Understanding the Page curve and resolving the black hole information puzzle in terms of the entanglement dynamics of black holes has been a key question in fundamental physics. In principle, the current quantum computing can provide insights into the entanglement dynamics of black holes within some simplified models. In this regard, we utilize quantum computers to investigate the entropy of Hawking radiation using the qubit transport model, a toy qubit model of black hole evaporation. Specifically, we implement the quantum simulation of the scrambling dynamics in black holes using an efficient random unitary circuit. Furthermore, we employ the swap-based many-body interference protocol for the first time and the randomized measurement protocol to measure the entanglement entropy of Hawking radiation qubits in IBM's superconducting quantum computers. Our findings indicate that while both entanglement entropy measurement protocols accurately estimate the Rényi entropy in numerical simulation, the randomized measurement protocol has a particular advantage over the swap-based many-body interference protocol in IBM's superconducting quantum computers. Finally, by incorporating quantum error mitigation techniques, we establish that the current quantum computers are robust tools for measuring the entanglement entropy of complex quantum systems and can probe black hole dynamics within simplified toy qubit models.

I. INTRODUCTION

Quantum entanglement [1] is paramount in quantum computing, quantum information science, quantum many-body physics, high energy and nuclear physics, and the physics of black holes. Its dynamics are tied to the non-equilibrium aspects and thermalization of quantum many-body systems [2, 3]. Besides, harnessing the dynamics of quantum information and entanglement is essential for developing quantum technologies and studying complex quantum systems [4, 5].

Recently, significant experimental progress has been made to measure entanglement entropy and characterize quantum systems [6–15] (for a review, see [16]). Quantum computers, with their impressive advancement over the past years, have positioned themselves as an important experimental tool offering in-depth understanding of the quantum many-body systems, as the fundamental building blocks of the many-body systems either have the same degrees of freedom or can be easily mapped to the qubits/qudits of the quantum computers. Moreover, the quantum computer as the quantum simulator [17–19] can probe not only the microscopic intricacies of the quantum systems but also the emergent collective phenomena not seen in their constituents. Therefore, quantum computers can be a perfect means to measure the entanglement entropy of quantum many-body systems.

Quantum entanglement also plays a crucial role in the Hawking radiation and the black hole information [20–28]. Inspired by the Hayden-Preskill thought experiment [29] (also known as Hayden-Preskill protocol) and Yoshida-Kitaev decoding protocol [30], both addressing the information retrieval and reconstruction of the quantum state from the Hawking radiation, we set to present how a quantum computer can probe the entanglement dynamics of the evaporating black hole. For this purpose, we consider a toy qubit model of the black hole, namely the qubit transport model [31] (similar models are [32–35]) which describes the unitary dynamics of the black hole evaporation and information transfer to the Hawking radiation. In our quantum simulation of the qubit transport model, the entropy of the Hawking radiation entails gradually measuring the entanglement entropy of qubit subsystems of different sizes.

We know that when the quantum state is in the random pure state, the averaged entanglement entropy of its subsystems, taken with respect to unitary-equivalent Haar measure, is given by the Page entropy [36–39]. The Page

† kyu@bnl.gov

entropy captures the universal feature of random pure states relevant to the unitary dynamics of the black holes and quantum many-body systems. In this work, we present a way to utilize the quantum computer to measure the Page entropy of subsystems of such a Haar-random quantum state. We use two protocols: the swap-based many-body interference (SWAP-MBI) protocol [40–42] and the randomized measurement (RM) protocol [8, 43–48], to measure the Rényi entropy of the subsystems, which we called the Hawking radiation qubits in later sections. We consider the Haar-random quantum state to represent the highly entangled state of the black hole qubits in our black hole quantum simulation setup. We mainly focus on the build-up of Rényi entropy in those subsystems under the random unitary dynamics, thus simulating the scrambling of information in black holes. Such random unitary dynamics in our quantum simulation are carried out using an efficient random unitary circuit (RUC) of the brickwall structure (for a review, see [49]) with quantum computers with limited qubit connectivity in mind. Furthermore, we minimize the circuit depth of each brickwall layer by adopting an optimal two-qubit entangling gate [50]. Subsequently, we implement our protocols in IBM’s superconducting quantum computers, and combining with quantum error mitigation techniques, we measure the entanglement entropy associated with different subsystems, thereby leveraging the quantum computers to directly probe the Page curve, which is pertinent to the black hole dynamics and the quantum information scrambling in quantum many-body systems.

The structure of the manuscript is as follows. In section II, we describe the Page entropy of a quantum system, the qubit transport model for the unitary black hole evaporation, and its quantum circuit implementation. Section III describes the implementation of black hole’s scrambling dynamics using our efficient random unitary circuit. In section IV, we delineate the implementation of two protocols for measuring the entanglement (Rényi) entropy in quantum computers: swap-based many-body interference protocol and the randomized measurement protocol, with IBM’s superconducting quantum computers in mind. We present the results from our numerical simulation and actual quantum computer in section V. Finally, we conclude in section VI.

II. QUBIT TRANSPORT MODEL OF THE BLACK HOLE IN QUANTUM COMPUTERS

A. Black hole as a quantum system

1. Page entropy

First, we introduce the general notion of entanglement entropy as it is associated with a quantum system. Consider a system of N qubits in a random pure state $|\psi\rangle$, whose density matrix is given by $\rho = |\psi\rangle\langle\psi|$. If we partition this system into two subsystems of L and $M = N - L$ qubits, the entanglement entropy, i.e., the n -Rényi entropy associated with the L -qubit subsystem is given by,

$$S_L^{(n)} = \frac{1}{n-1} \log[\text{Tr}(\rho_L^n)] \quad (1)$$

where ρ_L is the reduced density matrix of the subsystem with L qubits, obtained by tracing the subsystem of $M = N - L$ qubits, $\rho_L = \text{Tr}_M \rho$. The $n = 2$ case is the 2-Rényi entropy (Rényi entropy for simplicity), whose measurement we are focusing on in this study. Additionally, when $n \rightarrow 1$, the n -Rényi entropy boils down to the von Neumann entropy,

$$S_L^{vN} = -\text{Tr} \rho_L \log \rho_L. \quad (2)$$

Now the Page entropy, i.e. the average von Neumann entropy for the L -qubit subsystem over all random pure states ρ is given by

$$S_{L,M}^{vN} = \sum_{k=2^{M+1}}^{2^N} \frac{1}{k} - \frac{2^L - 1}{2^{M+1}}, \quad L \leq M \quad (3)$$

where, the average is taken with respect to unitarily invariant Haar measure on the space of unit vectors $|\psi\rangle$ in the 2^N dimensional Hilbert space [36, 39]. Besides, the space of such random states is equivalent to the volume of hypersphere $S^{2^{N+1}-1}$. For $L > M$ case, we make the following substitution ($L \leftrightarrow M$) in Eq. (3). When $1 \ll L$, it also simplifies to

$$S_{L,M}^{vN} \approx L \log 2 - (1/2^{N-2L-1}) \quad (4)$$

which further becomes the thermodynamic entropy for the L -qubit subsystem, $S_L^{\text{Th}} \approx L \log 2$ when $L \ll N$.

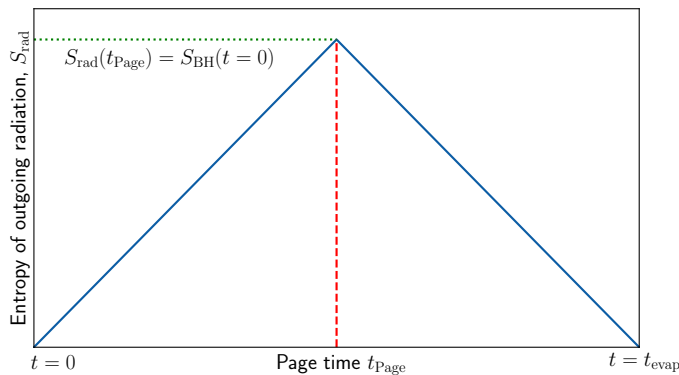

FIG. 1. Schematic behavior of the entropy of the outgoing Hawking radiation when the black hole is governed by unitary dynamics. This curve is known as the Page curve associated with the entropy of the Hawking radiation.

On the other hand, the average Rényi entropy corresponding to the L -qubit subsystem over the space of random states $|\psi\rangle$ is given by [51],

$$S_L^{(2)} = -\log\left(\frac{2^L + 2^{N-L}}{2^N + 1}\right). \quad (5)$$

Moreover, as the n -Rényi entropy satisfies the inequality¹ $S_L^{(m)} \geq S_L^{(n)}$ for $m \leq n$ for a L -qubit subsystem, we can see that the Page entropy, namely the von Neumann entropy given in Eq. (3) will serve as the upper bound of the corresponding Rényi entropy $S_L^{(2)}$ of the corresponding subsystem.

2. The entropy of the Hawking radiation

Now, we provide a lightning overview of the entropy of the Hawking radiation put forward by Page [23]. Consider a black hole is formed at some time $t = 0$ with an area A_0 . The Bekenstein-Hawking (BH) entropy [53, 54], S_{BH} associated with this black hole in Planck units ($\hbar = c = G = k_{\text{Boltzmann}} = 1$) is given by,

$$S_{\text{BH}} = \frac{A_0}{4} \quad (6)$$

Due to the finiteness of S_{BH} , we consider, assuming the entropy to be an integer, that the black hole consists of $N = S_{\text{BH}}/\ln 2$ qubits. Moreover, we assume that the quantum state associated with N qubits is in a pure state after the formation of the black hole. However, the qubits themselves are highly entangled with each other due to the fast scrambling governed by a complex unitary transformation. Similarly, the outgoing Hawking radiation can be thought of as made out of qubits. As the black hole evaporates gradually by the emission of Hawking radiation, in our qubit scenario of the black hole, this physical process is represented by the reduction of the black hole qubits N and the increase of Hawking radiation qubits denoted as N_{rad} . During the emission of the Hawking radiation, the Hawking radiation qubits will have a varying entanglement with the rest of the black hole qubits. At a specific time called the Page time, t_{Page} , the entanglement entropy S_{rad} of the outgoing Hawking qubits will be equal to the initial Bekenstein-Hawking entropy of the black hole, in other words, Hawking qubits are maximally entangled with the black hole qubits. After the Page time, the entanglement entropy of the Hawking qubits will gradually decrease because the information content of the black hole beyond the horizon is now transferred more and more to the Hawking qubits. When the black hole evaporates, all of its information content is transferred to the Hawking qubits, which are again in a pure state and thus will have zero entanglement entropy. In Fig. 1, we present the above schematic picture of the time dependence of the entanglement entropy associated with the Hawking radiation. In the subsequent sections, we will elaborate on these dynamics with a more microscopic but still toy model of a black hole with qubits, namely the qubit transport model of the black hole.

¹ For a detailed discussion [52]

B. Qubit Transport Model

In the qubit transport model of the black hole, we assume the black hole consists of N qubits, which are entangled due to the fast scrambling. Apart from this assumption, we consider N outgoing radiation qubits just outside and N infalling radiation qubits just inside the black hole's event horizon. Furthermore, an infalling radiation qubit and an outgoing radiation qubit form a singlet Bell state, and the vacuum state at the vicinity of the event horizon can be considered as the tensor product of such a singlet Bell state. As the $2N$ infalling and outgoing radiation qubits at the horizon are part of the vacuum fluctuations, as in the case of forming the Hawking radiation, the product of the singlet Bell state does not contribute to the entropy of the black hole. We denote the black hole qubits, infalling radiation qubits, and outgoing radiation qubits as q_i , a_i and b_i , respectively. The singlet Bell state of the infalling and outgoing radiation qubits is,

$$|B\rangle_{a_i b_i} = \frac{1}{\sqrt{2}}(|0\rangle_{a_i}|1\rangle_{b_i} - |1\rangle_{a_i}|0\rangle_{b_i}) \quad (7)$$

Initially the quantum state of the black hole and radiation qubits is given by

$$|\Psi_{\text{initial}}\rangle = \left(\sum_{s_1, s_2, \dots, s_N=0}^1 A_{s_1 s_2 \dots s_N} |s_1\rangle_{q_1} |s_2\rangle_{q_2} \dots |s_N\rangle_{q_N} \right) \otimes \prod_{i=1}^N |B\rangle_{a_i b_i} \quad (8)$$

where $|s_i\rangle_{q_i}$ is the quantum state of the i -th black hole qubit q_i in the computational basis.

In the qubit transport model, it is assumed that the quantum state of i -th black hole qubit q_i and the singlet Bell state associated with the i -th infalling and outgoing radiation qubits undergo the following transition,

$$|s_i\rangle_{q_i} |B\rangle_{a_i b_i} \rightarrow -|B\rangle_{q_i a_i} |s_i\rangle_{b_i} \quad (9)$$

which can be realized by the continuous unitary transformation $U(\theta)$ on the state $|s_i\rangle_{q_i} |B\rangle_{a_i b_i}$ where,

$$U(\theta) = e^{-i\theta P_{q_i a_i b_i}} \quad \text{with} \quad (10)$$

$$P_{q_i a_i b_i} = \frac{1}{2} [|0\rangle_{q_i} \langle 0|_{q_i} I_{a_i} |1\rangle_{b_i} \langle 1|_{b_i} - |1\rangle_{q_i} \langle 0|_{q_i} I_{a_i} |0\rangle_{b_i} \langle 1|_{b_i} - |0\rangle_{q_i} \langle 1|_{q_i} I_{a_i} |1\rangle_{b_i} \langle 0|_{b_i} + |1\rangle_{q_i} \langle 1|_{q_i} I_{a_i} |0\rangle_{b_i} \langle 0|_{b_i}]$$

At $\theta = \pi$ the unitary transformation $U(\pi) = \mathbb{I} - 2P_{q_i a_i b_i}$ executes the swap operation as in Eq. (9). One can consider the θ parameter of $U(\theta)$ is a function of radius r that changes 0 at the black hole horizon to π at the radial infinity. It can be also expressed as

$$\theta = \pi (1 - K/K_{\text{horizon}}) \quad (11)$$

where $K = R^{\mu\nu\rho\sigma} R_{\mu\nu\rho\sigma}$ is the Kretschmann scalar [55] associated with the Riemann curvature tensor $R_{\nu\rho\sigma}^{\mu}$ as it captures the curvature of the space-time with radial distance from the black hole horizon, and K_{horizon} is its value at the horizon. Therefore, we can see that due to the swap operation between the quantum states of the black hole qubit q_i and the outgoing radiation qubit b_i , the black hole qubit's quantum state emits through the Hawking radiation qubit. After the emission, the remaining singlet Bell state of the black hole qubit q_i and infalling radiation qubit a_i can be treated as the part of the vacuum state, so effectively the black hole will now have $N - 1$ black hole qubits. One can notice that although the Hawking radiation qubit is emitted from the black hole, its quantum state has been entangled with the rest of the black hole qubits due to the fast scrambling. For this reason, the Hawking radiation qubits will maintain the entanglement with the black hole qubits. As a consequence, after the emission of the N_{rad} Hawking radiation qubits, the quantum state of the effective $N - N_{\text{rad}}$ black hole qubits and N_{rad} Hawking radiation qubits will still be entangled. If we trace out the subsystem of the $N - N_{\text{rad}}$ black hole qubits, as one would never have any direct access to them, we can immediately compute the entanglement entropy of N_{rad} Hawking qubits given by the quantity S_{rad} .

Finally, when all of N of the original outgoing radiation qubits have left the black hole and propagated to become the Hawking radiation qubits, there are no qubits left for the black hole; hence, it is completely evaporated away. The quantum state associated with the initial N entangled black hole qubits is now transferred into N Hawking radiation qubits, which then form a pure quantum state, just like the original quantum state of the black hole qubits, as follows,

$$|\Psi_{\text{final}}\rangle = \sum_{s_1, s_2, \dots, s_N=0}^1 A_{s_1 s_2 \dots s_N} |s_1\rangle_{b_1} |s_2\rangle_{b_2} \dots |s_N\rangle_{b_N} \quad (12)$$

FIG. 2. The N black hole qubits, infalling qubits, and outgoing qubits are denoted by q_i , a_i and b_i , respectively, in the left quantum circuit. The i -th infalling and outgoing qubits form the singlet Bell state $|B\rangle_{a_i b_i}$, represented in the quantum circuit at right. Now, the outgoing qubits b_i interact with the highly entangled black hole qubits q_i through the swap gate. As a result, the quantum states of the black hole qubits q_i are now transferred to the outgoing Hawking radiation qubits. The resulting Bell states $|B\rangle_{q_i a_i}$ become part of the vacuum fluctuations and can be omitted from further computations.

C. Quantum Circuit for the Qubit Transport Model

One can represent the previous discussion of the qubit transport model in terms of quantum circuits. The initial representation of the model with the quantum circuit requires three N -qubit registers realizing the black hole qubits q_i , infalling radiation qubits a_i and outgoing radiation qubits b_i , respectively, as seen in Fig. 2. We can implement the scrambling dynamics of the black hole dynamics with the random unitary circuit or time evolution operator driven by some Hamiltonian. The explicit implementation of this scrambling dynamics is addressed in section III. In addition, the vacuum state is the product of N singlet Bell states $|B\rangle_{a_i b_i}$, each formed through the pairing of an infalling and an outgoing radiation qubit, a_i and b_i , respectively as shown in Fig. 2 (right). At this point, the quantum state associated with our quantum circuit represents the total quantum state of the black hole and its vacuum fluctuation $|\Psi_{\text{initial}}\rangle$ in Eq. (8). Now, instead of considering the unitary transformation given in Eq. (10) with the θ parameter depending on the curvature with respect to the radial distance from the horizon, we directly implement Eq. (9) through the consecutive swap gates between i -th black hole qubit q_i and the outgoing radiation qubit b_i . This operation will lead to the transfer of the black hole quantum state in the black hole qubit register $\{q_0, \dots, q_{N-1}\}$ to the outgoing radiation qubit register $\{b_0, \dots, b_{N-1}\}$ which is now the Hawking radiation qubits and the product state of the singlet Bell states $|B\rangle_{q_i a_i}$ between i -th black hole qubit q_i and the infalling radiation qubit a_i can be considered as the part of vacuum fluctuations. As such product state of the singlet Bell states is not used in overall computation, we can realize the physical aspects of the qubit transport model in a more compact way using the quantum circuit in Fig. 3.

In this case, we again implement the scrambling on the black hole qubits q_i . Now we select the subsystems of $N_{\text{rad}} = 1, 2, \dots, N$ qubits $\{q_0, \dots, q_{N_{\text{rad}}}\}$ as the Hawking radiation qubits in a subsequent manner as shown in Fig. 3. Due to the scrambling, all black hole qubits are entangled. Therefore, for every subsystem of N_{rad} qubits with increasing N_{rad} , the corresponding reduced density matrix will give rise to the entanglement entropy, i.e., the Rényi entropy $S^{(2)}$, of the Hawking radiation qubits. The gradual increase of the subsystem size of Hawking radiation qubits N_{rad} can be identified with the time of the black hole evolution as shown in Fig. 1. Therefore, in our simplified quantum circuit dynamics, the Page time t_{Page} will imply the maximum value of the entanglement entropy $S_{\text{rad}}^{\text{max}} = S_{\text{BH}}$ for the subsystem of $N_{\text{rad}} = N/2$ Hawking qubits. For $t > t_{\text{Page}}$, the subsystem of Hawking qubits will have $N_{\text{rad}} > N/2$, which leads to the decrease of its corresponding entanglement entropy because the information content of the Hawking qubit subsystem increases. Eventually, at $t = t_{\text{evap}}$, the Hawking radiation subsystem will contain $N_{\text{rad}} = N$ qubits and, therefore, will represent again the pure state of the black hole qubits.

As mentioned in section I, quantum computers are the perfect means of measuring the entanglement entropy of a subsystem. Therefore, we can adopt two possible uses of quantum computers in studying the entanglement entropy

FIG. 3. Another viewpoint of the qubit transport model in the quantum computer. Here, the scrambling operation prepares a highly entangled state of N black hole qubits. Then, the subsystems consist of q_0 , $\{q_0, q_1\}$, $\{q_0, q_1, q_2\}$ qubits, and so on, are considered as the Hawking radiation qubits.

of the black hole.

- An observer near the black hole continuously collects the Hawking radiation qubits right after its formation. The access to a quantum computer immediately allows the observer to measure the entanglement entropy associated with collected Hawking radiation qubits. Even if there is no accessible quantum computer nearby, the quantum state can be transmitted to an available one using the teleportation protocol. Thus, the quantum computer can be utilized to study the entanglement entropy of the Hawking radiation qubits directly. We present a schematic diagram of this viewpoint in Fig. 4.

FIG. 4. We could imagine collecting the Hawking radiation, thereby its quantum state, and using the quantum teleportation protocol to send it to the quantum computer, which can then be used to measure its entanglement entropy using the entanglement entropy measurement protocols.

- As the qubit transport model considers the unitary dynamics of the black hole, one can use the quantum computer to carry out the quantum simulation of the black hole's scrambling dynamics. As sketched in Fig. 3 and 5, the entanglement dynamics of the Hawking radiation qubits can be captured consecutively by measuring the entanglement entropy of qubit subsystems of increasing sizes.

FIG. 5. One can also imagine simulating the black hole dynamics, namely its scrambling dynamics in the quantum computer and measure the entanglement entropy of the subsystems using the protocols.

III. SCRAMBLING DYNAMICS OF BLACK HOLES IN QUANTUM COMPUTERS

We simulate the system of N black hole qubits with the one-dimensional spin chain with open boundary conditions, and the scrambling dynamics is implemented by the random unitary circuit (RUC) acting on the spin chain as shown

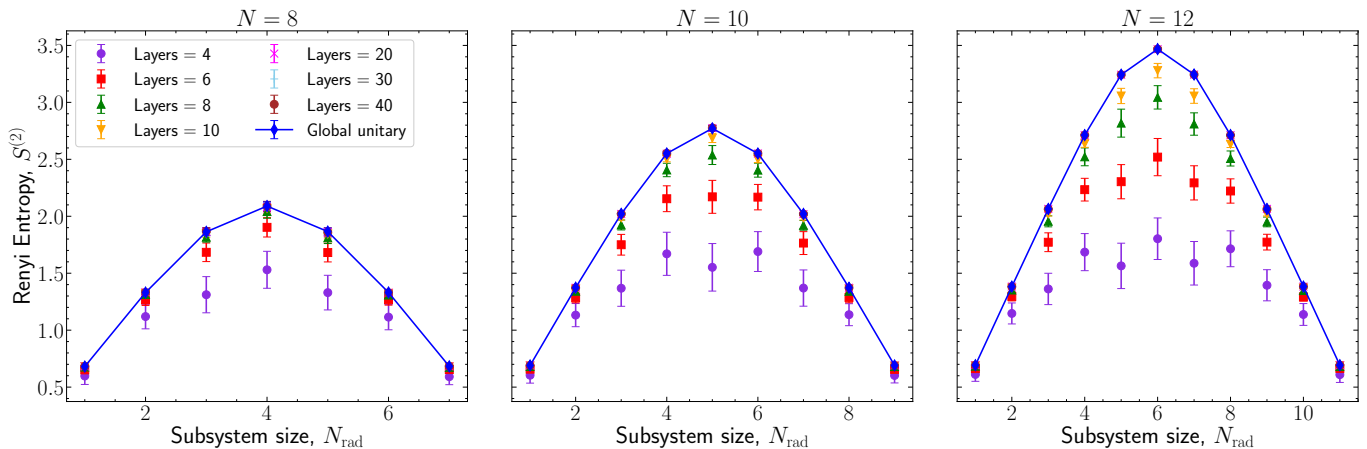

FIG. 7. The Rényi entropy $S^{(2)}$ of the left-block subsystems of sizes N_{rad} with increasing number of layers in the brickwall random unitary circuit for three cases $N = 8, 10, 12$. For each case, the average and the standard deviation of the Rényi entropy is determined from 100 realizations of the random unitary circuits and the global Haar-random unitary matrices.

where $R_z(\theta) = \text{diag}(e^{-i\frac{\theta}{2}}, e^{i\frac{\theta}{2}})$. The circuit depth associated with this circuit is 13 which can be minimized by the following optimal circuit² [50] for the $U_{\text{entangle}}^{(4)}$ gate,

whose circuit depth is 7.

In Fig. 7 we see the buildup of the entanglement in the subsystems of the $N = 8, 10$ and 12 qubits with an increasing number of brickwall layers. For all three cases we can see that when the subsystem size is $N_{\text{rad}} = N/2$, i.e., the Hawking radiation qubits to be the half of the black hole qubits, the Rényi entropy associated with the subsystem becomes the maximum, whose value depends on the total size of the qubits N .

IV. ENTANGLEMENT ENTROPY MEASURING PROTOCOLS IN QUANTUM COMPUTERS

Consider a quantum computer given access to a quantum state whose purity and Rényi entropy we would like to probe. In this regard, we can consider the two protocols to measure the purity and Rényi entropy of the corresponding state: 1. swap-based many-body interference protocol and 2. randomized measurement protocol. The following sections present a detailed overview of the two protocols.

A. Swap-based many-body Interference Protocol

Consider two systems A and B of N qubits with density matrices $\rho_A = |\alpha_A\rangle\langle\alpha_A|$ and $\rho_B = |\beta_B\rangle\langle\beta_B|$, respectively. Now the action of the swap operation V_{SWAP} on the states is

$$V_{\text{SWAP}}|\alpha_A\rangle|\beta_B\rangle = |\beta_B\rangle|\alpha_A\rangle \quad (16)$$

Now immediately we can compute the following quantity,

$$v = \text{Tr}[V_{\text{SWAP}}(\rho_A \otimes \rho_B)] = \text{Tr}[\rho_A \rho_B] \equiv |\langle\alpha_A|\beta_B\rangle|^2 \quad (17)$$

² For previous works see [61–63]

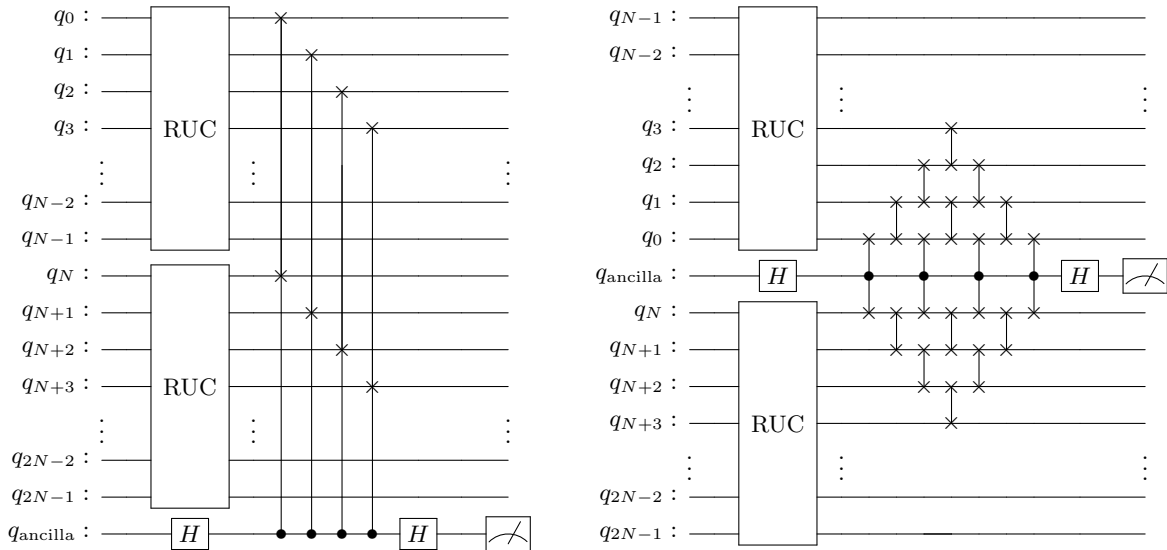

FIG. 8. (Left) Measuring the Rényi entropy of the left-subsystem containing L qubits using the SWAP-based many-body interference protocol. Here, using the same random unitary circuit RUC, we prepare two identical random pure states in $\{q_0, \dots, q_{N-1}\}$ and $\{q_N, \dots, q_{2N-1}\}$ qubit registers, respectively. Afterward, we employ the swap operation between qubits $q_i \leftrightarrow q_{N+i}$ of two left-subsystems with L (here, $L = 4$ as an illustration) qubits and proceed to measurement at the ancilla qubit q_{ancilla} . (Right) To measure the purity and Rényi entropy of the left-subsystem of L qubits in a quantum computer with limited qubit connectivity, we rearrange the qubit registers to prepare identical states and use a series of swap gates to bring the qubits q_i and q_{i+N} ($i = 0, 1, \dots, L$) closest to the q_{ancilla} before executing the required controlled-swap for the SWAP-MBI protocol.

We can estimate v using the probability of finding the ancilla qubit in $|0\rangle$ state P_0 , i.e., $v = 2P_0 - 1$, of the following quantum circuit:

Now if one have two identical copies of the L -qubit subsystem with reduced density ρ_L , the swap-based many-body interference protocol presented above will allow us to estimate the purity $\text{Tr}(\rho_L^2)$ and consequently, the Rényi entropy, $S^{(2)} = -\log \text{Tr}(\rho_L^2)$, as shown in Fig. 8. In the following steps, we summarize the swap-based many-body interference (SWAP-MBI) protocol to measure the purity and the Rényi entropy of a L -subsystem within a system of N qubits,

1. First, we take a quantum register of $2N + 1$ qubits. Then we prepare two identical copies of a quantum state $|\psi\rangle$ by applying the same unitary operator U , for example the random unitary circuit RUC or the time evolution operator e^{-iHt} , on the initial state $|i\rangle$ over $\{q_0, \dots, q_{N-1}\}$ and $\{q_N, \dots, q_{2N-1}\}$ qubit registers, respectively.
2. Then for our considered subsystem of L qubits $\{q_{i_1}, \dots, q_{i_L}\}$ where indices i_1, \dots, i_L are chosen from $[0, N - 1]$, we first apply the Hadarmard gate to the ancilla qubit q_{ancilla} followed by series of controlled-swap on qubits $q_{i_j} \leftrightarrow q_{N+i_j}$ for $j = 1, \dots, L$, and then another Hadarmard gate to q_{ancilla} . Finally, we measure the ancilla qubit on a computational basis.
3. If we estimate the probability of finding the q_{ancilla} in $|0\rangle$ as P_0 from our measurements, then the purity associated with the L -qubit subsystem will be given by $v = \text{Tr}(\rho_L^2) = 2P_0 - 1$, and consequently the estimated Rényi entropy as $S^{(2)} = -\log(v)$.
4. For cases of limited qubit connectivity as in Fig. 8 (right), when the left-subsystem contains L qubits, the number of swap gates needed to bring q_i and q_{i+N} where $i = 0, 1, \dots, L$ scales as $L(L - 1)$. Besides, the number of controlled-swap gates scales as L .

B. Randomized Measurement Protocol

The randomized measurement protocol (RM protocol) uses the fact that the Rényi entropy of a quantum system is contained in the statistical correlations between the outcomes of measurement performed on random bases. We are dealing with a pure quantum state ρ of the N qubits produced from the random unitary circuit. Therefore, the purity and the Rényi entropy are determined for the reduced density matrices associated with the subsystem A of $L < N$ qubits, in other words, the Hawking radiation qubits. We present a schematic quantum circuit of the RM protocol in Fig. 9. The experimental implementation of this protocol contains several steps, which we present below.

First, the quantum state ρ is prepared by applying the random unitary circuit on N qubits. This operation will produce a highly entangled quantum state of the qubits. We aim to measure the purity and Rényi entropy associated with the subsystem A of L qubits. Now, one applies a product of single-qubit unitary operators where each of them acts on the i -th qubit of the A subsystem, i.e., $i \in A$, as

$$\hat{U}_a = U_1^{(2)} \otimes U_2^{(2)} \otimes \dots \otimes U_L^{(2)} \quad (18)$$

Additionally, each of the single-qubit unitary $U_i^{(2)}$ is drawn independently from the circular unitary ensemble (CUE) of the $SU(2)$. Subsequently, one measures the qubits on the computational basis (Z -basis). For each \hat{U}_a , the repeated measurements are made to obtain the statistics (generally known as shots), which leads one to estimate the occupation probabilities, $P_{\hat{U}_a} = \text{Tr}[\hat{U}_a \rho \hat{U}_a^\dagger |j_L\rangle\langle j_L|]$ of computational basis states $|j_L\rangle = |s_1, s_2, \dots, s_L\rangle$ with $s_i = 0, 1$. Here, \hat{U}_a acts only on the subspace of L qubits. Afterward, the entire process is repeated for N_U different randomly drawn instances of \hat{U}_a .

After determining the set of outcome probabilities $P_{\hat{U}_a}(j_L)$ of the computational basis states $|j_L\rangle$ for one instance of random unitaries, \hat{U}_a , one computes the following quantity,

$$X_a = 2^L \sum_{j_L, j'_L} (-2)^{-D[j_L, j'_L]} P_{\hat{U}_a}(j_L) P_{\hat{U}_a}(j'_L) \quad (19)$$

where, j_L and j'_L are different bitstring outcomes for the L qubits, and $P_{\hat{U}_a}(j_L), P_{\hat{U}_a}(j'_L)$ are their corresponding outcome probabilities for the corresponding \hat{U}_a . In addition, $D[j_L, j'_L]$ is the Hamming distance between bitstrings $j_L = s_1 s_2 \dots s_L$ and $j'_L = s'_1 s'_2 \dots s'_L$, measuring how different two bitstrings are, i. e., $D[j_L, j'_L] \equiv \#\{i \in A | s_i \neq s'_i\}$. Consequently the ensemble average of X_a , denoted by \bar{X} ,

$$\bar{X} = \frac{1}{N_U} \sum_{a=1}^{N_U} X_a \quad (20)$$

is nothing but the second-order cross-correlations across the ensemble of discrete N_U random unitaries \hat{U}_a , and provides the estimation of the purity $\text{Tr}(\rho_A^2)$ associated with a subsystem of L qubits, $\{q_{i_1}, \dots, q_{i_L}\}$ where indices i_1, \dots, i_L are chosen from $[0, N - 1]$ in a system of N qubits. Finally, the Rényi entropy is

$$S^{(2)} = -\log \bar{X} \quad (21)$$

In passing, as shown in [46], the RM protocol can be recast as the swap-based many-body interference protocol where the swap operator effectively acts on the two virtual copies of ρ_A .

FIG. 9. The randomized measurement (RM) protocol, where the quantum state is prepared using RUC. Then randomized measurements on a subsystem A (here, $L = 4$ left-subsystem as an example) are performed by applying N_U product of local random unitaries $\hat{U}_a = \otimes_{i=1}^L U_i^{(2)}$ where each $U_i^{(2)}$ is sampled from CUE. Subsequently, a measurement in the computational basis is performed. Finally, the statistical correlation of the outcomes of such randomized measurements is used to estimate the purity $\text{Tr}(\rho_A^2)$ and Rényi entropy of the reduced density matrix ρ_A .

V. RÉNYI ENTROPY OF THE HAWKING RADIATION IN QUANTUM COMPUTERS

A. Numerical Simulation

We consider three cases for our numerical simulation: $N = 8, 10$, and 12 . First of all, for computing the Rényi entropy of a subsystem, we use the simplest, most accurate, but most limited method, which is applying the brickwall layers of $SU(4)$ two-qubit unitary gates in the random unitary circuit Fig. 6 to the vector of 2^N complex coefficients, representing the quantum statevector of N qubits. Afterward, we choose the subsystem of N_{rad} qubits and numerically carry out the partial trace and singular value decomposition to compute the corresponding Rényi entropy. The numerical matrix computations corresponding to RUC use QuSpin [64] and Qiskit’s `qiskit.quantum_info.Statevector` [65]. We denote the results from these computations as ‘Statevector’ in our plots.

To implement the $SU(4)$ two-qubit unitary gates corresponding to the Haar-random $U^{(4)}$, first we determine the $U^{(4)}$ (with $\det U^{(4)} = 1$) using the numerical routine `scipy.stats.unitary_group` prescribed in [66]. Then, we use the Cartan-Weyl decomposition Eq. (15) to determine the unitary gates of the two-qubit quantum circuit from $U^{(4)}$. Moreover, we use `scipy.stats.unitary_group` to determine the global haar-random unitary matrices acting on the $N = 8, 10$, and 12 , respectively. In Fig. 7, we can see that the RUC with increasing numbers of brickwall layers can achieve the saturated value of the Rényi entropy for different subsystems of N_{rad} qubits, where the saturated value can be obtained by the respective global Haar-random unitary matrix acting on the N qubits. On the other hand, when N is larger, a larger number of brick wall layers is needed to reach the saturated value of Rényi entropy.

For numerical simulation of the two Rényi entropy measuring protocols, SWAP-MBI and RM protocols, we use `qiskit-aer`, a high-performance quantum circuit simulator for Qiskit. For the randomized measurement protocols, the number of unitaries chosen are $N_U = 10$ and $N_U = 20$ for $N = 8, 10$ and $N = 12$ cases, respectively. In addition, we take 100 realizations of RUC for each of $N = 8, 10, 12$ cases.

B. IBMQ Results

We implement the RM protocol and SWAP-MBI protocols on the IBM Quantum computer, `ibm_marrakesh`, and compare it with our numerical simulation results. `ibm_marrakesh` has 156 qubits with basis gates `CZ`, `ID`, `RX`, `RZ`, `RZZ`, `SX`, `X`. Besides, its lowest two-qubit error rate from all edges measured by isolated randomized benchmarking is about 9.28×10^{-4} , and two-qubit error rate per layered gate (EPLG) for a 100-qubit chain is about 3.71×10^{-3} .

Still, running quantum algorithms on current quantum devices, such as IBM Quantum processors, poses a significant challenge due to the errors and noise present in these systems. To address these issues, quantum error correction (QEC) has been proposed [67, 68]. However, implementing QEC comes with a substantial qubit overhead, making it daunting to apply to larger problems, even though they are optimized [69, 70].

Alternatively, quantum error mitigation (QEM) accepts the imperfections of current quantum devices and employs methods to reduce or suppress quantum errors and noise. One of the advantages of QEM is that it often has low or no qubit overhead. Various QEM techniques have been developed in recent years, and their effectiveness has been demonstrated in practical applications [71–75].

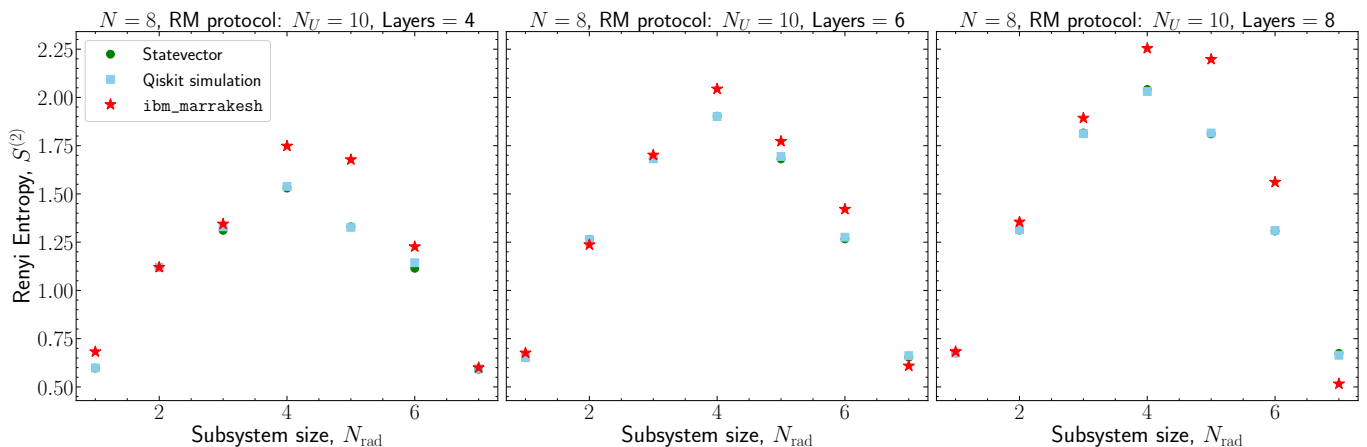

FIG. 10. For the system size $N = 8$, the Rényi entropy $S^{(2)}$ associated with the left-block subsystem, is determined by the randomized measurement protocol (RM protocol) for increasing brickwall layers of the random unitary circuit. Here, the number of local unitaries is set to $N_U = 10$. Besides, for both Statevector computation and Qiskit simulation of the RM protocol, we use 100 realizations of the random unitary circuit, respectively.

In our experiments, we apply four QEM methods to mitigate the errors and noise inherent to quantum devices: Zero-Noise Extrapolation (ZNE), Pauli Twirling (PT), Dynamic Decoupling (DD), and Matrix-free Measurement Mitigation (M3). We refer [75] for further details about these methods. In addition, we adapted an optimized brickwall implementation described in Ref. [50] which reduces the number of CNOT to 3 from 6 in two-qubit unitary gates of RUC. Besides, in the subsequent Qiskit simulations and IBMQ computations, the number of shots is taken as 100000.

1. Randomized Measurement Protocol

We measure the Rényi entropy using RM protocol for two cases: $N = 8$ and $N = 12$ for brickwall layers of 4, 6, and 8, respectively. We want to point out that the number of brickwall layers required for RUC to reach the saturation value of the Rényi entropy given by the respective global Haar-random unitary matrix for a fixed N is not possible for the current real quantum devices because of their limited maximum coherence time. Therefore, we focus on measuring the buildup of the entanglement with an increasing number of brickwall layers in this work.

In Fig. 10 and 11, we see that there is a good agreement between the Rényi entropy for different subsystem sizes N_{rad} , obtained with the statevector (exact) computation, and the RM protocol using Qiskit simulation (noiseless) and `ibm_marrakesh`. Here, we choose the number of unitaries $N_U = 10$ and $N_U = 20$ for $N = 8$ and 12, respectively.

The corresponding circuit depths associated with RUC for brickwall layers 4, 6, and 8 are 126, 181, and 235 for both $N = 8$ and 12 cases. However, the CNOT gate count turns out to be 84, 126, 168 for brickwall layers 4, 6, and 8, respectively with $N = 8$ whereas for $N = 12$ it is 132, 198, 264, respectively. For ten brickwall layers or more, due to the limited coherence time of the actual device, the results, even with error mitigation, deviate significantly from the theoretical values. Therefore, in real device measurement, we limit ourselves to a maximum of 8 brickwall layers in RUC.

2. Swap-based many-body interference protocol

We also implement the swap-based many-body interference protocol, for the first time, in `ibm_marrakesh`, a superconducting quantum computer. To overcome the limited qubit connectivity of the IBM device, we use the series of swap gates to bring the corresponding qubits closest to the ancilla qubit and execute the controlled-swap gate as described in Fig. 8 (right). As we see from Fig. 12, the numerical results from the Qiskit simulation of SWAP-MBI protocol and Statevector (exact) computations match very well. However, the results from `ibm_marrakesh` disagree with the numerical results. We see that for the case of $N = 8$ and four brickwall layers, the Rényi entropy of $N_{\text{rad}} = 1$ subsystem agrees with the numerical values, and for $N_{\text{rad}} = 2$ the results differ significantly from theoretical values. The SWAP-MBI protocol implementation leads to more circuit depths and CNOT counts compared to the RM protocol. In this case, for $N = 4$ and 4 brickwall layers, the circuit depths are $\{176, 231, 281, 335\}$ and CNOT gate counts are

FIG. 11. For the system size $N = 12$, the Rényi entropy $S^{(2)}$ associated with the left-block subsystem, is determined by the randomized measurement protocol (RM protocol) for increasing brickwall layers of the random unitary circuit. Here, the number of local unitaries is set to $N_U = 20$. Besides, for both Statevector computation and Qiskit simulation of the RM protocol, we use 100 realizations of the random unitary circuit, respectively.

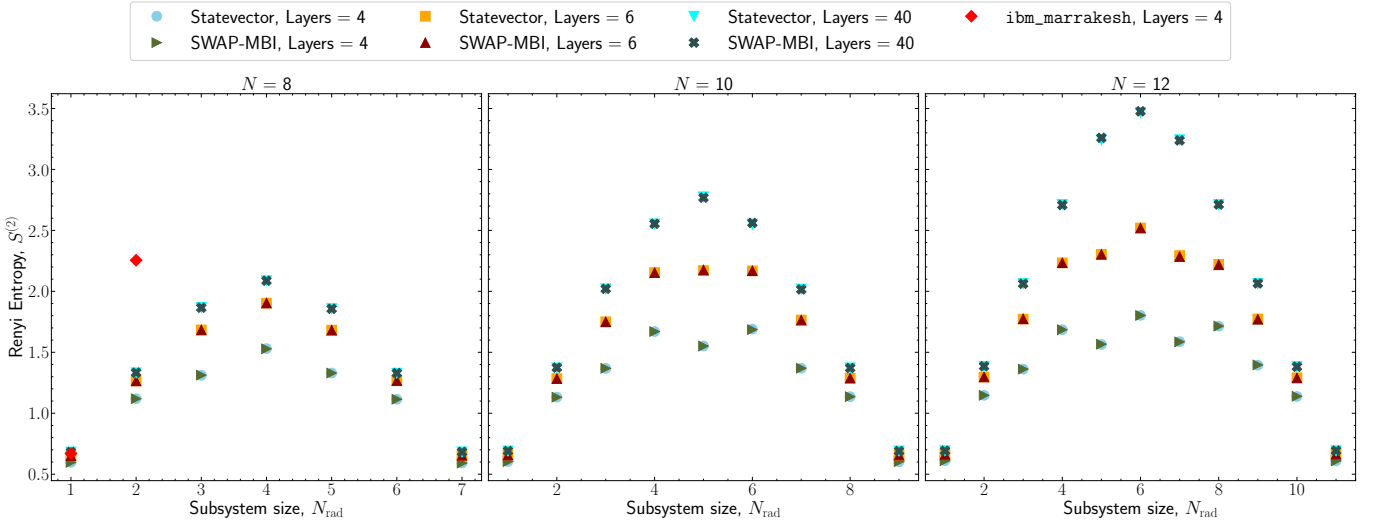

FIG. 12. The Rényi entropy $S^{(2)}$ with respect to the subsystem size N_{rad} for different systems $N = 8, 10$ and 12 , determined by the swap-based many-body interference (SWAP-MBI) protocol. Although the numerical (Qiskit) simulation of the protocol for different numbers of layers 4, 6 or 40 matches well with the Statevector (exact) computations, the result from `ibm_marrakesh` for only the single qubit subsystem with 4 brickwall layers is close to the exact value and already deviate significantly for two-qubit subsystem.

$\{181, 201, 226, 258\}$ for subsystem sizes $N_{\text{rad}} = 1, 2, 3, 4$, respectively. The quantum circuit executing the swap test of the SWAP-MBI protocol involves circuit depths of $\{55, 110, 160, 214\}$ and CNOT gate counts $\{97, 117, 142, 174\}$ for $N_{\text{rad}} = 1, 2, 3, 4$ subsystem sizes, respectively. Therefore, we can see a significant increase in the circuit depth and total CNOT gate counts for the SWAP-MBI protocol compared to the RM protocol, which causes the SWAP-MBI protocol to perform poorly in the IBM devices. Moreover, the noise from the quantum computers could make the two copies of the quantum state deviate, contributing to the error. For this reason, the SWAP-MBI protocol warrants developing more optimized quantum circuits and investigations, which we set for future works.

VI. CONCLUSION AND OUTLOOK

The investigation of black hole information dynamics through the perspective of quantum computing provides a significant avenue for addressing one of the crucial questions in modern theoretical physics: the resolution of the

black hole information paradox. Our work focused on utilizing the qubit transport model of black hole evaporation to examine the entanglement structure of Hawking radiation in the quantum computer. By systematically applying random unitary scrambling circuits alongside entropy measurement protocols, we have shown that quantum computers can effectively model and analyze the evolution of entanglement entropy, shedding light on the Page curve, a crucial indicator of information recovery in black hole physics.

Our findings highlight the potential of quantum computers, especially IBM’s superconducting quantum devices, to simulate the intricate entanglement dynamics related to black hole evaporation. By evaluating two different methods for measuring the entanglement entropy of Hawking radiation, the swap-based many-body interference technique and the randomized measurement approach, we have discovered notable strengths and shortcomings associated with each method. Specifically, while the swap-based approach is straightforward and effective in ideal simulations, it encounters practical difficulties arising from hardware-induced decoherence in IBM’s superconducting qubits. Conversely, the randomized measurement protocol exhibits greater resilience to these noise sources, resulting in more reliable outcomes in actual quantum hardware experiments. This difference emphasizes the importance of choosing suitable measurement methods when working with real quantum devices.

A key aspect of our research is the implementation of quantum error mitigation techniques. Given the unavoidable noise in contemporary quantum hardware, error mitigation is vital for deriving meaningful physical insights. By incorporating these techniques into our entanglement entropy measurement protocols, we have significantly enhanced the precision of estimated Rényi entropies. Our results indicate that, with effective error mitigation, current quantum computers can explore complex entanglement structures within toy qubit models of black holes. This achievement demonstrates that modern quantum hardware is more than just a proof-of-concept; it is a practical platform for addressing profound questions in quantum gravity and high-energy physics.

In conclusion, our work lays a solid groundwork for future investigations into black hole information recovery utilizing quantum computers. By enhancing methods for measuring entanglement entropy in noisy quantum devices, we demonstrate that current quantum computers are well-positioned to tackle some of the most profound challenges in physics. Our work opens avenues for further studies into more sophisticated models of black hole evaporation and the eventual development of large-scale, error-corrected quantum simulations of black hole physics. This research showcases the potential of quantum information science to elucidate the complexities of black hole information dynamics, bringing us closer to a comprehensive understanding of quantum gravity.
