future scopes are discussed in section 6.

2. SETUP FOR THE BLINDED MOCK DATA CHALLENGE

The Blinded-MDC is set up to find out the robustness of a GW cosmology analysis pipeline in inferring the cosmological parameters in two aspects, namely (i) in the presence of statistical uncertainties of the GW source parameters without any modeling error in the astrophysical population of BBHs and (ii) in the presence of modeling error(s). For this Blinded-MDC we have focused on two scenarios, (i) the vanilla case: where the underlying population model is POWER LAW + GAUS-SIAN PEAK (PLG) without any redshift evolution (Abbott et al. 2023b), but the values of the parameters in PLG (discussed in the next section, 3.1) and the values of the cosmological parameters are blinded, and (ii) the Redshift Dependent scenario: where the underlying population model is PLG with redshift-dependent parameters (as discussed in the next section, 3.2). This differs from the usual assumption of the no redshift evolution of the mass distribution of BBHs (Abbott et al. 2021; Mastrogiovanni et al. 2024; Gray et al. 2023).

The injected values are chosen from a wide prior range of the astrophysical and cosmological parameters and the Blinded-MDC is made blind to ensure that the choice in the analysis settings is independent of the injected values, to test the reliability of the pipelines and to avoid any confirmation bias. As a result, two disjoint research groups are prepared, (i) the simulation team, and (ii) the analysis team, which are coordinated by the MDC coordinator. The exact setup of the Blinded-MDC is shown by a schematic diagram in Fig. 1. We describe below each of the cases:

Blinded-MDC Simulation setup: The code GWSIM (Karathanasis et al. 2023b) is used for the generation of the simulated GW mock data using the LVK O1+O2+O3+O4 noise power spectral densities (PSDs) for the vanilla case and with the O4 noise PSD for the Redshift-Dependent scenario (Aasi et al. 2015; Acernese et al. 2015; Aso et al. 2013) with the duty cycles as mentioned in Tab. 1. The values of the BBH source parameters, merger rate parameters, and cosmological parameters are drawn randomly from a fixed prior range before passing it to the simulation code GWSIM. The GWSIM code has gone through an internal review for the validation of the injected simulation set with the expected distribution for the model of the astrophysical population. For the vanilla case, the simulation set that was passed to the analysis team is for the values for which the GWSIM code was validated. This is to ensure that there is no error in the pipeline of Blinded-MDC setup, which includes both injection and analysis parts. The values of the injected parameters and whether they are

the same as the one for which the code is tested remained blinded until the analysis was completed. The matched filtering Signal to Noise Ratio (SNR) denoted by ρ thresholds used for the Vanilla case is $\rho_{\rm th} = 10$. For the Redshift-Dependent scenario, the matched filtering SNR threshold is $\rho_{\rm th} = 12$. As the Redshift-Dependent MDC scenario, explores the impact on H_0 due to the mis-modeling of the astrophysical population assumption, we have chosen a higher SNR threshold for this case to make sure that the contamination from noise fluctuation is not significant and hence impact from statistical fluctuation is limited on the error budget of the cosmological and astrophysical population. This helps in understanding more clearly the effect of systematic errors over the statistical uncertainties.

The injection set is prepared for ten cases (denoted by I(j, $\rho_{\rm th}$), where the index j runs from j = 1 to j = 10) for each threshold with the values of the cosmological and astrophysical population parameters are drawn randomly from a uniform distribution over the range by different members of the simulation team (at least by three members). Then a particular simulation from $I(j', \rho_{th})$ is randomly chosen by the coordinator and a simulation team member for which estimation of the GW source parameters is performed using the package Bilby (Ashton et al. 2019). The particular realization (denoted by j') chosen for the PE and the corresponding values of the cosmological and astrophysical parameters chosen are not known to anyone in the Blinded-MDC team until the end of the analysis by the analysis team. As for every different realization, the underlying population parameters and the cosmological parameters are different, a randomly chosen realization makes the injection part blind to everyone, except the coordinator and one member of the simulation team. For the other simulations, Bilby parameter estimations were not performed to reduce the computation cost. However, these sets are available after the unblinding and can be used for any checking purposes.

Blinded-MDC analysis setup: The code icarogw (Mastrogiovanni et al. 2024) is used for the analysis purpose of exploring the interplay between the cosmological parameters and the population parameters. The analysis team used a realization given by the simulation team of the posteriors on the GW source parameters (\mathcal{M} , q, d_L , Dec, RA, i, Ψ , ϕ , and t_c) without any information about the cosmological and astrophysical population parameters used to generate them. Using this set the analysis team performs the joint inference of the cosmological parameters and the population parameters

L	-	-	-	0.75	

for the underlying model considered as the fiducial astrophysical model PLG without redshift evolution and Flat LCDM cosmological model. The analysis team explores the impact of different choices such as the number of samples in the selection function (or in the injection set), the impact of wider priors, and the impact on the inference with a change in the number of detected events. Finally, once the analysis members are satisfied with all the checks, the values of the cosmological and the population parameters used for the simulations get unblinded and are compared with the inferred values.

The Vanilla case allows us to verify the analysis setup on whether the analysis code can infer the values correctly for a known scenario. For the second case i.e. Redshift-Dependent scenario, the Blinded-MDC inspects the impact on the inference of the parameters (both astrophysical and cosmological), when the underlying true astrophysical model differs from the fiducial assumption of the model. In the remainder of the paper, we describe in detail the results from the injection and the analysis parts.

simulation team

3. CASES STUDIED IN THE BLINDED-MDC

As introduced in section 2, the scope of the Blinded-MDC is twofold, in the first place, we want to quantify statistical uncertainties under the assumption that the settings used to generate and analyze data are the same. This is the Vanilla case. It allows us to assess the impact due to detector noise and the fact that our data represent a limited sample. Specifically, we want to study the presence of statistical fluctuations and outliers among data that might bias the overall results. Secondly, our goal is to evaluate systematic errors arising from astrophysical mis-modeling. To do this, we will only assume a redshift dependence in the data generation process, not in the analysis. We address this in the Redshift-Dependent scenario. We provide a detailed explanation of the astrophysical models used to create the events dataset for both scenarios.

In this work, the GW source parameter estimation for the simulated mock events is performed with Bilby (Ashton et al. 2019) using the IMPRhenomPv2 waveform approximant (Husa et al. 2016a,b; Hannam et al. 2014), using the standard Bilby priors for BBHs with all the spin parameters fixed to zero (delta-function prior). An example event analysis is shown in the appendix in Fig. 21. The analysis is done on the following 9 parameters: the chirp mass \mathcal{M} (a combination of the twocomponent masses in detector frame¹), the mass ratio q(defined as the ratio between the lightest and the heavi-

¹ The chirp mass is defined as in terms of component masses (m_1, m_2) :

$$\mathcal{M} \equiv \frac{(m_1 m_2)^{\frac{3}{5}}}{(m_1 + m_2)^{\frac{1}{5}}}$$

est mass component), the luminosity distance d_L to the source, the sky position given by the right ascension RA and declination Dec, the inclination angle ι (defined as the angle between the line of sight and the perpendicular to the orbital plane of the binary), the polarization angle Ψ , the phase ϕ of the GW signal and the time of coalescence t_c . The choice of the non-spinning waveform will not have any noticeable impact on the cosmology results obtained in this paper for this detector noise.

3.1. Vanilla model

We assume black holes to have an astrophysical origin and consequently model the binary merger rate R(z) with a function similar to the one used for fitting the star formation rate (SFR) (Madau & Dickinson 2014a). We use a parametric form for the BBHs merger rate evolution captured by the parameters γ and κ as

$$R(z) = R_0 (1+z)^{\gamma} \frac{1 + (1+z_p)^{-(\gamma+\kappa)}}{1 + (\frac{1+z_p}{1+z_p})^{(\gamma+\kappa)}}, \qquad (1)$$

where R_0 is the merger rate of BBHs at z - 0 and z_p denotes the peak of the merger rate. The simulated events are drawn from the PLG source frame probability distribution, motivated by the analysis of previously detected GWs events (Abbott et al. 2023b; Karathanasis et al. 2023a), which can be analytically expressed by

$$P_1(m_1|m_{\min}, m_{\max}, \alpha) = \begin{cases} (1-\lambda) \mathcal{P}(m_1, -\alpha) + \lambda \ G(m_1, \mu, \sigma), & m_{\min} < m_2 < m_{\max}, \\ 0, & \text{otherwise} \end{cases}$$
(2)

$$P_2(m_2|m_{\min}, m_1, \beta) = \begin{cases} \mathcal{P}(m_2, -\beta), & m_{\min} < m_2 < m_1, \\ 0, & \text{otherwise} \end{cases}$$
(3)

where m_1 and m_2 are source-frame primary and secondary mass respectively. \mathcal{P} and G are normalized power-law function and Gaussian function respectively. For this case 286 GW events are detected with an SNR threshold of $\rho_{\rm th} = 10$ for three years of observation time and duty cycle as given in Tab. 1. The sampled events detector-frame mass distributions are shown in Figs. 2(b)-2(c). The mock event distribution as a function of distance is shown in Fig. 2(a). The population and rate parameters used to obtain the events are given in Tab. 2.

3.2. Redshift-Dependent Scenario

In this scenario, we make the same assumptions as the Vanilla model, but the mass model parameters now include an additional linear dependence on redshift. In this case, we obtained events with an SNR greater than an SNR threshold $\rho_{\rm th} = 12$ with one year of observation time and duty cycle as given in Tab. 1. The total number of events selected is 80 for this case. The primary mass and secondary mass distribution is modeled with all parameters of the mass distributions varying with redshift as

$$P_{1}(m_{1}|m_{\min}, m_{\max}, \alpha, z) = \begin{cases} ((1 - \lambda(z)) \mathcal{P}(m_{1}, -\alpha(z)) + \lambda(z) G(m_{1}, \mu(z), \sigma(z)), & m_{\min}(z) < m_{2} < m_{\max}(z), \\ 0, & \text{otherwise} \end{cases}$$
(4)

$$P_{2}(m_{2}|m_{\min}, m_{1}, \beta, z) = \begin{cases} \mathcal{P}(m_{2}, -\beta(z)), & m_{\min}(z) < m_{2} < m_{1}(z), \\ 0, & \text{otherwise,} \end{cases}$$
(5)

We express the redshift dependence of all parameters as $x(z) = x_0 + z\epsilon_x$, where x_0 represents the parameter value at redshift z = 0 (Karathanasis et al. 2023b). This linear redshift dependence is applied uniformly to all mass distribution parameters. The specific choices for the redshift dependence are outlined in Tab. 2. The motivation for introducing redshift dependence arises from the fact that stellar evolution is significantly influenced by the environment in which stars form. Studies show that in low-metallicity environments, more massive stars are more likely to form compared to high-metallicity environments (Dopcke et al.

Figure 2. Histogram of the number of detected events as a function of a) luminosity distance, b) detector-frame primary mass, c) detector-frame secondary mass, for the Vanilla scenario.

2013; Li et al. 2023). This occurs because low-metallicity gases are less efficient at cooling, leading to a higher Jeans mass and reducing the likelihood of fragmentation into smaller stars (Clarke & Bromm 2003; Dopcke et al. 2013). Additionally, stars with higher metallicity tend to lose more mass through stellar winds com-

Figure 3. Primary mass distribution for the Redshift-Dependent scenario at different redshifts.

Figure 4. Merger rate as a function of redshift for the Redshift-Dependent scenario with the fiducial values mentioned in Tab. 2.

pared to their low-metallicity counterparts, resulting in lighter remnants (Vink et al. 2001; van Loon 2005; Mokiem et al. 2007). Consequently, BHs are expected to be more massive at high redshifts, where metallicity is lower compared to low redshifts. The impact of metallicity evolution on BBHs population from GWTC-3 was previously studied, indicating mild hints towards redshift-dependent mass distribution (Mukherjee 2021; Karathanasis et al. 2023a).

The primary mass distribution for the Redshift-Dependent scenario is illustrated in Fig. 3. The peak (μ_g) of the GAUSSIAN component of the primary mass distribution is located at $40.9 M_{\odot}$ at z = 0, shifting to higher masses at a rate of $2.84 M_{\odot}$ per unit redshift. Similarly, the standard deviation of the GAUSSIAN (σ_g) is 7.63 M_{\odot} at z = 0, increasing linearly with redshift at a rate of $2.7 M_{\odot}$. The power-law index of the primary mass distribution takes a value of 5.3 at z = 0, increasing

Figure 5. Histogram of the number of detected events as a function of a) luminosity distance, b) detector-frame primary mass, c) detector-frame secondary mass, for Redshift-Dependent scenario.

linearly with redshift at a rate of 2.99, while the powerlaw index of the secondary mass distribution decreases at a rate of 1.063 per unit redshift.

For the merger rate, we assume a Madau-Dickinsonlike redshift evolution (Madau & Dickinson 2014b), similar to that in a redshift-independent vanilla scenario (see Eq. (1)). The merger rate for the injected parameters is relatively flat (see Fig. 4), with a maximum value at z = 0 before gradually decreasing with increasing redshift. The maximum redshift of the injection is 1.7. The sources are located at relatively smaller luminosity distances compared to the vanilla scenario, due to the high injected value of H_0 , which is 173.28 kms⁻¹Mpc⁻¹.

In Figs. 5(a), 5(b), and 5(c), we depict the histogram of luminosity distance (d_L) and the component masses $(m_1, \text{ and } m_2)$ respectively of the injected sources. The minimum mass is set to $7.8M_{\odot}$ at z = 0, with only a tiny redshift dependence. Compared to the vanilla scenario, there is a relatively smaller fraction of sources between $10 M_{\odot}$ and $30 M_{\odot}$, which is a consequence of the steeper power law for both the primary and secondary mass distributions. The luminosity distance of the sources in this scenario is more concentrated at lower values compared to the vanilla scenario. This is because the merger rate here is relatively constant with redshift, whereas, in the vanilla scenario, it increases steeply with redshift.

4. METHODS

In what follows, we first give an overview of the spectral sirens method used to infer at the same time cosmological and population parameters given the two starting sets of BBH events: one for the Vanilla case and one for the Redshift-Dependent scenario. We present a reconstruction of both the rate and mass models for two cases, comparing them to the distributions used to sample the two populations. The main results on the inference of H_0 are then presented and discussed in full details².

4.1. Spectral sirens method: icarogw setup

We use the icarogw package (Mastrogiovanni et al. 2024) to infer the population and cosmological parameters simultaneously (a brief description of all the parameters is provided in Tab. 2). Within this package, we use Bilby's (Ashton et al. 2019) sampler dynesty (Speagle 2020) to generate posterior samples for the hyperparameters. The source distributions assumed in the analysis coincide with the ones used during the generation of the GW population only in the Vanilla case. For the Redshift-Dependent scenario, we keep the same assumptions of the Vanilla analysis, even though the underlying population is now Redshift-Dependent.

The combined posteriors on the source population and cosmological hyper-parameters, given N_{obs} GW detections each with data $\{x\} = (x_1, x_2, \ldots, x_{\text{obs}})$, are obtained using the following equation (Mandel et al.

² All the scripts used to produce the results in this paper are available on GitLab repository.

R_0	Local merger rate in $[\text{Gpc}^{-3}\text{yr}^{-1}]$	20	16.1	

(2019); Vitale et al. (2020); Mastrogiovanni et al. (2021)):

$$p(\Lambda|\{x\}, N_{\rm obs}) \propto \pi(\Lambda) \prod_{i=1}^{N_{\rm obs}} \frac{\int p(x_i|\Lambda, \theta) p_{\rm pop}(\theta|\Lambda) d\theta}{\int p_{\rm det}(\theta, \Lambda) p_{\rm pop}(\theta|\Lambda) d\theta},$$
(6)

where $\pi(\Lambda)$ is the prior on the hyper-parameters (both population parameters and cosmological ones, see Tab. 3). Since each GW event is independent, we multiply across the $N_{\rm obs}$ observations. The probability of each GW event can be broken down into two main components: the parameters of the individual source, represented by θ , and the population-induced prior, $p_{\rm pop}$, which describes the expected distribution of the hyperparameters at the population level.

The denominator of the likelihood, $\int p_{det}p_{pop}d\theta$, corrects for the selection bias. The data set that is analyzed has been obtained after applying selection criteria. In this study, we required that the events' match-filtering SNRs ρ are above a fixed threshold ($\rho_{th} = 10$ for the Vanilla case and $\rho_{th} = 12$ for the Redshift-Dependent scenario). This selection must be accounted for, to avoid the Malmquist bias (Malmquist 1922; Loredo 2004; Mandel et al. 2019). The correction method consists of estimating the probability of detection of gravitational wave events, using the very same selection criterium and for any values of hyperparameters Λ , describing the cosmology, the population parameters, and the mergers rate (see Tab. 2). This probability of detection is given by the ratio of the expected number of detected events $N_{\text{exp}}(\Lambda)$ to the total number of mergers $N(\Lambda)$:

$$\frac{N_{\exp}(\Lambda)}{N(\Lambda)} = \int p_{\det}(\theta, \Lambda) p_{\mathrm{pop}}(\theta|\Lambda) \mathrm{d}\theta, \qquad (7)$$

 θ being the set of the individual parameters of the binary system: $\theta = (m_1, m_2, z, \iota, \text{RA}, \text{Dec...})$. We chose to study a population model that only depends on the mass and redshift so that we restrict θ to $\theta = (m_1, m_2, z)$ and we consider the domain where the events are detected, i.e. when $p_{\text{det}} = 1$:

$$\frac{N_{\exp}(\Lambda)}{N(\Lambda)} = \int_{\rho \geqslant \rho_{\rm th}} p_{\rm pop}(m_{1s}, m_{2s}, z | \Lambda) \mathrm{d}m_1 \mathrm{d}m_2 \mathrm{d}z.$$
(8)

The last integral is estimated by Monte-Carlo integration using a large set of $N_{\rm sim}$ realizations $(m_{1,i}, m_{2,i}, z_i)$ corresponding to $N_{\rm det}$ detected $(\rho \ge \rho_{\rm th})$ simulated events. These injected events are randomly drawn from an initial probability density function $\pi(m_1, m_2, z | \Lambda)$ so that the probability of detection is evaluated as:

$$\frac{N_{\text{exp}}(\Lambda)}{N(\Lambda)} = \int_{\rho \geqslant \rho_{\text{th}}} p_{\text{pop}}(m_1, m_2, z|\Lambda) \mathrm{d}m_1 \mathrm{d}m_2 \mathrm{d}z,$$

$$= \frac{1}{N_{\text{sim}}} \sum_{i=1}^{N_{\text{det}}} \frac{p(m_{1,i}, m_{2,i}, z_i|\Lambda)}{\pi(m_{1,i}, m_{2,i}, z_i|\Lambda)}.$$

Table 3. List of priors used in the analysis for both the Vanilla and the Redshift-Dependent scenarios.

4.2. Priors settings

We examine 14 hyperparameters listed in Tab. 2. We assign broad and uninformative priors to each of them. The priors for the hyperparameters in the two scenarios are summarized in Tab. 3. Three parameters prior ranges differ between the two scenarios: H_0 , μ_g , and σ_g . Initially, the prior ranges for both scenarios were the same. After our preliminary results exhibited railing on either side of their prior range, we decided to enlarge the prior settings for the Redshift-Dependent scenario. We refer to this aspect of the study as the impact from astrophysical prior on H_0 inference in the remaining paper. Due to the blinded nature of the MDC (as discussed in Sec. 2), different prior choices are made for the analysis.

5. RESULTS FROM THE BLINDED-MDC

5.1. Vanilla model results

The results of the Vanilla model serve as an overall validation of the setup and demonstrate its consistency with the initial assumptions. We start from the reconstruction of both the rate and mass models, as shown in Figs. 6 and 7. The colored lines represent the posterior samples from the 68% highest density interval, while the solid black lines indicate the starting distribution derived from the injection values in Tab. 2. We find good agreement with the injected rate and mass distributions.

Our estimate for H_0 using all 286 events and the full set of 10⁶ injections is $62.08^{+28.07}_{-21.15}$ km s⁻¹Mpc⁻¹ at 1σ , compared to the injected value of 67.8 km s⁻¹Mpc⁻¹. In most cases, the inferred values of parameters are recov-

Figure 6. Posterior samples plots for the Vanilla scenario following Eq. 1. The black line represents the injected values. The colored lines show the posterior samples from the 68% highest density interval.

Figure 7. Posterior samples plots for the Vanilla scenario for the primary mass distribution following Eq. 2. The black line represents the injected values. The colored lines show the posterior samples from the 68% highest density interval.

ered at the 1σ level, with some exceptions like α , m_{\min} , σ_g , and γ , which are slightly outside the 1σ range but within 2σ , as can be seen from the full corner plot in Fig. 23. Fig. 8 illustrates a reduced corner plot that highlights the distributions of the H_0 posterior samples along with the parameters that demonstrate the strongest correlations with H_0 , specifically μ_g and σ_g , which are negatively correlated with H_0 . This means that higher values of μ_g suggest a more massive BBH population, leading to lower inferred redshifts and a lower H_0 to match observed signals at specific luminosity distances.

Figure 8. Reduced corner plot for the Vanilla scenario of H_0 and parameters that mostly correlate with H_0 , which are μ_g and σ_g . The injected (true) values are plotted as black lines. For the full corner plot refer to Fig. 23.

We then performed the following series of checks to pinpoint potential sources of statistical uncertainties:

• Impact of the injection samples: number and realization: to study the robustness of the population inference scheme, we vary the realization of GW signals, (referred to as injection samples), that are used to compute the denominator of Eq. (6). The denominator is evaluated as a Monte-Carlo sum, hence we expect to have more accurate results for a larger amount of samples. The hyperparameter posterior is obtained for three simulations, with 10^4 , 10^5 , and 10^6 samples. We generally find that the inferred values of all hyperparameters are compatible with their true values at 90% credible region. In Fig. 9, we show H_0 posteriors for the three cases. We also varied the sample of 10^5 injections and obtained comparable results, as shown in Fig. 10. The distribution confirms that the evaluation of the denominator partially depends on the number of injections and not the specific realization of the sample, once we reached a sufficient number of injections for the denominator to converge, which in our case means 10^5 injections. The posteriors for all the parameters are shown in appendix C in Fig. 25 varying the number of injections and in Fig. 26 varying the injections sample.

Figure 9. Check with the Vanilla scenario events. Posterior samples of the H_0 parameter varying the number of injections. The dashed black line is the injected value. See also the full plot with all the parameters in Fig. 9).

- Dependence on the number of events: we study how the inferred cosmological and population parameters depend on the number of GW events used for the analysis. We compare the results using different numbers of GW events, specifically [150, 180, 200, 220, 250, 286], with 10^5 injections (once we assessed 10^5 and 10^6 injections were producing the same outcome, as shown in the previous point). The results shown in Fig. 11 demonstrate that we obtain more accurate constraints on the parameters as more GW events are used. In Fig. 11 we show H_0 posteriors only for clarity (the full parameter set is displayed in appendix C in Fig. 27).
- Dependence on event sample realization: due to the homogeneity principle, the analysis of subsets of the observed gravitational wave catalog is expected to yield parameter values with random deviations (which statistically average out) from the parameter values extracted from the whole catalog. For further validation of the analysis scripts, we test this expectation. We split the observed GW catalog in batches of 50 and analyze the resulting sub-populations with 10⁵ injections used to compute the denominator of Eq. (6). In Fig. 12 we show some example results for the posterior distribution restricted to H_0 . We find that there are no outliers in our sets of events. The posteriors are summarized in appendix C in Fig. 28.

Figure 10. Check with the Vanilla scenario events. Posterior samples of the H_0 parameter varying the realization sample with 10^5 injections. The dashed black line is the injected value. See also the full plot with all the parameters in Fig. 26).

Figure 11. Check with the Vanilla scenario events. Posterior samples for the H_0 parameter using a different number of events for the Vanilla case. The dashed black line is the injected value. See also the full plot with all the parameters in Fig. 27).

In summary, the Blinded-MDC analysis for the Vanilla scenario shows that when the underlying true model of the astrophysical population is the same as the model used in the analysis, the inference of parameters is not biased. However, due to the degeneracy between the cosmological parameters and the astrophysical population parameters, the inferred value of H_0 can shift away from

Figure 12. Check with the Vanilla scenario events. Posterior samples of the H_0 parameter varying the events sample. The dashed black line is the injected value. See also the full plot with all the parameters in Fig. 28).

the true value. We also show the impact of prior on the astrophysical parameters in inferring H_0 in the repository. The plot in Fig. 29 indicates that wider prior on the parameters related to black hole mass distribution moves the H_0 posterior to a lower value. The Vanilla model analysis served as a validation tool to assess the robustness of the inference pipeline against statistical and sampling uncertainties under the scenarios analyzed above: injection sample size and realization, number of events, and event sample realization).

5.2. Redshift-Dependent Scenario Results

The goal of analyzing the Redshift-Dependent scenario is to understand the impact of the redshift evolution of the mass distribution on the inference of the Hubble constant due to mis-modeling the astrophysical population model of BBHs by assuming a redshiftindependent scenario. So, we use the redshift independent PLG model, which is currently a setup for the population inference, for the analysis of this mock simulations. However, it is important to stress here, that though the analysis is performed for a specific mass model, the impact on the inference of H_0 can happen for any other astrophysical population model as well, if there is a mismatch with the simulation.

We perform a joint parameter estimation for the astrophysical population and cosmological parameters using *icarogw* on 80 detected events in the mock data. Our main result for the Redshift-Dependent scenario is the one obtained with all 80 events and the full set of 10^6 injections. The corresponding full corner plot

Figure 13. Reduced corner plot for the Redshift-Dependent scenario of H_0 and parameters that mostly correlate with H_0 , which are μ_g and σ_g . The injected (true) values are plotted as black lines. For the full corner plot refer to Fig. 24. See also Fig. 14 and Fig. 15 for a redshift evolution of μ_g and σ_g .

Figure 14. Posterior samples for μ_g for the Redshift-Dependent scenario are plotted in *black*. The dotted vertical line represents the median of the distribution. The colored region represents the values of the injected μ_g , 40.9 + 2.84z, at different redshifts specified in the color bar.

with the parameters posteriors is shown in the appendix Fig. 24. The main result we find is that the injected value of Hubble constant is outside ~ 90% C. I. of the inferred posterior distribution. A few other parameters related to the mass distribution of the GW sources such as $\alpha, \beta, m_{\min}, \mu_g, \sigma_g, \lambda_{\text{peak}}$ shows about 1- σ discrepancy from the injected value.

Figure 15. Posterior samples for σ_g for the Redshift-Dependent scenario are plotted in *black*. The dotted vertical line represents the median of the distribution. The colored region represents the values of the injected σ_g , 7.63 + 2.70z, at different redshifts specified in the color bar.

To explore the impact of redshift evolution of the mass distribution on the value of H_0 , we show the joint contour of H_0, μ_g , and σ_g in Fig. 13, and the comparison between the injected value of μ_a and σ_a with the recovered posterior from all the events in Figs. 14 and 15 respectively. These plots indicate that posterior on the parameters $\mu_{g,z}$ and σ_z agrees with the injected values at different redshifts (shown by color-bar) within about 68% C. I. of the inferred posterior distribution. Furthermore, the samples within 68% on the mass distribution for different redshift bins of the injected value are shown in Fig. 16 along with the injected distribution. We divided the population into three sets, redshift-wise (we chose $z < 0.65, 0.65 \le z < 1.05$, and $z \ge 1.05$ to ensure a similar number of events in each bin). We then compare the reconstructed posteriors with three reference models, evaluated at parameter values in the center of each redshift bin following Tab. 2. In all cases, we used posterior samples within the 68% highest density interval. These show a good agreement with the injected values in the simulation.

Among the parameters that control the merger rate such as R_0, γ , and κ , the recovered values match well the injected value, as the underlying model is the same and there is no negative impact on the inference of the Hubble constant. The parameter z_p which denotes the peak of the BBH merger rate distribution does not show a good recovery due to the fewer number of detected events at the injected value of high redshift ($z_p = 3.86$), as shown in the full corner plot in Fig. 24 (given in the appendix). The merger rate realizations from the samples of the posteriors with the 68% C.I. are shown in Fig. 17.

Figure 16. Posterior samples plots for the Redshift-Dependent scenario for the primary mass distribution following Eq. 4. In each plot, The colored lines show the posterior samples from the 68% highest density interval. These samples have been categorized based on the redshift range of the events used for the analysis. The redshift range is shown on the left y-axis: the top panel represents events with z < 0.65, the central panel shows events with $0.65 \leq z < 1.05$, and the bottom panel corresponds to events with z > 1.05. In each subplot, there are three darker lines (solid, dashed, and dotted) that remain consistent and represent the model at different redshift values, as defined in Tab. 2. These redshift values have been selected to fall in the middle of the redshift ranges we divided the events into. The highest-redshift event is at z = 1.7.

The impact of a partial number of samples to show the distribution on the inferred parameter H_0 is shown in Fig. 18 for different numbers of events varying from 35 to 80. The distribution shows nearly consistent behavior between all the sub-samples having different number

Figure 17. Same as in Fig. 6 but for the Redshift-Dependent scenario.

of events. This indicates that the statistical uncertainty due to a fewer number of events is not causing any pronounced difference in the observed discrepancy in the H_0 posterior from the injected value shown by the black dashed line. For all the cases, the peak of the inferred H_0 posterior is at least 76 percentile away (towards a lower side) from the injected value.

We also performed statistical tests on the impact of the injection samples and dependence on event sample realization. For the former, we used 10^5 and 10^6 injection sets samples, and for the latter, we split the GW events into batches of 25 to analyze the resulting sub-populations. (For all statistical tests the results obtained are similar to the cases obtained for the vanilla case³.) The impact of prior on the astrophysical parameters in inferring H_0 is also shown in the repository. The conclusion is similar to the Vanilla case, that the change in the prior mass distribution has a noticeable impact on H_0 posterior.

5.2.1. Discussion

In this section, we discuss our findings from the **Blinded-MDC** for the Redshift-Dependent scenario. As stated at the beginning of the motivation section, the reason for exploring a redshift-dependent mass model is to understand its impact on the inference of cosmology, due to ignorance of such evolution in reality due to complicated BBH formation channels and its dependence on parent star metallicity. As a result, we consider a mock simulation with redshift evolution in the mass and merger rate, where the merger rate evolution model agrees with the analysis model, but the mass distribu-

³ The plots for these tests are shown in the repository.

Figure 18. Check with the Redshift-Dependent scenario events. Posterior samples for the H_0 parameter using a different number of events. The dashed black line is the injected value.

tion in the mock data differs from the one used in the analysis. The corresponding results obtained from the Blinded-MDC are presented in the previous section.

The key result we are interested in exploring is to understand what is the impact of the mis-modeling on the inference of the Hubble constant. We find that the value of the Hubble constant is about 1.5 σ discrepant from the injected value. To understand the origin of this discrepancy better, we scrutinize the results with events in three groups, divided based on their source redshift (which are known from the simulation set) as group-1 $(z \in \{0, 0.65\})$, group-2 $(z \in \{0.65, 1.05\})$, and group-3 (z > 1.05) with a nearly equal number of sources in each group. The analysis in groups is performed by implementing the product over samples in Eq. (6) in these three groups. The selection function of the analysis does not change for this sub-divided run, except for a reduction in T_{obs} by one-third for each group. This can be seen from Eq. (6) that the term in the denominator, which captures the selection function, does not depend on the index (denoting individual events) over which the product in the numerator is carried out. The corresponding results on H_0 (after marginalizing over other parameters) are shown in Fig. 19. For the results from group 1, the value of H_0 matches very well with the injected value of the Hubble constant as shown by the solid black line. This is also valid for the other parameters μ_q and σ_q which are strongly correlated with H_0 . However, as we move towards higher redshift bins, i.e. group-2 and group-3, the posterior on H_0 moves towards a lower value, and the posteriors on μ_g and σ_g moves towards a higher value.

This is arising because the sources contributing from the lowest redshift bin (in group-1) have the least impact on the redshift evolution of the mass distribution for the injection model discussed in Sec. 3.2. As a result, when one is making an inference using a model with no redshift evolution, the error due to mis-modeling is minimal. On the other hand, for sources in group-2 and group-3, the redshift evolution of the μ_a and σ_a parameter moves the values by about 10% and 50% respectively towards a higher value in comparison to the lowest redshift bin case, resulting into larger mis-modeling. As a result, the inferred value of the Hubble constant H_0 is shifted towards a lower value from the injected one, as shown in Fig. 19. The shift towards a lower value arises due to a strong negative correlation with the mass parameters (μ_q, σ_q) and H_0 . As the values at a higher redshift have intrinsically higher mass distribution, an analysis model that does not capture this effect associates this to a higher value of μ_q and σ_q , resulting in a lower value of inferred redshift than the true one⁴. As a result, the corresponding inferred H_0 is lower than the true value of the H_0 used in the simulation. This effect gets pronounced from group-2 to group-3 samples, as the change due to redshift in μ_g and σ_g are large.

The comparison of the marginalized posterior with respect to the injected value does not show any strong deviation for μ_g and σ_g as shown in Fig. 20 due to large uncertainties. However, the value of H_0 starts showing deviation at 91 percentile from the injected value due to the reasons mentioned above. This implies that even though the lowest distance bin value of H_0 does not show any discrepancy, a mild 10% variation in μ_g can lead to more than 1.5σ deviation from the injected value due to the sources at higher distance. Though due to the blinded nature of the **Blinded-MDC**, in this analysis the value of the injected Hubble constant H_0 is large, the key finding showing the impact of redshift evolution of mass distribution will cause a discrepancy in the inferred value of H_0 remains valid.

A redshift evolution of the black hole mass distribution and also the merger rate is an expected outcome from an astrophysical perspective due to the dependencies of these on progenitor metallicity and SFR. The metallicity of the Universe varies by a few orders of magnitude with redshift, with a decreasing trend at high redshift. Furthermore, from galaxy to galaxy, there is

⁴ As the observed masses m_z are redshifted, $m_z = m(1+z)$. An incorrect inference of true source frame mass will lead to an incorrect inference of redshift z by m_z/m .

Figure 19. Reduced corner plot for H_0 , μ_g and σ_g parameters for the Redshift-Dependent scenario. We show results obtained selecting events in three different redshift ranges: at low redshift z < 0.65, medium $0.65 \le z < 1.05$, and at redshifts higher than $z \ge 1.05$. The maximum redshift does not exceed z = 1.7. The injected values are shown in *black*. For μ_g and σ_g they refer to the injected value at z = 0 as in Tab. 2.

a large variation in the metallicity. As a result, along

with a monotonic redshift evolution, there is going to be additional stochastic behavior in the masses of BHs at a redshift. This can lead to a dispersive mass distribution from any monotonic behavior in redshift. In this Blinded-MDC, we have considered a simplistic scenario of linear evolution with redshift of the parameters controlling the mass distribution (as discussed in Sec. 3.2). However, in reality, the mass distribution evolution can be even more severe. Future analysis will be conducted to understand this impact for a larger number of GW samples and better sensitivity for several astrophysical scenarios.

6. CONCLUSION

This work presents the first Blinded-MDC for the inference of the cosmological parameters from GW observations feasible using BBHs from the currently ongoing network of LVK detectors with O4 sensitivity (Aasi et al. 2015; Acernese et al. 2015; Abbott et al. 2018). This study aims to explore the reliability of standard siren cosmology in inferring the true values of the cosmological parameters when the dark siren technique using a BBH mass distribution is used assuming an underlying model. Through this Blinded-MDC we explore both statistical and systematic uncertainty due to the interplay between astrophysical model assumptions on the BBH mass distribution and the inference of Hubble constant H_0 from the GW data.

Table 4. Summary of the systematic and statistical tests performed in the analysis. The impact of systematic and statistical uncertainties on different objectives are shown in color ranging from green (not impacted) to red (impacted) and the shade of the color denotes the strength of its influence, darker shade implies strong influence and lighter shade implies mild influence.

Type of Tests	Objective	Vanilla Case	Redshift Dependent Case
Systematic Uncertainties	Inference of H_0	not impacted	impacted
	Impact of population prior on H_0	impacted	impacted
	Inference of BBH mass distribution	not impacted	not impacted
	Inference of BBH Merger rate	not impacted	mildly impacted
Statistical	Impact of number of samples in p_{det}	impacted	impacted
Uncertainties	Impact of sub-sample of events	mildly impacted	mildly impacted

To explore this aspect, we considered two astrophysical scenarios namely, (i) the Vanilla model, which represents the currently known model of BBH mass distribution, and (ii) a Redshift-Dependent scenario which considers a mass distribution model with redshift evolution, which differs from the fiducial assumption. For both cases, GW mock samples are generated from the code GWSIM (Karathanasis et al. 2023b) by two indepen-

Figure 20. Summary plot of results for both the Vanilla (*lighter shade*) and the Redshift-Dependent (*darker shade*) models. The runs used all the available events (286 for the Vanilla case and 80 for the Redshift-Dependent one) with 10^6 injections for selection effects. The x-axis represents the inferred hyperparameters, while the y-axis shows all the posterior samples divided by the median value of each distribution for easier comparison on a single plot. The boxplots are designed to encompass 1σ of the data around the median in the darker shade and up to 2σ with the lighter shade. The whiskers extend from the minimum to the maximum value to represent all the data. The black triangles represent the injected values divided by the corresponding median of the distribution. The text represents the median value of the parameter and the 68% confidence interval around it. For the Redshift-Dependent model, the values shown in Tab. 2 (considering z = 0) are being referred to.

dent simulation teams which are disjoint from the analysis team members. The key findings from this analysis are listed below and are also summarized in Tab. 4:

Ò

Ş

MIII

- 1. For a given astrophysical model consistent with the Vanilla scenario, the cosmology inference code can infer the injected value for all the parameters correctly in a blinded setup using the mass distribution (See Fig. 8).
- 2. The impact of fewer samples in the injection set for the calculation of the detection probability mildly overestimates (underestimates) the posterior on the Hubble Constant H_0 at the lower (higher) values in comparison to a case with more samples (See Fig. 9).
- 3. If the mass distribution of the BBHs shows mild redshift evolution (as shown in Fig. 3) which is theoretically unknown (or unknown from independent observations) due to the evolution of stellar properties with redshift, then the inferred value of the Hubble constant shows discrepancy from the injected value at more than 1σ for O4 noise sensitivity (See Fig. 13).
- 4. For the case of redshift evolving mass distribution, the observed statistical fluctuation in the inferred

value of the parameters (in particular the value of H_0) is not significant in comparison to the systematic error due to mass mis-modelling (See Fig. 18).

2

5

Ro

1R

- 5. The inferred parameters describing the astrophysical mass distribution do not show any significant departure from the injected parameters of the mass distribution when the underlying true model is unknown. As a result, even if the mass distribution evolves mildly (considered in this analysis), the values of μ_g and σ_g agree well with the inferred posterior distribution (See Figs. 14 and 15).
- 6. The last point implies that in an analysis performed in different redshift bins of the GW sources, the mass distribution in individual redshift bins does not show any significant deviation from the injected value due to large error bars. However, the combined posterior on the Hubble constant leads to a noticeable discrepancy from the true value (See Fig. 19).

This study indicates that the analysis method and setup of the code work well when the model used in the mock data generation is the same as the one used in the analysis. But if there are departures in the mass

-2

H0

Juno

model that are redshift dependent, then even though the impact on the inference of the astrophysical population model is not pronounced, it becomes more pronounced on the inference of H_0 . This arises because the value of H_0 gets constrained by all the sources located at different redshift ranges. If there is a monotonic evolution (increase or decrease) in the mass distribution of the BBHs, then the inferred redshift starts to differ from the true value of the redshift in a monotonic way. As a result, the corresponding value of the Hubble constant H_0 will monotonically decrease or increase. In reality, inferred mass distribution with a wrong model may still give a reasonable astrophysical understanding of the mass distribution, but a value of H_0 towards a lower (or higher) value from the true value, depending on whether the mass distribution is increasing (or decreasing) with redshift. The findings from the Blinded-MDC obtained here have a crucial impact on the robustness of standard siren

cosmology when the astrophysical assumptions on mass

distribution are made. As expected, the discrepancy

gets pronounced with a higher number of GW events. In the future, it will be crucial to understand the interplay between the astrophysical assumptions and cosmological parameters with better sensitivity and a higher number of events. It will be important to investigate the robustness in inferring cosmological parameters for different astrophysical scenarios of BBH formation, depending on their delay time distribution, and stellar metallicity. Along with these, understanding the robustness of other dark sirens techniques related to galaxy incompleteness and the assumptions on host galaxy luminosity for the statistical host techniques will be necessary (Perna et al. 2024; Hanselman et al. 2024). Similarly, for the cross-correlation technique, understanding the impact on H_0 inference due to the redshift dependence of the GW bias parameter (Diaz & Mukherjee 2022; Dehghani et al. 2024). In summary, this study performs the first Blinded-MDC and provides a framework to check the reliability of cosmological inferences from the standard sirens cosmology for the scenarios of dark sirens, which can be extended for other techniques as well. To make a robust measurement of H_0 from standard sirens which can shed light on the ongoing H_0 - TENSION (Verde et al. 2019; Abdalla et al. 2022), Blinded-MDC of the analysis techniques will be crucial to explore possible sources of modeled and un-modeled systematic uncertainties. We will explore different such scenarios in future Blinded-MDC analyses.

APPENDIX

A. Bilby RUNS FOR EVENTS PE

We used 286 events and 80 binary black hole events for the Vanilla and the Redshift-Dependent scenarios, respectively. The population models used to generate the events are described in Sec. 3. We employed Bilby (Ashton et al. 2019) to obtain the parameter estimation for all of these events. The two models' events analysis settings are common and are described in the following.

As stated in the main text, the analysis was done for the \mathcal{M} , q, d_L , Dec, RA, i, Ψ, ϕ , and t_c parameters (see a brief description in Sec. 3). The remaining spin parameters (6 in total) were fixed to zero with a δ -prior. We used the dynesty sampler and the IMRPhenomPv2 waveform approximant. The detectors settings are outlined in Tab. 1. For the Vanilla scenario, we considered 3 years of observations corresponding to a combination of the first four observing runs. Instead, we limited our analysis to the fourth observing run corresponding to 1 year of observing time for the redshift-dependent case.

In Fig. 21 and Fig. 22, we show the parameter estimation results for the Vanilla and the Redshift-Dependent scenarios, respectively. The posterior samples for the 9 parameters considered in the analysis are shown in *orange*, and the true (injected) values are indicated with a *black* line. We chose one event per scenario as a reference example.

B. FULL HYPER-PARAMETERS POSTERIORS

In this appendix, we report the full corner plots of the hyper-parameters in both the Vanilla and the Redshift-Dependent scenarios, shown in Fig. 23 and in Fig. 24, respectively. For both scenarios, we used all the selected events (286 for the Vanilla case and 80 events for the Redshift-Dependent), and use 10^6 injections for the selection effects computation.

C. ADDITIONAL ANALYSES OF THE VANILLA MODEL

We report the full plots for the statistical tests done for the Vanilla case. We refer to Sec. 5 for the detailed description of the tests. In summary:

- In Fig. 25, we show that changing the number of injections to evaluate selection effects between 10⁴, 10⁵ and 10⁶ gives different results for all the hyper-parameters.
- In Fig. 26, we show that changing the realization of the injection sample while keeping the number of injections fixed at 10⁵ does not have any effect on the results.
- In Fig. 27, we show the impact of choosing a different number of events in the analysis. Apart from H_0 and $\Omega_{m,0}$, which are slightly affected, all the other hyper-parameters do not show major discrepancies if the number of events is larger than 180. We notice that with 150 events only we have some deviations from the general trend.
- In Fig. 28, we show that changing the set of events with a total number fixed to 50, does not result in major discrepacies. This confirms that we do not have any particular outlier in our dataset.
- In Fig. 29 with show a companion plot to Fig. 8, where we did the analysis using a larger prior on both the H_0 and the σ_g parameters to see if this would have reduced the railing of H_0 on the left and the one of σ_g on the right. We see that we are getting less support for σ_g at higher values, but still the strong correlation with H_0 allows for low values for the Hubble constant.

Figure 21. Posterior samples from the Bilby run for one event from the Vanilla case. The injected values are indicated in *black*.

Figure 22. Posterior samples from the Bilby run for one event from the Redshift-Dependent scenario. The injected values are indicated in *black*.

Figure 23. Posterior samples for the Vanilla scenario, obtained by analysing all the 286 events using 10^6 injections to estimate the detection probability p_{det} .

Figure 24. Posterior samples for the Redshift-Dependent scenario, obtained by analysing all the 80 events using 10^5 injections to estimate the detection probability p_{det} .

Figure 25. Vanilla case test on the dependence on the number of injections.

Figure 26. Vanilla case test on the dependence on the sample of injections, which number is fixed to 10^5 .

Figure 27. Vanilla case test on the dependence on the number of events.
