Abstract. The standard cosmological model currently in force, aka Λ CDM, has been plagued with a variety of phenomenological glitches or tensions in the last decade or so, which puts it against the wall. At the core of the Λ CDM we have a rigid cosmological term, Λ , for the entire cosmic history. This feature is unnatural and even inconsistent in the context of fundamental physics. Recently, the results from the DESI collaboration suggested the possibility that dark energy (DE) should be dynamical rather than just a cosmological constant. Using a generic w_0w_a CDM parameterization, DESI favors quintessence behavior at $\sim 3\sigma$ c.l. However, to alleviate the tensions the DE needs more features. In the proposed w XCDM model [43], the DE is actually a composite cosmic fluid with two components (X, Y) acting sequentially: first X (above a transition redshift z_t) and second Y (below z_t). Fitting the model to the data, we find that the late component Y behaves as quintessence, like DESI. However, to cure the H_0 and growth tensions, X must behave as ‘phantom matter’ (PM), which in contrast to phantom DE provides positive pressure at the expense of negative energy density. The PM behavior actually appears in stringy versions of the running vacuum model (RVM). Using the SNIa (considering separately Pantheon+ and DESY5), cosmic chronometers, transversal BAO, LSS data, and the full CMB likelihood from Planck 2018, we find that both tensions can be completely cut down. We also compare the w XCDM with our own results using the standard w CDM and w_0w_a CDM parameterizations of the DE. In all cases, model w XCDM performs much better. Finally, we have repeated our analysis with BAO 3D data (replacing BAO 2D), and we still find that the dynamical DE models (including composite ones) provide a much better fit quality compared to Λ CDM. The growth tension is alleviated again, but in contrast, the H_0 -tension remains significant, which is most likely reminiscent of the internal conflict in the BAO sector.

1 Introduction

Despite the standard or concordance model of cosmology, aka Λ CDM [1], has proven to be a rather successful theoretical framework for the description of the Universe’s evolution as a whole, in the last few decades the model has led to a number of pitfalls which shed doubts about its phenomenological viability, not to mention other (much deeper) theoretical problems. A core ingredient of the model is the cosmological constant (CC), Λ , introduced by A. Einstein more than a century ago [2]. The CC is traditionally connected to the vacuum energy density (VED) through $\rho_{\text{vac}} = \Lambda/(8\pi G_N)$, with G_N Newton’s gravitational constant. It was later observed that this connection may generate a big theoretical conundrum, the so-called ‘cosmological constant problem’ (CCP) [3]. Basically, it stems from the inordinately large prediction on the value of the VED (and hence of Λ) made by quantum field theory (QFT) and in particular by the standard model of elementary particles. Such a weird prediction amounts indeed to a value of ρ_{vac} which is at least 55 orders of magnitude bigger than the current critical density of the Universe [4–6]. Whether this interpretation of the CCP is correct or not is a matter of debate. In the meantime, recent theoretical developments in the context of the running vacuum model (RVM) [7–10] have provided a new QFT perspective for tackling the CCP and the tensions themselves. In the new context, the VED, and hence also Λ , are free from the very large (quartic mass) $\sim m^4$ effects associated with the vacuum fluctuations of the quantized matter fields, which are at the root of the need for extreme fine tuning in the CCP context [11–14]. Moreover, in this framework the VED evolves smoothly with the cosmological expansion, i.e. $\rho_{\text{vac}} = \rho_{\text{vac}}(H)$, rather than retaining a rigid value $\rho_{\text{vac}} = \text{const.}$ for the entire cosmic history, specifically the evolution is like $\delta\rho_{\text{vac}}(H) \sim \nu H^2$ in the current universe, where $|\nu| \ll 1$ is a calculable coefficient in QFT. Such a dynamics of the VED has been substantiated in the context of QFT in curved spacetime in the previously mentioned works as well as in the framework of low-energy effective string theory [15–19]. Very recently, the evolution law $\delta\rho_{\text{vac}}(H) \sim \nu H^2$ has also been highlighted in lattice quantum gravity studies [20]. With these developments at hand, the CCP has gained a new perspective¹. Intriguingly enough, this year’s release of the measurements by the Dark Energy Spectroscopic Instrument (DESI) suggest tantalizing evidence of dynamical DE [22, 23], which is in accordance with the mentioned theoretical works. The possibility of dynamical DE was strongly emphasized a few years ago from devoted studies involving a large set of cosmological data [24–27] using the framework of the RVM. Other analyses from different perspectives reached similar conclusions around that time [28–30].

The phenomenological pitfalls of the Λ CDM referred to above are concerned with the persisting tensions involved in the measurement of the current Hubble parameter $H_0 \equiv 100h$ km/s/Mpc ($h \simeq 0.7$) and the growth of large scale structures (LSS), see [31, 32] for summarized explanations about each of these tensions, and [33–35] for comprehensive reviews and lists of references. The first sort of tension leads to a serious mismatch between the CMB observations when analyzed under the assumption of Λ CDM cosmology, and the local (distance ladder) measurements of the Hubble parameter today. It amounts to a severe inconsistency of $\sim 5\sigma$ CL between the two kinds of determinations of the H_0 value. The second kind of tension points to an overproduction of large scale structure at low redshifts in the context of the Λ CDM as compared to observations, the discrepancy being here at the more modest level of $\sim 2 - 3\sigma$. A disruption in the opposite direction has recently appeared from the LSS data collected by the James Webb Space Telescope (JWST) [36, 37], which has discovered populations of very massive galaxies at large redshifts $z \gtrsim 10$, a fact which is completely unexpected within the Λ CDM model.

The myriad strategies concocted in the literature to cope with the above phenomenological tensions have nevertheless not been able to fix the situation completely, and since the tensions do

¹An informal introduction to the Cosmological Constant Problem can be found in [21]. For a more formal approach, see the reviews [7–10], which are framed along the lines of the current work.

not seem to fade away in the scientific horizon after years of struggle, this topic remains as one of the main focuses of current cosmological research. We refer once more the reader to the above mentioned reviews for comprehensive lists of references dealing with multifarious models. In our opinion, however, the problem with the tensions and the CCP are not necessarily independent issues, and as shown in specific analyses [38,39], frameworks capable of alleviating the CCP (such as the RVM) have a bearing on fixing the tensions as well. Herein we shall exclusively focus on the possibility that the DE is a composite DE fluid, which represents a real novelty to tackle the tensions, despite some composite models existed already in the past aiming at different purposes (such as the cosmic coincidence problem). A well-known example is the composite running vacuum model Λ XCDM studied in [40–42]. A recent work inspired along these lines [43] has put forward the idea of the w XCDM model (not to be confused with the standard w CDM parameterization [44]). The w XCDM is a nice prototype of ‘transitional composite model’ which proves extremely effective in cutting down the tensions under specific conditions, especially when data on angular BAO are employed in the fitting analysis [45]. In it, we have two components (X, Y) which are subject to dynamical evolution, each one having a different equation of state (EoS), denoted (w_X, w_Y). The Y component behaves effectively as a dynamical vacuum term and hence it mimics the RVM, since in the latter the VED is dynamical and, in addition, it possesses a dynamical EoS slightly departing from -1 [13]. Component X , on the other hand, can play the exotic role of “phantom matter” (PM) [40], namely an intriguing form of DE which, in contradistinction to the usual phantom DE, is characterized by positive pressure ($p_X > 0$) at the expense of a negative energy density ($\rho_X < 0$). An example of fundamental PM behavior appears in the stringy RVM context of [15,16]. A model which can be viewed as a particular case of the w XCDM appears when w_X and w_Y are both stuck to -1 and one assumes a transition from AdS to dS, a situation which was studied in [46] and called the Λ_s CDM model. It has no flexibility to accommodate dynamical DE though. It is important to emphasize that components X and Y must act chronologically in sequence during the late cosmic evolution (i.e. after decoupling of the CMB): namely, X acts first until a transition redshift z_t near our time, and below that redshift Y takes over. The latter is the only DE component that shows its face to us since it is the one that reaches up to our days and is responsible for the cosmic acceleration that we observe.

Upon fitting the three parameters (w_X, w_Y, z_t) of the w XCDM to a large set of cosmological data we find the following: i) the transition point is relatively close: $z_t \sim 1 - 2$, ii) component Y behaves as quintessence ($w_Y \gtrsim -1$), a result which is compatible with the recent DESI results [22,23,47]; and iii) the component X behaves as PM (this means $w_X \lesssim -1$ but also, as indicated, $\rho_X < 0$). Now since X has a negative energy density, the observed value of H_0 in the low redshift range, which is governed by the Y component, must be larger (closer to the SH0ES value [48]) in order to compensate for the fact that the PM component X makes the distance from z_t to the last scattering surface larger. Thus, as a result of the composite (X, Y) structure of the w XCDM model, the H_0 tension can be fixed from the interplay between the PM and quintessence behaviors of the two components of the DE. At the same time the growth tension may be highly alleviated since in the recent universe (ruled by the Y component of the DE) the structure formation is slowed down under quintessence-like behavior, as it will be shown in our study. But by the same token the X component of the DE, which carries positive pressure $p_X = w_X \rho_X > 0$ and is in force at the upper redshift range $z > z_t$, may on its own produce unsuspected large scale structures at high redshifts, providing a chance to explain the aforementioned JWST observations [37].

In this Letter, we further explore the w XCDM and shall present the main fitting results with a more recent set of SNIa as compared to [43]. In addition, we analyze for the first time the differences between using BAO 2D versus BAO 3D data along with the remaining set of observations, which involve cosmic chronometers, LSS data, the SNIa calibration from SH0ES and the full CMB likelihood from Planck 2018. Finally, we compare the behavior of the w XCDM, not only with the

standard Λ CDM model, but also with the mentioned Λ_s CDM and with our own fitting results obtained with the w CDM and w_0w_a CDM parameterizations of the DE used recently by DESI [22,23]. The w_0w_a CDM is sometimes also called the CPL parameterization [49,50]. We find that w XCDM and w_0w_a CDM provide a very efficient description of the observations, both with BAO 2D and BAO 3D, but it is the composite model w XCDM that provides the optimal fitting results with BAO 2D and in this context the tensions can be fully accounted for.

2 Monocomponent versus composite dark energy

‘Ordinary’ formulations of the DE are monocomponent, i.e. they involve just one cosmic substance or fluid. For example, in the standard Λ CDM the single ‘fluid’ is the VED associated with the CC term Λ . Similarly, DE proposals such as quintessence or phantom DE [5,6,51] are usually monocomponent since they involve a single scalar field. However, the DE can also be multicomponent or composite, i.e. with two or more cosmic components or fluids. For example, in some formulations (take the old quintom model [52], for instance) quintessence and phantom DE components may participate together. Herein we do not wish to consider scalar field models of the DE, as they are committed to specific forms of the effective potential (s). In what follows, we instead focus on generic forms of the DE of unspecified nature, both monocomponent and composite, which in some cases are grounded on fundamental physics (such as QFT or string theory). In doing this we wish to compare usual parameterizations of the DE, such as w CDM [44] or w_0w_a CDM [49,50] (usually presuming monocomponent scenarios) with alternative parameterizations mimicking composite scenarios of the DE, specifically those involving the possibility of a sign flip of the DE density. As we shall see, this sign flip feature can be particularly efficient to improve the overall fit quality of the cosmological observations and can be instrumental for alleviating the cosmological tensions [43,45,46,53]. In the following, we mention a few models of the DE, one of them being a pretty standard parameterization of the dynamical DE usually based on assuming an underlying monocomponent fluid, and the other three incorporate the sign flip feature:

- i) w_0w_a CDM (or CPL) parameterization [49,50] of the DE, characterized by the following dynamical EoS:

$$w(z) = w_0 + w_a(1 - a) = w_0 + \frac{w_a z}{1 + z}, \quad (1)$$

which is given either in terms of the scale factor or the redshift ($1 + z = 1/a$). A particular case is the w CDM parameterization [44], in which w_0 is simply called w and $w_a = 0$, hence the EoS in this situation is non-dynamical (although, of course, the DE is still evolving with the expansion). In our analysis, we will also provide separated results corresponding to this simpler parameterization, together with the more general form (1) used by the DESI Collaboration [22,23]. The corresponding Hubble rate $H = \dot{a}/a$ for the more general EoS (1) can be readily derived:

$$H(a) = H_0 \left[(\Omega_b^0 + \Omega_{cdm}^0)a^{-3} + \Omega_\gamma^0 a^{-4} + \frac{\rho_\nu(a)}{\rho_{c0}} + \Omega_{DE}^0 a^{-3(1+w_0+w_a)} e^{-3w_a(1-a)} \right]^{1/2}. \quad (2)$$

Here H_0 is the current value of the Hubble rate, and $\Omega_i^0 = \rho_i^0/\rho_c^0$ are today’s energy densities of baryons, cold dark matter, photons and DE normalized with respect to the current critical density. We note that the exact neutrino contribution, $\rho_\nu(a)$, cannot be expressed analytically since it contains a massive component, $\rho_{\nu,m}(a)$, apart from the massless relativistic one with the usual behavior $\rho_{\nu,r} \sim a^{-4}$. Therefore, during the expansion of the universe, the neutrino transits from a relativistic into a nonrelativistic regime. Being this process nontrivial, it has to be dealt with numerically. In this work, we use in all cases one massive neutrino of 0.06 eV and two massless neutrinos.

- ii) Λ XCDM model [40–42]. In this case, the cosmic fluid contains, in addition to the usual matter energy density ρ_m , a composite DE sector constituted of two subcomponents, to wit: one is the running vacuum energy density ρ_{vac} , and the other is an effective entity called X , whose energy density is ρ_X . Since the model is formulated within the RVM framework [7], the evolution of the VED can be determined within the QFT formalism of, [11–14], in which $\rho_{\text{vac}} = \rho_{\text{vac}}(H)$ evolves with the expansion rate. In the current universe, the VED evolution adopts the RVM form

$$\rho_{\text{vac}}(H) = \rho_{\text{vac}}^0 + \frac{3\nu_{\text{eff}}}{8\pi} (H^2 - H_0^2) m_{\text{Pl}}^2, \quad (3)$$

in which ρ_{vac}^0 is the current VED value, m_{Pl} is the Planck mass and $|\nu_{\text{eff}}| \ll 1$ is a small parameter which can be computed in QFT, see the aforementioned papers. For $\nu_{\text{eff}} > 0$ the VED decreases with expansion and hence the model mimics quintessence, while for $\nu_{\text{eff}} < 0$ the VED increases with the expansion and in this alternative situation the model behaves effectively as phantom DE. In the original version of Λ XCDM [40], there is an exchange of energy between the VED and the X component, and as a result the solution of the cosmological equations in terms of the scale factor or the cosmological redshift is a bit cumbersome despite being fully analytic. The study of cosmic tensions within the Λ XCDM framework will be presented elsewhere. A simplified version of this model, which nevertheless emulates the basic features of the latter, is the w XCDM model defined in the next point.

- iii) w XCDM model [43]. In this model, we have two dynamical components for the DE, denoted (X, Y) , with respective EoS parameters (w_X, w_Y) . The component X has similarities to the aforementioned Λ XCDM, whereas Y mimics the dynamical behavior of Λ in the Λ XCDM. Upon fitting the model to the data, the X component is phantom-like ($\omega_X \lesssim -1$) while the Y component is quintessence-like ($\omega_Y \gtrsim -1$). However, X does not behave as usual phantom DE since its energy density is negative ($\rho_X < 0$) and therefore its pressure is positive, $p_X = w_X \rho_X > 0$, which is why it is called ‘phantom matter’ (PM) – first introduced in the context of the aforementioned Λ XCDM model [40]². Despite we will treat here PM in a pure phenomenological manner, let us recall that there are fundamental scenarios where the existence of PM can be substantiated, e.g. in stringy formulations of the RVM [15, 16]. As mentioned in the Introduction, it is important to clarify that X and Y do not act simultaneously along the cosmic evolution: X acts first until a transition redshift z_t (fitted from the data), i.e. for $z > z_t$, while Y acts below that redshift ($z < z_t$) until the present day (see Fig. 1). Therefore, Y is the ‘visible’ face of the composite DE fluid. In fact, the Y component has positive density $\rho_Y > 0$ and negative pressure $p_Y < 0$. Since its EoS is quintessence-like ($\omega_Y \gtrsim -1$), as noted, this component appears to us as a pretty ‘standard’ DE fluid. What about the hidden face of the composite DE, i.e. the PM component X ? Although it only reigns over far domains of our past, specifically for $z > z_t \sim 1.4$ (see Sec. 4 for details), and hence is not directly accessible to us, it nevertheless has dramatic consequences for improving the fit quality to the overall fit to the cosmological data, as we shall see in our analysis. We should immediately clarify at this point that the free parameters of the w XCDM model are just three: (z_t, w_X, w_Y) . The density parameters for the DE components are not independent degrees of freedom, since, e.g. the value of $\rho_Y^0 \equiv \rho_Y(z = 0)$ can be obtained from the fitting values of the standard parameters $H_0, \omega_b, \omega_{\text{dm}}$. Furthermore, it is assumed that the condition $|\rho_X(z)| = \rho_Y(z)$ holds at the transition redshift $z = z_t$, and hence the values of the two DE densities ρ_X and ρ_Y on both sides of z_t (i.e. just above and below this value) are taken to be equal in absolute value but opposite in sign. This assumption is intended to reduce the number of free parameters in composite models with a sign flip of the DE density.

- iv) Λ_s CDM model [46]. As indicated in the introduction, this model can be conceived as a particular case of the w XCDM, in which X and Y are assumed to be rigid (non-evolving) Λ -like

²We refer the reader to Sec. 3 and Fig. 1 of [43] for a clear discussion and graphical illustration of the position of phantom matter in the context of the energy conditions satisfied by the various cosmic fluids.

components: $w_X = w_Y = -1$. The model involves a transition redshift z_t , above which the X component forms an anti-de Sitter (adS) phase ($\Lambda < 0$) and below it the Y component behaves as a standard (positive) cosmological constant (i.e. a de Sitter phase, $\Lambda > 0$). It is also assumed that there is a sign flip of Λ at $z = z_t$ which preserves the absolute value of the DE (cf. Fig. 1). Strictly speaking, Λ_s CDM is not a genuine composite model, although we will still refer to it as such.

In the following, we will furnish detailed numerical analyses of five models of the DE, to wit: w CDM and w_0w_a CDM mentioned in i), the basic composite model w XCDM described in iii), and the particular case Λ_s CDM indicated in iv). At the same time, we will provide the corresponding results for the standard Λ CDM. All five models will be confronted to the same set of cosmological data and compared statistically to the Λ CDM. Thus, in the present study we shall assess the impact of composite scenarios iii) and iv) against monocomponent scenarios, represented here by the two conventional parameterizations in i) and the Λ CDM model.

3 Data

We constrain the w XCDM model as well as the benchmark models described in Sec. 2 using a very similar methodology to the one employed in our previous work [43]. In particular, we use: the full Planck 2018 CMB temperature, polarization and lensing likelihoods [54]; 33 data points on $H(z)$ from cosmic chronometers (CCH) in the redshift range $z < 2$ [55–64]; and galaxy clustering data extracted from the analysis of redshift-space distortions (RSD) and peculiar velocities [65–75]. As in [43], we take into account the CCH non-diagonal covariance matrix [76] and treat the LSS data in terms of the observable $f(z)\sigma_{12}(z)$, which is more robust than the usual $f(z)\sigma_8(z)$ since the former encapsulates the clustering information at a fixed scale of $R_{12} = 12$ Mpc, which is independent from h and, therefore, less prone to biases [77–80]. These subsets of data coincide exactly with those employed in [43], but in this paper we make important updates both in the SNIa and BAO samples, namely: (i) we replace the Pantheon+ SNIa compilation [81] with the recent full five-year SNIa dataset from the Dark Energy Survey, referred to as DES-Y5 [82, 83]. This sample has proved to be more sensitive to dark energy dynamics, see, e.g. [22, 23]. We also use a prior on the absolute magnitude of SNIa, as measured by the SH0ES Team in the first two rungs of the cosmic distance ladder, $M = -19.253 \pm 0.027$ mag [48]; and (ii) we combine the CMB+CCH+LSS+DESY5+SH0ES data set with two different types of BAO measurements separately, the so-called transverse (aka angular or 2D) BAO data from Refs. [84–88] and anisotropic (or 3D) BAO data from Refs. [70, 89–92]. They complete the two data sets used in this work, to wit: CMB+CCH+LSS+DESY5+SH0ES+BAO_2D and CMB+CCH+LSS+DESY5+SH0ES+BAO_3D. The 2D BAO measurements are extracted from the raw tracer maps in the space of angles and redshifts without requiring the use of a fiducial model to convert redshifts into distances. They are, in principle, less affected by model dependencies, which can have a significant impact on 3D analyses [93, 94]. Despite being extracted from the same or very similar catalogs of tracers, these two types of BAO data are obtained following different methodologies and turn out to be in tension [95]. Indeed, they lead to completely different solutions to the Hubble tension [45, 96], see also [43, 46, 97–99]. It is, therefore, of utmost importance to analyze the models with 2D and 3D BAO separately in order to understand their impact on the discussion of the cosmological tensions. This is one of the main focuses of the current study.

4 Numerical analysis and discussion

We use a modified version of the Einstein-Boltzmann code CLASS [100, 101] to solve the coupled system of cosmological background and linear perturbation equations and compute all the theoret-

tical predictions of the models under study. We employ `MontePython` [102, 103] to run the Monte Carlo analyses and the Python code `GetDist` [104] to analyze the chains and obtain constraints on the model parameters. Our main fitting results for the various models and for both types of BAO (2D and 3D) are displayed in the upper and lower parts of Table 1, respectively. Furthermore, for the convenience of the reader, in Table 2 of the Appendix we provide the specific contributions of each observable entering our analysis to the total χ^2_{\min} for the two fits, one using BAO 2D-only and the other BAO 3D-only. For lack of space, in this Letter we omit the full triangle contour plots for the various models studied in this paper under the two BAO sorts, which display the two-dimensional marginalized likelihood distributions for each parameter. They are similar to those presented in [43].

As is well known, to compare the fitting performance of the various models more fairly, it is necessary to penalize the use of additional parameters, which is tantamount to implementing Occam’s razor. This is why in Table 1 we not only report the minimum values of χ^2 obtained for each model, but we also display the differences between the deviance (DIC) [105] and Akaike (AIC) [106] information criteria found between the Λ CDM and the various mono- and multicomponent DE models, expressed in our case as $\Delta\text{DIC} \equiv \text{DIC}_{\Lambda\text{CDM}} - \text{DIC}_i$ and $\Delta\text{AIC} \equiv \text{AIC}_{\Lambda\text{CDM}} - \text{AIC}_i$, respectively, with i referring to any of the models w XCDM, Λ_s CDM, w CDM or w_0w_a CDM. The DIC itself is defined as

$$\text{DIC} = \chi^2(\bar{\theta}) + 2p_D, \quad (4)$$

with $p_D = \overline{\chi^2} - \chi^2(\bar{\theta})$ the effective number of parameters in the model, $\overline{\chi^2}$ the mean value of χ^2 and $\bar{\theta}$ the mean of the parameters entering the Monte Carlo analysis. It incorporates the information encapsulated in the full Markov chains. Similarly, when the number of points is much larger than the number of parameters n_p (which is certainly the case here), the AIC is defined as

$$\text{AIC} = \chi^2_{\min} + 2n_p. \quad (5)$$

With the above definitions, a positive difference in these information criteria indicates a better performance of the composite/dynamical DE models than the standard Λ CDM. If $0 \leq \Delta\text{DIC} < 2$ it is said that one finds *weak evidence* in favor of the new model under test, compared to the standard model. If $2 \leq \Delta\text{DIC} < 6$, we speak instead of *positive evidence*. If $6 \leq \Delta\text{DIC} < 10$, there is *strong evidence* in favor of the composite DE models, whilst if $\Delta\text{DIC} > 10$ we can conclude that there is *very strong evidence* supporting the new model against the standard Λ CDM. An analogous consideration can be made using AIC, of course. Despite the simplicity of AIC as compared to DIC, we obtain respective values for these two information statistics that are fully consistent.

Let us now first focus on analyzing the results obtained using the data set with BAO 2D-only. It has been shown that with this BAO type and in models exhibiting a transition from negative to positive dark energy densities around $z_t \sim 1.5 - 2$, the Hubble tension can be strongly alleviated, if not completely erased [45]. This has been explicitly demonstrated in previous works both in the context of the Λ_s CDM [46] and the w XCDM [43]. Nevertheless, the overall fitting performance of these two models is by no means the same owing to the different behavior of the DE, namely rigid versus dynamical, respectively. In [43], we demonstrated that current data strongly prefers the w XCDM model to Λ_s CDM, essentially due to a substantial improvement in the description of the SNIa apparent magnitudes from the Pantheon+ compilation, and we already advanced in the conclusions that the analysis with the DES-Y5 sample would probably enhance the differences between these two models in favor of w XCDM. Our conjecture gets now fully confirmed in the current study. From the main fitting table, we can see that the values of ΔAIC and ΔDIC are ~ 30 units larger in the w XCDM than in the Λ_s CDM, which points to an outstanding preference for the former model. The combination of BAO 2D and DES-Y5 SNIa with the other data sets

Table 1: Mean values and uncertainties at 68% CL obtained with the full data sets CMB+CCH+SNIa+SH0ES+BAO_2D+ $f\sigma_{12}$ (upper half) and CMB+CCH+SNIa+SH0ES+BAO_3D+ $f\sigma_{12}$ (lower half). We show the best-fit values in brackets. We use the standard notations for the Λ CDM parameters, and H_0 is given in km/s/Mpc. In the last three lines of the two subtables, we display the values of the minimum χ^2 , ΔDIC and ΔAIC , as defined in Eqs. (4) and (5), respectively.

(which include the SH0ES prior) forces the value of Ω_m^0 in both models to be pretty small, close to $\sim 0.27 - 0.28$. This is due to the large (positive) values of the DE density after the transition (at $z < z_t$), which are needed to compensate the flip of DE sign occurring at $z = z_t$ (see the left plot of Fig. 1). This transition is required to properly fit the angle θ_* (the angular size of the sound horizon) measured by Planck [54], which can be translated into a very precise measurement of the distance to the last scattering surface if the model does not introduce new physics before recombination. As it is obvious from Fig. 7 of [82], such low values of the matter fraction are disfavored at $\sim 3\sigma$ CL by DES-Y5 SNIa if DE is non-dynamical, i.e. if $w = -1$ (as in Λ_s CDM)³. This causes a sizable enhancement of χ_{SNIa}^2 in the Λ_s CDM fit as compared to the more flexible w XCDM fit, see Table 2. Indeed, such low values of Ω_m^0 can only accommodate the SNIa data if and only if DE is of quintessence type, with $w \gtrsim -0.9$. This is why w XCDM is able to do an excellent job: we obtain $w_Y = -0.86 \pm 0.03$ (cf. Table 1), which lies in the correct region of the parameter space and is fully consistent with the DESI results with a comparable dataset [22, 23]. Λ_s CDM offers also a much poorer fit to Planck’s CMB data, and this is the second fact that makes this model to perform much worse than w XCDM. In both models we obtain fitting values for the transition redshift in the range $z_t \sim 1.5 - 1.9$, similar to the those reported in [43, 45, 46].

Regarding the Hubble tension, within the w XCDM we obtain a large value of H_0 ($H_0 = 70.94$ km/s/Mpc), slightly lower though than that obtained within the Λ_s CDM ($H_0 = 72.36 \pm 0.91$ km/s/Mpc). However, it is important to notice that the SH0ES calibration of the absolute magnitude parameter, $M = -19.253 \pm 0.027$, when combined with the apparent magnitudes of the DES-Y5 SNIa in the Hubble flow, leads to a measurement of $H_0 = 70.5 \pm 1.1$ km/s/Mpc [108], which is indeed fully compatible with the posterior value that we have obtained for the w XCDM (within only 0.36σ), while in contrast lies $\sim 1.3\sigma$ below the Λ_s CDM value⁴. Moreover, no tension is observed between the SH0ES calibration of M and the values obtained for this nuisance parameter in the two models. Using the w_0w_a CDM parameterization, there is no sizeable tension either, whereas within Λ CDM the tension in M reaches $\sim 3.7\sigma$ CL. The take-home message that ensues from our analysis, therefore, is that the Hubble tension is basically washed out in the transitional composite DE models and the w_0w_a CDM when BAO 2D is employed in the fitting analyses. Now, in terms of global fit quality, the balance is much better for the composite w XCDM model. Indeed, among the dynamical models fitted using BAO 2D-only data, we find that the information criteria clearly select w XCDM in the first place, followed by w_0w_a CDM at considerable ‘distance’ in AIC and DIC space, and finally Λ_s CDM in the third position (see the upper half of Table 1). The three of them do fit however the data substantially better than the Λ CDM. This is nevertheless in stark contrast to the simplest w CDM parameterization, where the EoS is not dynamical, which provides no improvement whatsoever with respect to the Λ CDM, as it is manifest in Table 1.

At the end of the day, it turns out that the standard Λ CDM becomes extremely disfavored compared to all other dynamical models (except w CDM) in light of the large CMB+CCH+LSS+DES+Y5+SH0ES+BAO.2D dataset. It is true that BAO 2D also allows H_0 to increase within the standard Λ CDM, reaching in this case $H_0 \sim 69.3$ km/s/Mpc. However, this boost is not as efficient as in the transitional DE models because, as mentioned above, the value of M remains in 3.7σ tension with SH0ES. In addition, Λ CDM has to pay a high price to make this increase possible; for, as is apparent from Table 2 in the Appendix, the Λ CDM worsens the description of all the individual data sets compared to the other models. In particular, we can see in that

³Similar conclusions are drawn from Fig. 18 of the Union 3 paper [107] and, with lower statistical significance, from Fig. 9 of the Pantheon+ paper [81].

⁴In this work we compare the posterior values of H_0 obtained in the various models and fitting analyses with the determination obtained by combining the SH0ES calibration of M and the SNIa in the Hubble flow from DES-Y5, which are the ones that we are using in this study. This is more consistent than making the comparison using the Pantheon+SH0ES measurement, $H_0 = 73.04 \pm 1.04$ km/s/Mpc [48]. The shift in the value of H_0 extracted from the distance ladder could be caused by systematics either in the low- z SNIa of Pantheon+ or DES-Y5 [109, 110].

Figure 1: *Left upper plot:* Dark energy fraction $\Omega_{\text{DE}}(z) = \frac{\rho_{\text{DE}}(z)}{\rho_c(z)}$ as a function of the redshift for Λ CDM, w_0w_a CDM, Λ_s CDM and w XCDM, obtained using the best-fit parameters with CMB+CCH+LSS+DESY5+SH0ES+BAO_2D data (cf. Table 1); *Right upper plot:* The corresponding curves for the deceleration parameter, $q = -\ddot{a}a/\dot{a}^2$; *Lower plot:* Evolution of the EoS parameter of the various models. For the w XCDM, $w_X < -1$ at $z > z_t$ and X behaves as phantom matter. At $z < z_t$, $w_Y > -1$ and Y evolves as quintessence. For Λ CDM and Λ_s CDM, $w = -1$, and for w_0w_a CDM we use Eq. (1).

table that the increase of H_0 is accompanied by a significant enhancement of χ_{CMB}^2 , of about 10 units compared to the value obtained when BAO 3D is used instead of BAO 2D. As discussed in [43], the fitting value of the reduced matter density parameter in the Λ CDM, $\omega_m = \omega_b + \omega_{dm} \sim 0.139$, lies much below the value preferred by the CMB under the assumption of the standard model, $\omega_m = 0.142 \pm 0.001$ [54]. This discrepancy is less pronounced or even non-existent in the other models. In summary, the alleviation of the Hubble tension in the Λ CDM found with angular BAO is unsatisfactory, since it comes at the expense of rocketing essentially the entire individual χ_i^2 , as recorded in Table 2. If taken at face value, the Akaike and Deviance information criteria let us conclude that the Λ CDM model is, compared to the main dynamical DE models under study, firmly ruled out when analyzed under the rich and powerful lens of multifarious CMB+CCH+SNIa+SH0ES+BAO_2D+ $f\sigma_{12}$ observations.

In view of the results we have obtained, we find that it is not only the dynamical character of the DE, but also the possibility that the DE changes its EoS during different stages of the cosmic expansion, that may prove instrumental to achieve an outstanding quality fit to the overall cosmological data, compared to the Λ CDM. Thus, while the w CDM entails dynamical DE, it fails to overcome the Λ CDM because its EoS remains constant throughout the cosmic history. In contradistinction to that, the richer parameterization w_0w_a CDM with dynamical EoS performs exceptionally well and is actually strongly preferred over the Λ_s CDM model [46], whose EoS is the same as in the Λ CDM. These important results were not disclosed in [43], but now appear crystal clear in light of the values of ΔAIC and ΔDIC displayed in the upper half of the current Table 1 for all models. Thus, if only from a mere quantitative point of view, speculations about a possible

adS→dS transition (as first advocated in [46]) might not be necessary if we consider the yield of the more conventional w_0w_a CDM description, which does not need any such exotic transition to render a much better fit than the Λ CDM. This is quantitatively evidenced by the substantially higher values of ΔAIC (~ 14 units) and ΔDIC (~ 17 units) obtained from w_0w_a CDM compared to Λ_s CDM. The large improvement of w_0w_a CDM over Λ_s CDM is due to a better description of the SNIa and CMB data (see the detailed breakdown of χ^2_i contributions in Table 2 of the Appendix).

Does this mean that transitional composite models are not competitive? Not at all, for the w XCDM shows no less versatility, as it has two EoS parameters to improve the description of the DE. Thus, despite the great performance of the w_0w_a CDM over the standard Λ CDM and over Λ_s CDM, the genuine composite model w XCDM still beats w_0w_a CDM by far, specifically with 13.9 units of ΔDIC and 12.6 units of ΔAIC . We refer the reader once more to Table 2 of the Appendix, where we can see that the w XCDM succeeds in decreasing the value of χ^2_{CMB} by 4.4 units, the value of $\chi^2_{f\sigma_{12}}$ by 5.5 units and the value of χ^2_{CCH} by 3.9 units, so the total favorable payoff comes from a rather democratic combination of background and LSS data. In particular, we may wonder why there is such a big improvement in the description of the LSS data from the w XCDM. Consider why w_0w_a CDM cannot do better here. Our constraints on the w_0w_a CDM parameters yield: $w_0 = -0.550^{+0.084}_{-0.043}$ and $w_a = -2.04^{+0.16}_{-0.39}$. With these numbers, we can immediately check from Eq. (1) that there is a crossing of the phantom divide at $z \approx 0.3$ (represented in the lower plot in Fig.,1). To be more precise, the DE exhibits phantom behavior up to $z \sim 0.3$ and quintessence behavior for $z \lesssim 0.3$. Since the DE behavior is phantom-like before that redshift, this compensates for the quintessence behavior after the crossing and in this way the model w_0w_a CDM can keep the correct distance to the last scattering surface. Hence, it is kind of natural that our best fit w_0w_a CDM model unduly enhances the amount of LSS compared to w XCDM in the late universe because there is less dark energy in the past. In fact, we obtain $\sigma_{12} = 0.774$ in the best-fit w XCDM model, while $\sigma_{12} = 0.803$ for w_0w_a CDM, which is obviously less competitive.

For a better understanding of the optimal description of the growth of structure in the w XCDM, it is worth having a closer look at the evolution of matter perturbations in this model since it is nontrivial. In the PM phase with negative energy density and positive pressure, and for typical values of the cosmological parameters, we actually expect a larger growth of matter perturbations within the w XCDM compared to the standard model and the w_0w_a CDM. Before the transition at z_t (i.e. for $z > z_t$), the equation for the density contrast $\delta_m = \delta\rho_m/\rho_m$ reads [43]

$$\delta_m'' + \frac{3}{2a}(1 - \Omega_X(a)w_X)\delta_m' - \frac{3}{2a^2}(1 - \Omega_X(a))\delta_m = 0, \quad (6)$$

with primes denoting derivatives with respect to the scale factor. PM has a negative energy density ($\Omega_X < 0$) and a positive pressure $P_X = w_X\rho_X$ (owing to $w_X < -1$) and therefore induces a decrease of the friction term and an increase of the Poisson term in equation (6). We can define the functions

$$F(z) \equiv \Omega_{\text{DE}}(z)w_{\text{DE}}(z) - \Omega_{\Lambda}(z)w_{\Lambda} = \Omega_{\text{DE}}(z)w_{\text{DE}}(z) + \Omega_{\Lambda}(z) \quad (7)$$

and

$$P(z) \equiv -\Omega_{\text{DE}}(z) + \Omega_{\Lambda}(z) \quad (8)$$

in order to study the evolution of the friction and Poisson terms, respectively, entering Eq. (6). These two functions allow us to compare the behavior of w XCDM (for which $\Omega_{\text{DE}}w_{\text{DE}}$ is $\Omega_Xw_X > 0$ for $z > z_t$ but $\Omega_Yw_Y < 0$ for $z < z_t$) with respect to Λ CDM ($\Omega_{\Lambda} > 0$). If $F(z)$ and $P(z)$ are both positive, they favor an enhancement of matter linear perturbations in the w XCDM (since the latter has then less friction and less DE repulsion than Λ CDM); if, on the contrary, these functions are negative, they favor a slower growth in w XCDM. We plot these functions in Fig. 3

Figure 2: Comparison of the functions $\sigma_{12}(z)$ and $\sigma_8(z)$ of the various models obtained using the best-fit values from the fitting analysis with CMB+CCH+LSS+DESY5+SH0ES+BAO_2D data (cf. Table 1). In the inner plot we show the relative difference $\Delta\sigma/\sigma_{12}(z) \equiv (\sigma_8(z) - \sigma_{12}(z))/\sigma_{12}(z)$. The curves of $\sigma_8(z)$ exhibit an artificial enhancement across all redshifts, which is more pronounced for larger values of H_0 since σ_8 depends on the h^{-1} Mpc units. This introduces an important bias that can be corrected by making use of $\sigma_{12}(z)$ instead of $\sigma_8(z)$, see [77, 80] for dedicated discussions on these matters.

using the best-fit values of w XCDM and Λ CDM displayed in the upper half of Table 1, obtained by using BAO 2D. As expected, they are positive before the transition, so in the presence of phantom matter there is more structure formation. This would not occur for ordinary phantom DE, for which the friction term gets enhanced and the Poisson term suppressed, i.e. just opposite to PM. Due to the phantom nature of the X component, its (negative) energy density gets very diluted in the remote past compared to non-relativistic matter and eventually becomes negligible, so these enhancement effects are not important if we go to sufficiently high redshifts⁵. However, these same effects enhance the power in the redshift range $z \in (1 - 2)$, as is apparent from the plot on the left of Fig. 2. Just after the transition (for $z \lesssim z_t$), DE increases up to large positive values (cf. Fig. 1) and starts to evolve (decrease) as quintessence. In that part of the cosmic expansion, the equation of the density contrast takes the following form [43]:

$$\delta_m'' + \frac{3}{2a} (1 - \Omega_Y(a)w_Y) \delta_m' - \frac{3}{2a^2} (1 - \Omega_Y(a)) \delta_m = 0, \quad (9)$$

with $\Omega_Y > 0$ and $w_Y > -1$. The functions $F(z)$ (7) and $G(z)$ (8) are mostly negative for $z < z_t$ and this fact induces a net suppression of growth that eventually brings the curve of $\sigma_{12}(z)$ of the w XCDM below those of the other models in that range, and this despite the fact that the friction term becomes positive again for $z \lesssim 0.6$ (this was a non-trivial feature to be noted here) – see again the left plot of Fig. 2 and Fig. 3. It is apparent that the LSS phenomenology in the w XCDM model is very rich. In the remote past it can make clustering more efficient, whereas at small redshifts there can be an important suppression of growth.

In Fig. 2, for completeness, we also compare the evolution of the functions $\sigma_{12}(z)$ (in the left plot) and $\sigma_8(z)$ (in the right plot). This comparison is very useful to understand our choice to use $\sigma_{12}(z)$ instead of $\sigma_8(z)$, following our previous work [43]. The common practice of using $\sigma_8(z)$ introduces a bias that becomes more significant for larger values of H_0 owing to the dependence of the scale R_8 on h , specifically on the h^{-1} Mpc units [77, 80]. This bias induces an artificial relative shift that is approximately independent of the redshift [80]. As a result, it can even invert the proper classification of models based on their ability to explain the LSS of the universe [80]. Notice in Fig. 2 that the curves of $\sigma_{12}(z)$ for the various models seem to converge at high redshifts,

⁵There is nonetheless a caveat here, as there could be, in principle, more PM bubbles at higher redshifts. This was noted in [43]. If so, they could play an important role to explain the JWST observations of extremely massive galaxies at $z \gtrsim 10$ [111, 112]. The study of this possibility, however, will be presented elsewhere.

Figure 3: The functions $F(z)$ (7) and $G(z)$ (8) allow us to study the effect of the friction and Poisson terms appearing in the equations of the density contrast of w XCDM (6)-(9) compared to Λ CDM. Positive values of these functions indicate that the aforesaid terms favor a larger growth in w XCDM than in Λ CDM. This is actually what happens during the PM phase, before the transition. After it, $\Omega_{\text{DE}} = \Omega_Y > \Omega_\Lambda$ (see the left upper plot of Fig. 1), so the Poisson term is smaller than in w XCDM. This helps to slow down the aggregation of matter in the quintessence phase. The friction term, instead, transits from negative to positive values at $z \sim 0.5$, once the deceleration parameter goes below the one of Λ CDM in magnitude, see the right upper plot in Fig. 1. However, the overall effect is a decrease of the amplitude of matter fluctuations in the late universe, as it is apparent from the left plot of Fig. 2.

meaning that the data are able to constrain the amplitude of fluctuations at linear scales for all models in a consistent way. In transitional models, this is possible despite the presence of PM because the best-fit values of the amplitude of the power spectrum are much lower than those encountered in the Λ CDM and the w_0w_a CDM. The convergence of $\sigma_{12}(z)$ at high redshifts is a feature that is also lost if we analyze the results in terms of $\sigma_8(z)$. In the inner plot of Fig. 2 we show the bias introduced by $\sigma_8(z)$, obtained using our best-fit models from the fitting analyses with CMB+CCH+LSS+DESY5+SH0ES+BAO_2D data (cf. Table 1). The use of $\sigma_{12}(z)$ eliminates the aforementioned bias because it characterizes the amplitude of the power spectrum at a fixed scale $R_{12} = 12$ Mpc [77], and this is why we adopt it in our work.

The results we have obtained with the data set CMB+CCH+DESY5+SH0ES+BAO_2D+ $f\sigma_{12}$ are fully consistent with those presented in [43]. However, replacement of Pantheon+ SNIa data with those of DES-Y5 enhances the signal in favor of w XCDM compared to Λ_s CDM and allows excluding Λ CDM with higher statistical significance. Moreover, we have checked that the w_0w_a CDM parameterization is also able to fit very efficiently this data set, even improving the performance of Λ_s CDM, despite providing a weaker fit to the LSS data. To the best of our knowledge, it is the first time in the literature that the w_0w_a CDM parameterization is constraint using BAO 2D measurements.

We turn now the discussion to the results of our analysis using BAO 3D-only, in combination with the rest of the data sources. Due to the existing tension between the angular and anisotropic BAO data, and given the pivotal role that BAO plays in the building of the inverse distance ladder and the discussion of the Hubble tension [45,95,96], it is of utmost importance to study how the results change when we replace the BAO 2D with BAO 3D. This represents one of the primary objectives of this paper. The fitting results obtained with CMB+CCH+DESY5+SH0ES+BAO_3D+ $f\sigma_{12}$ data are displayed in the lower half of Table 1. We observe that there is again very strong evidence against Λ CDM and in favor of the other models (except for the w CDM), since we find $\Delta\text{DIC} > 10$ in all relevant cases, accompanied with consistent values of ΔAIC . Notwithstanding, it is a fact BAO 3D does not give room for a notable increase of H_0 . But this is not a big surprise, since we know that in order to solve the Hubble tension BAO 3D does not only require an abrupt (phantom-like) increase of ρ_{DE} at ultra-small redshifts ($z \lesssim 0.15 - 0.2$), but also a simultaneous

increase of the absolute magnitude of SNIa [45, 113, 114], an scenario that we do not contemplate in this work. The tension, when analyzed in terms of M (which is the primary measurement of SH0ES) remains at 4.32σ (Λ CDM), 4.46σ (w CDM), 3.74σ (w_0w_a CDM), 3.60σ (w XCDM) and 3.44σ (Λ_s CDM), so the tension is quite high regardless of the model. This is so even including the SH0ES prior in the fitting analysis, cf. Sec. 3. Instead, if we quantify the tension in terms of the H_0 values, we obtain the following results: 1.7σ (Λ CDM), 2.0σ (w CDM), 2.4σ (w_0w_a CDM), 1.7σ (w XCDM) and $\sim 1\sigma$ (Λ_s CDM)⁶. All these features were already advanced in our conclusions of [43], but now we can reply the question of why the Λ CDM is also strongly disfavored in the light of the data set CMB+CCH+SNIa+SH0ES+BAO_3D+ $f\sigma_{12}$. The answer is given in the lower half of Table 2. On the one hand, the transitional DE models and the w_0w_a CDM fit better both the CMB and DESY5+SH0ES data sets, offering a substantial decrease of the corresponding χ_i^2 . On the other hand, the w_0w_a CDM is able to improve the description of the SNIa data and BAO 3D compared to the transitional models. This explains why the w_0w_a CDM parameterization leads to larger values of Δ DIC and Δ AIC. For instance, Δ DIC is 1.6 and 6.8 units larger for w_0w_a CDM than for w XCDM and Λ_s CDM, respectively. The fitting values of the w_0w_a CDM parameters read, in this case: $w_0 = -0.762 \pm 0.039$ and $w_a = -0.87^{+0.14}_{-0.16}$, which are in full accordance with those reported by DESI [22, 23] and other works that, like us, do not include DESI data [118, 119]. For instance, using DESI(FS+BAO)+CMB+DESY5 the authors of [23] find $w_0 = -0.761 \pm 0.065$ and $w_a = -0.96^{+0.30}_{-0.26}$, whereas using DESI(FS+BAO)+CMB+PantheonPlus, $w_0 = -0.858 \pm 0.061$ and $w_a = -0.68^{+0.27}_{-0.23}$. The agreement with our results is evident, although our uncertainties are smaller, also for Ω_m^0 and H_0 (cf. our Table 1 and Table 2 of [23]). For w_0 and w_a we find a significant decrease in the errors of a factor of 1.6–1.7. Using the best-fit values of these parameters we find that the crossing of the phantom divide now happens at $z \sim 0.4$, quite close to the one found with BAO 2D.

Our constraints at 68% CL on w_X and w_Y in w XCDM read: $w_X < -1.08$ and $w_Y = -0.933 \pm 0.025$. They are consistent with the results obtained with BAO 2D and favor, again, a quintessence evolution of the DE after the transition and a PM phase with $w_X < -1$ before the transition. However, it is important to comment on the fact that we find $w_X < -0.75$ at 95% CL, so the dataset built with BAO 3D does not exclude the region $w_X > -1$ in a statistically significant way. The transition redshift is moved from $z_t \sim 1.5$ (with BAO 2D) to $z_t \sim 2$ (with BAO 3D). Now, the transition happens almost in the region where there is no background nor LSS data. In fact, we have checked that our data set does not exclude the possibility of this transition to happen at much larger redshifts if w_X approaches 0 from below with increasing accuracy, since this is sufficient to produce the correct distance to the last scattering surface. These effects complicate the convergence of the chain. We have imposed a prior $w_X \in [-2, -0.5]$ to keep them under control. The data set CMB+CCH+DESY5+SH0ES+BAO_3D+ $f\sigma_{12}$ sets strong constraints on w_Y , but the actual constraints on z_t and w_X would be quite loose in the absence of this prior.

The fit to the LSS data is very similar in all the models under study when we consider BAO 3D. We find values of $\sigma_{12} \sim 0.79 - 0.80$ for all of them. We deem important also to highlight some other aspects that can be found when looking carefully at Table 2: (i) The values of $\chi_{\text{DESY5+SH0ES}}^2$ obtained in the analyses with BAO 3D are significantly larger in the w_0w_a CDM and w XCDM models compared to those obtained in the analyses with BAO 2D. This is essentially due to the Hubble tension, which is not cured if we use anisotropic BAO. In contrast, for Λ_s CDM the value remains quite stable and larger than in the other non-standard cosmologies in both analyses. This might be related to the fact that DES-Y5 data prefers dynamical DE rather than a rigid Λ term

⁶It has been argued in many papers that the true tension has to be quantified in terms of M , see, e.g., [115–117]. Notice that the Hubble tension evaluated in terms of H_0 and using the distance ladder measurement of the Hubble function obtained from the SH0ES calibration of M and the SNIa in the Hubble flow from DES-Y5 ($H_0 = 70.5 \pm 1.1$ km/s/Mpc [108]) is found to be artificially small when BAO 3D is employed in the fitting analyses.

(even if changing sign at a transition point); (ii) CMB data is much better accommodated by Λ CDM if use is made of BAO 3D. However, the other models still decrease χ_{CMB}^2 by ~ 3 units.

To summarize, although we find a very different response of the various models studied in this work to the cosmological tensions when we build the inverse distance ladder using angular or anisotropic BAO data, we consistently find evidence supporting physics beyond Λ CDM, regardless of the BAO type and using a very rich and diverse set of cosmological measurements.

5 Conclusions

In this Letter, we have assessed the impact of composite DE scenarios versus monocomponent scenarios concerning a possible resolution of the cosmological tensions [34]. We have revisited standard parameterizations of the DE, such as w CDM [44] and w_0w_a CDM [49, 50] assuming one single DE fluid against transitional models with two fluids, wherein the DE density undergoes a sign flip at some point in the ‘recent’ past (typically at around $z_t \simeq 1 - 2$). We have compared the results of these parameterizations with the model w XCDM [43], used as an archetype of composite model exhibiting an EoS transition at a point z_t , and we have compared all these models with the simplest situation, in which the DE is represented by a rigid cosmological term, i.e. the standard Λ CDM model. We have found that in general the dynamical DE models (above all w XCDM and w_0w_a CDM) prove to be more efficient than the Λ CDM to fit the overall cosmological data. This is a major result of our study, which is fully in line with previous large scale analyses of cosmological data made a few years ago [24–30], in which dynamical DE was already being strongly advocated. In particular, the suitability of the dynamical character of the DE also applies to the composite models under discussion; and we should furthermore stress that the statement holds good both under transversal-only and anisotropic-only BAO data (or BAO 2D and BAO 3D, respectively, for short). This result is highly remarkable in itself, especially if we take into account that these two versions of the BAO data are still in conflict; see, in particular, the analyses of [45, 95, 96] and references therein. We cannot exclude the fact that the ultimate reason (or at least a major influence) behind the H_0 -tension lies precisely in such a BAO conflict. But even if it is the case, we have proven here that the overall fit with all the cosmological data, which means that with any of these BAO types alone together with the remaining CMB+CCH+LSS+DESY5+SH0ES data sets, can be significantly improved with dynamical models of the DE and particularly with composite DE models involving a sign flip of the energy density at a transition redshift z_t . We have also shown that exceedingly simple DE parameterizations with a fixed EoS parameter, such as the w CDM, fail short to improve the yield of the standard Λ CDM. Successful parameterizations require dynamical EoS or a composite DE structure with more than one EoS parameter acting at different stages of the cosmic evolution.

As indicated, the basic composite model that we have used to illustrate our claim is the w XCDM model proposed in [43], consisting of two DE components X and Y acting in sequence and possessing respective EoS parameters w_X (for $z > z_t$) and w_Y (for $z < z_t$) together with sign-flipped DE densities $\rho_X < 0$ and $\rho_Y > 0$. We have compared this model with a particular implementation of it (or at least it can be viewed effectively as such), the so-called Λ_s CDM model [46], in which the two EoS parameters w_X and w_Y are both fixed at -1 (corresponding to a cosmological constant Λ) with a sign flip of Λ at the transition point z_t . Despite this setting reducing the number of parameters to just one (z_t), our analysis clearly demonstrates that if w_X and w_Y are left as part of the fitting degrees of freedom (as is indeed the case in the w XCDM) the increase in quality of the fit can be so high that it more than compensates for the penalty received by the information criteria for the two extra free parameters that the w XCDM has as compared to the Λ_s CDM. The outcome is that w XCDM performs optimally and, in addition, it provides dynamical DE results compatible with the last DESI measurements, [22, 23] since the late component of w XCDM, i.e.

Y , is found to have a quintessence-like EoS behavior ($w_Y \gtrsim -1$). Obviously, this feature is not possible within the rigid structure of the Λ_s CDM. We also note that despite the fact that the Λ_s CDM model performs better than the Λ CDM (as a global fit), it nevertheless performs less than the w_0w_a CDM parameterization under the present data. The composite scenarios may actually serve as generic parameterizations for possible fundamental models of the DE. As previously noted, the w XCDM composite structure with phantom matter (PM) mimics the old Λ XCDM model [40] and it also appears in stringy versions of the running vacuum model (RVM) [15, 16].

Although the overall fit quality obtained from the composite DE scenarios can be much better than the Λ CDM, we find that insofar as concerns the specific amelioration of the tensions, the result depends on whether our global fit is performed using BAO 2D (only) or BAO 3D (only). Remarkably, the growth tension can be highly relieved for all models when expressed in terms of the σ_{12} parameter [77], the alleviation being complete only in the w XCDM under BAO 2D. However, the H_0 tension can be fully cut down only in the BAO 2D case, but not for BAO 3D.

All in all, dynamical DE models admitting a variable EoS and/or a transitional EoS structure around a transition redshift z_t prove highly successful in improving the standard model description of the cosmological data. In particular, the archetype composite model w XCDM with a transition redshift offers an outstanding quality fit with BAO 2D data and a possible solution to the cosmological tensions. In addition, this model mimics the conceptual framework capable of affording a better understanding of the potentially involved physical phenomena, which is the stringy RVM [15, 16]. As explained in [43], within this fundamental framework the generation of a phantom matter (PM) bubble is induced by quantum fluctuations. The phenomenon can be iterated throughout the cosmic expansion: the bubbles of PM might be behind the anomalous outgrowth of structures found at redshifts in the high range $z \sim 10$. If so, the w XCDM scenario would offer a possible explanation for the appearance of the supermassive galaxies recently spotted by the JWST mission [37, 111, 120]. We believe that such a possibility deserves a separate study.
