The dominance of short-range spin Ising coupling in α-RuCl₃ within a temperature range from 120 K to 7 K establishes it as a highly promising candidate Here, employing for the Kitaev spin liquid. scanning tunneling microscopy/spectroscopy measurements, we present our observations on the temperature-dependent dI/dV spectra of monolayer α -RuCl₃ directly grown on graphite. We observe a pronounced softening of the Mott gap upon warming the temperature from liquid nitrogen temperature to approximately 120 K, characterized by the shift of charge states in the edges of Hubbard bands toward the Mott gap. This transition temperature corresponds to the crossover from the Kitaev paramagnetic Mott insulator to the conventional paramagnetic Mott insulator of α -RuCl₃. The same transition can also be seen in bulk form of α -RuCl₃. Our findings suggest that the recombination of spinons and chargons during the disappearance of Kitaev spin coupling has significantly impacted the charge

dynamics in the Mott insulator, even without altering the ratio between Coulomb repulsion and bandwidth. The results imply that α-RuCl₃ could serve as an ideal platform for investigating the Mott physics across various spin states, encompassing antiferromagnetic-, spin-frustrated- and paramagnetic-phases.

I. INTRODUCTION

The Mott insulators and their insulator-to-metal transitions (MIT) are intricate phenomena that arise in strongly correlated electronic systems, constituting one of the most active research topics in condensed matter physics [1-3]. In Mott's original proposal [4], the insulating state emerges as a consequence of the strong on-site Coulomb interaction among electrons, highlighting the localization of charge sector, which is referred to as a Mott-type insulator. However, subsequent theorists such as Slater argued that the charge gap could also be opened due to magnetic ordering and treated the Coulomb interactions perturbatively [5]. In certain Mott insulators, the situation, as a matter of fact, can become increasingly complex beyond both Mott and Slater's proposals. One typical case is the potential separation of the charge and spin sectors into fractionalized spinon and chargon [6], which displays distinct dispersion characteristics while maintaining an intrinsic connection to a single electron. The charge-spin separation in Mott insulators holds great promise for the emergence of novel physics, for instance the quantum spin liquid (QSL) states [7–11]. On the other hand, the intrinsic coupling between charge and spin can also give rise to a variety of phenomena [12–14], fascinating quantum including topological superconductivity [15–18] and the unconventional Mott transitions with quantum critical points [19–24].

Recently, the SOC assisted layered Mott insulator α-RuCl₃ has garnered significant attention due to its manifestation of Kitaev physics [25-29]. Magnetism studies have revealed that α-RuCl₃ exhibits strong quantum spin frustration and is in close proximity to Kitaev QSL phase between 7 and 120 K, characterized by itinerant Majorana spinon and flux excitations [30–32]. Various spectral techniques have observed the low-energy continuum [31–37], providing evidence for the presence of the Majorana fermions in α-RuCl₃. Moreover, thermal transport measurements under external magnetic fields have detected half-quantization of the thermal Hall conductance, suggesting the existence of chiral Majorana edge modes [38–46]. During these investigations, an interlayer structural phase transition was also discovered at a temperature comparable to the magnetic transition from paramagnet to Kitaev quantum paramagnet at approximate 120-150 K [25,47-49], which significantly impacts measurements of fractional excitations. The aforementioned observations underscore the significance of α-RuCl₃ as an optimal platform for investigating fractionalized spin excitations, while simultaneously serving as a distinctive compound for exploring the spin-charge separation physics in Mott insulating phase. Additionally, α -RuCl₃ is an insulating 4d transition-metal halide with honeycomb layers composed of nearly ideal edge-sharing RuCl₆ octahedra and can be exfoliated into a two-dimensional monolayer [29], enabling studies on its Mott physics in the 2D limit.

II. SYNTHESIZATION OF MONOLAYER α-RuCl3

In this study, we successfully deposited monolayer α -RuCl₃ directly onto a pristine graphite surface. Temperature-dependent dI/dV measurements revealed a peculiar softening of the charge gap within the tunneling spectrum in the crossover between Kitaev quantum paramagnet and conventional paramagnet in α-RuCl₃ at approximately 120 K. A similar spectral transition can be observed in bulk α-RuCl₃ at a comparable temperature. The weakening of charge localization within the Mott-Hubbard bands in conventional paramagnets can effectively explain the observed decrease in resistivity in prior transport experiments. Our findings suggest that the Kitaev spin frustration and the emergent Majorana spinon as well as the flux excitations have played a crucial role in maintaining the well-defined full Mott gap. Upon the fading of Kiteav interaction, the chargons and spinons again recombines into the electrons, leading to the observed softening of Mott gap, despite the unchanged Coulomb interaction and bandwidth. The theoretical framework of continuous Mott transition [21,21,22] provides a reasonable explanation for the experimental findings in the current study, where the processes of charge-spin separation and recombination alter the effective mass of the charge carriers within the Mott-Hubbard bands.

A monolayer of α -RuCl₃ was synthesized on a cleaved highly oriented pyrolytic graphite (HOPG) substrate through evaporation of purified anhydrous α -RuCl₃ powder at 350 °C in a K-cell under a base chamber vacuum of 6E-10 Torr. The substrate temperature was kept constant at 220 °C during growth, followed by annealing at the same temperature for 45 minutes. Subsequently, the sample was transferred to an STM chamber and cooled down to the liquid nitrogen temperature (77 K) for STM/STS measurements. The dI/dV spectra were collected using the lock-in techniques with a frequency of 707 Hz and an amplitude modulation of 5-10 mV. The temperature dependent dI/dV spectra were collected during the warming process of the system, ensuring fine control over stability at the measuring temperatures. The broad-view STM image in Fig. 1a reveals the presence of an α -RuCl₃ thin film on the graphite surface, characterized by a number of trapezoidal interspaces. This thin film consists of multiple domains with different lattice orientations, as indicated by the colored dashed lines along the edges of trapezoidal interspaces, suggesting that the obtained α -RuCl₃ film is poly-crystalline. The effectively suppression of β -RuCl₃ in the thin film benefited from the pre-purification applied to the commercially available α -RuCl₃ powder. The height profile along the dashed white line in Fig. 1b indicates that the thickness of this monolayer thin film is approximately 800 pm, significantly thicker than that of transferred monolayer α -RuCl₃ on graphite in our previous works [50]. We hypothesize that there exists a disparity in interlayer coupling strength between the transferred and growth monolayers due to unknown reasons. An enlarged STM image in Fig. 1d exhibits several vacancy defects on the surface; however, despite observing anisotropic textures around these defects and along the lattice both in STM and FFT images, we have observed the well-preserved hexagonal symmetry within the lattice as demonstrated by the FFT image in Fig. 1d. The anisotropic textures can be induced by the hetero-interfacial coupling. Further magnification (Fig. 1e) enables the clear visualization of a honeycomb lattice formed by Ru atoms, indicating that the grown

monolayer α -RuCl₃ possesses the comparable crystallographic property to those in cleaved samples. Additionally, it can be observed that the edges of each trapezoidal interspace marked in Fig. 2b align with the armchair directions within this honeycomb lattice.

Fig. 1. Monolayer α -RuCl₃ grown on graphite surface. (a) Large scale STM morphology of the growth of α -RuCl₃ on graphite substrate ($V_{\text{bias}} = 1.5 \text{ V}$, $I_{\text{set}} = 200 \text{ pA}$). The colored dashed lines along the edges of trapezoidal interspaces indicate the lattice orientations of different crystal domains; (b) An enlarged STM image of the α -RuCl₃ domain on graphite ($V_{\text{bias}} = 1.5 \text{ V}$, $I_{\text{set}} = 200 \text{ pA}$); (c) Height profile along the white dashed line in (b) illustrates the thickness of the α -RuCl₃ film; (d) Enlarged STM image of the square area in (b) ($V_{\text{bias}} = 1.5 \text{ V}$, $I_{\text{set}} = 100 \text{ pA}$); inset shows a FFT of the image; (e) STM atomic-resolved morphology of the α -RuCl₃ ($V_{\text{bias}} = 1.5 \text{ V}$, $I_{\text{set}} = 100 \text{ pA}$). The lattice constructions are presented with the indication of armchair edge.

In a recent study, the imaging of quantum interference around defects is observed

in the monolayer α -RuCl₃ grown on graphite by pulse laser depositing system (PLD), which is believed to be associated with the perturbation of the Majorana spinon fermi surface (FS) [51]. This quantum interference bears resemblance to our previously reported incommensurate charge order in transferred samples [52]. However, in the current work, we did not observe the similar patterns of quantum interference in the STM images with a positive sample bias at the elevated temperature, as depicted in Fig. 1. In Fig. 2, we conducted measurements at various sample biases within a fixed region. It is evident that the STM morphology exhibits an atomically flat surface under positive sample bias (1.6 eV), akin to those shown in Fig. 1. Nevertheless, when transitioning to a negative sample bias, the surface becomes increasingly unstable and exhibits more pronounced instability as the bias further shifts towards the negative side. The bias dependent surface instability is also consistent with the findings reported in previous publications [53,54]. However, this instability does not follow a regular supermodulation pattern. We propose that this phenomenon is attributed to the presence of inhomogeneous interfacial dipoles, as discussed in our previous works on transferred samples [55].

Fig. 2. Fluctuation of bias-dependent STM morphologies. (a-d) Bias-dependent STM images of the ML α -RuCl₃ film on graphite with setting sample bias of $V_{\text{bias}} = 1.6$ V, - 0.8 V, -1.0 V and -1.6 V, respectively, $I_{\text{set}} = 1$ nA.

III. TEMPERATURE-DEPENDENT dI/dV SPECTRA ON α-RuCl3

The averaged dl/dV spectrum of the monolayer α -RuCl₃ is presented in Fig. 3a, closely resembling those observed on grown monolayer α -RuCl₃ in the previous studies [51,53], which exhibits a well-defined (full) charge gap of approximately 0.6 eV. Based on our acknowledge gathered from transferred samples [52], we believe that the above spectra reveal the charge transfer insulating (CTI) nature of α -RuCl₃ when it is in close proximity to the underneath graphite. In Fig. 3b, we compare the averaged spectra obtained at two distinct temperatures: 77 K and 127 K, respectively. The spectrum obtained at 127 K clearly demonstrates a significantly reduced charge gap in comparison to that acquired at 77 K, as evidenced by the shifting of band edges towards the Fermi level and the emergence of finite low-energy states within the charge gap

regime. It needs to be emphasized that the dI/dV spectra at 127 K still display a residual full charge gap at the Fermi level, thereby demonstrating its maintaining of Mott (CTI) insulating nature and precluding MIT.

To gain further insight into temperature-dependent behavior, we collected dI/dVspectra across a range of temperature spanning from Kitaev quantum paramagnet to conventional paramagnet (without Kitaev spin coupling) around $T_c=120$ K. The results clearly demonstrate that the emergence of in-gap states indeed occurs at the expected temperature (around 120 K), as shown in the normalized spectral curves in Fig. 3c. We observed that, despite the emergence of in-gap states, there is minimal alteration in the position of the peaked states adjacent to the gap, *i.e.* the upper Hubbard band (UHB) and the lower charge transfer band (CTB). Such behaviors can be seen more clearly in the logarithm plots of the lines in Fig. 3d. The amplified image of the UHB above the charge gap (shadow region in Fig. 3c) is illustrated in Fig. 3e, revealing a significant shift of the spectral weight towards the gap with increasing the temperature, while exhibiting minimal change on the opposite side. A similar phenomenon is observed for the band edge of the CTB. Therefore, the reduction of the charge gap can be characterized as the release of charge states in the band edges into the gap, leading to the softening of the entire charge gap. The Mott-Hubbard mechanism is insufficient to explain such a softening of charge gap with the temperature passing the critical region, as the pure Mott gap should persist at significantly higher temperature due to the large Coulomb repulsion [4,56]. Nevertheless, the observations imply a strong correlation between charge and spin sectors in the magnetic crossover between correlated Kitaev

quantum paramagnet and conventional paramagnet.

Fig. 3. Temperature-dependent dI/dV spectra on ML- α -RuCl₃. (a) Averaged STS spectrum taken on ML α -RuCl₃ thin films at 89 K with $V_{\text{bias}} = 680$ mV, $I_{\text{set}} = 1$ nA; (b) Comparison of the averaged dI/dV spectra taken at two different temperatures: 77 K and 127 K; (c) A series of normalized dI/dV spectra taken on ML α -RuCl₃ during warming of the sample displays the evolution of the charge gap as a function of temperature; (d) The logarithm plot of the averaged dI/dV curves in (c); (e) Zoomed-in the spectra of the shadow regime in (c) show the evolution of the peaked DOS as variation of temperature.

IV. DISCUSSION

We have plotted the relationship of the charge gap as a function of temperature in Fig. 4b, which clearly demonstrates that the sharp transition from a large, fully open charge gap to a softened one primarily occurs within a temperature range centered at around 120 K, coinciding with the magnetic crossover. These findings unequivocally

illustrate that at low temperature (<120 K), the electrons are well localized within the formation of a full charge gap; whereas, at temperature above 120 K, while maintaining the original Mott-Hubbard framework (the fixed position of HBs), the movements of band edges toward the low energy states facilitates the presence of finite itinerant electrons within a narrow residual charge gap. The preservation and enhancement of interaction monolayer α-RuCl₃ the Kitaev in have been previously demonstrated [57,58]. Thus, the results depicted in Fig. 3a further emphasize the crucial role of Kitaev spin coupling in maintaining the full charge gap observed in monolayer α-RuCl₃.

To confirm our hypothesis, we need to verify that the observations on grown monolayer α -RuCl₃ are intrinsic natures of α -RuCl₃ rather than its uniqueness in grown monolayer α -RuCl₃ on graphite with hetero-hybridization. We conducted identical measurements on a thicker transferred α -RuCl₃ flake, as depicted in Fig. 4c. Our findings demonstrate that there is comparable full charge gap in *dl/dV* spectra taken at 4.2 K and 77 K, spanning the transition from antiferromagnetic state to the Kitaev paramagnetic state. It indicates that the suppression of long-range antiferromagnetic order does not ultimately impact the electronic structure. For the monolayer case, we also compared the spectra obtained at 77 K in this study to the data acquired at 4.2 K that below the Curie temperature in reference [51]. This comparison reveals a remarkable similarity, providing strong evidence that the long-range magnetic order indeed has negligible effect on the charge gap. Two possible mechanisms can explain the independence of the Mott gap on the long-range spin order at low temperatures: one

is that the long-range order exerts an equivalent influence to the short-range Kitaev coupling; the second is that despite the emergence of long-rang spin order, the Kitaev coupling continues to dominate the influence on the charge gap.

Subsequently, in bulk α -RuCl₃, Fig. 4c illustrates that significant in-gap states start to emerge within the Mott gap at temperatures above 130 K, when the short-range Kitaev spin coupling becomes negligible (as depicted in Fig. 4a). The apparent disappearance of Kitaev spin coupling seems to have exacerbated the softening of the charge gap in the bulk form, leading to completely gapless at temperatures exceeding 170 K, surpassing the effect observed in monolayers. We hypothesize that the interlayer hopping of weakly localized in-gap states is responsible for the further softening of the Mott gap. These findings provide an explanation for the significant disparity in dI/dV spectra obtained at low temperatures (with fully gap) [50,52–55,59] and room temperature (gapless or softly gapped) [60,61]. Additionally, it also provides a comprehensive explanation for the significant decrease in resistivity observed during warming within the temperature range of 100 to 150 K in previous transport experiments [62,63].

Although we have confirmed that the spin interaction has significantly influenced the low energy charge dynamics in the Mott gap, the underlying physics remains unclear. We have noticed that another 5*d* KQSL material Na₂IrO₃, has sparked intense debate regarding its unconventional Mott insulating nature [64–66], as the full charge gap also persists well crossing the Neel temperature T_N (~15 K) until the disappearance of Kitaev spin coupling. Subsequently, there is a significant decrease in the charge gap with increasing temperature [67–69]. This also suggests that the charge gap, primarily influenced by the Kitaev spin Ising coupling, may be a universal phenomenon in Kitaev materials that remains incompletely understood.

A well-established theory exists regarding the continuous metal-to-insulator transition in Mott insulators within the spin liquid (SL) state [20–22]. In the scenario, a quantum critical region bridges the SL and the Fermi liquid (FL) phases at finite temperature, where the FS continuously transforms into a neutral spinons FS coupled to an emergent gauge field, while Landau quasiparticles are destroyed due to the chargespin separation. Meanwhile, upon approaching the SL from FL, the effective mass of the charge excitations increases and leads to a larger electric resistivity [21,22]. However, the theoretical framework fails to consider the crossover between SL Mott and conventional paramagnetic Mott states, where the strong spin coupling disappears while U/t is preserved, *i.e.* the spin frustration dissipates prior to MIT. The Kitaev QSL materials, such as α-RuCl₃ and Na₂IrO₃, offer a platform for comprehending the impact of spin interaction on the Mott-Hubbard framework without MIT. From the aforementioned experimental results, we believe that the short-ranged Kitaev spin interaction and the consequent Majorana spinon as well as the flux excitations have effectively enhanced the effective mass of chargons (as proposed in the continuous Mott transition theory [22]), leading to an enhanced localization effect for charge sectors, as schematically shown in Fig. 4d. This is manifested by a full charge gap in dI/dV spectra and the high resistivity in charge transport, as observed in the current work and previous publications [62,63,68,70]. When the spin interaction disappears and the system enters

into conventional paramagnetic states, the recombination of charge and spin then significantly reduce the effective mass of charges. It leads to a weak localization or delocalization of charges in Mott-Hubbard bands and manifesting as the softening of the Mott gap in dI/dV spectra and decreasing of resistivity in transports. It demonstrates that, despite the constancy of the parameter U/t, the spin interaction can exert a significant influence on the Mott physics.

Fig. 4. Modulation of Mott-Hubbard framework by Kitaev spin coupling. (a) Phase diagram of the spin dynamic in α -RuCl₃ as a function of temperature, at a temperature lower than 7 K, the compound becomes a antiferromagnet with zigzag spin orders; at temperature higher than approximately 120 k, the compound goes into the conventional paramagnetic phase; in the medium temperature between 7 to 120 K, it is a Kitaev quantum paramagnet with short-ranged Ising spin coupling; (b) Plot of the charge gap magnitude of the ML α -RuCl₃ as a function of temperature; (c) *dI/dV* spectra taken on thick transferred α -RuCl₃ flake at different temperatures; (d) schematically shown the

difference between Kitaev Mott insulator and paramagnetic Mott insulator. In the Kitaev Mott state, although the charges are gapped by the Colombo repulsion, the spin performs as gapless spinon with emergent of flux excitations due to the charge-spin separation; while in the conventional Mott states, the recombination of charge and spin will change the Mott-Hubbard framework such as the effective mass of the charges.

V. CONCLUSION

In summary, we have investigated the temperature dependent dI/dV spectra in both grown monolayer and the exfoliated thick α -RuCl₃. Both samples display a significant softening of charge gap when the temperature crosses the critical region from SL Mott insulator to paramagnetic Mott insulator. It is believed that the recombination between spinon and chargon in the critical region has led to the decrease of the effective mass of the charge sector, which results in the decrease of localization on charge carries in the Mott-Hubbard bands. Our results demonstrated that α -RuCl₃ offers an ideal platform for studying the spin-charge interaction, in particular exploring the impact of spin on the charge sector within the Mott-Hubbard framework.
