(Dated: December 23, 2024)

We perform unrestricted Hartree-Fock calculations on the 2D Hubbard model on a honeycomb and bilayer honeycomb lattice at both zero and finite temperatures. Finite size real space calculations are supplemented with RPA calculations in the thermodynamic limit. Our motivation comes from high doping levels achieved in graphene and Bernal bilayer graphene by interacalation. We present phase diagrams in doping and temperature for a moderate Hubbard interaction. The magnetic states we find are classified systematically based on the dominant Fourier components of their spin patterns, their average magnetization and spin incommensurabilities. The dominant spin patterns are Néel order and various types of stripes. Around Van Hove filling, we resolve the competition between stripe and chiral spin density waves in the symmetry-broken regime. We also investigate the effect of an applied external displacement field on the spin patterns of BBG.

I. INTRODUCTION

The Hubbard model in its minimalist setup is a key model for understanding strongly correlated materials. Despite its simplicity, it can give rise to a rich variety of interaction-induced ordered phases and more exotic correlation phenomena, such as antiferromagnetism, superconductivity, or a pseudogap phase. While impressive progress on its phase diagram was achieved, the large possible parameter space continues to provide unexplored regions, including its application to different lattice geometries in two spatial dimensions [\[1,](#page-11-0) [2\]](#page-11-1).

In the most prominent representative - the squarelattice Hubbard model - a Neél antiferromagnet arises at half filling, and makes room for various magnetic or charge-ordered phases, such as spirals $[3-15]$ $[3-15]$ or stripes [\[16–](#page-11-4)[30\]](#page-12-0). Due to the many possible states, an unbiased approach towards this zoo of states is desirable and extensive numerical efforts start to converge towards a phase diagram [\[2,](#page-11-1) [31\]](#page-12-1). Interestingly, many of these ordered phases already appear within mean-field theory, and a recent study revealed the Neél-to-spiral-to-stripe transitions using unrestricted Hartree Fock calculations in real space [\[32,](#page-12-2) [33\]](#page-12-3). While such mean-field calculations tend to overestimate ordering tendencies and violate the Mermin-Wagner theorem, they still provide valuable insights about dominant correlations and can serve as guidance for numerical studies or gauge theories of fluctuating magnetic order [\[34](#page-12-4)[–36\]](#page-12-5).

It is an open question how much of the square-lattice phenomenology can be transferred to other lattices. We take this as a motivation to study the phase diagram of the Hubbard model on a single- and bi-layer honeycomb lattice. The model can be used to study interaction effects in graphene and Bernal bilayer graphene (BBG) [\[37,](#page-12-6) [38\]](#page-12-7). Previously, interaction-induced ordered states in these systems were theoretically studied mainly at charge neutrality and Van Hove filling. A competition between different quantum spin, charge, or valley Hall states arises at charge neutrality, which a (layered) Ne^{\acute{e} l antiferromagnet was predicted to win for a Hub-} bard interaction above a critical value [\[39](#page-12-8)[–52\]](#page-12-9). To see this in BBG, trigonal warping or self-energy effects need to be taken into account [\[53\]](#page-13-0). Around Van Hove filling, the interplay between magnetism and superconductivity was investigated [\[54](#page-13-1)[–58\]](#page-13-2). An approximately nested Fermi surface at this filling enables three degenerate spin density wave states with symmetry-related nesting vectors M_i . Their collinear or orthogonal combination leads to a gapped chiral or a half-metallic uniaxial spin density wave [\[59](#page-13-3)[–62\]](#page-13-4).

Experimentally, single-layer graphene is a stable semimetal at charge neutrality. In contrast, suspended samples of BBG show signatures of interactioninduced ordered states including a layered antiferromagnet, quantum anomalous Hall, and nematic states [\[63–](#page-13-5) [71\]](#page-13-6). Furthermore, it was demonstrated that high doping regimes can be achieved by intercalation in both singleand bi-layer graphene [\[72–](#page-13-7)[76\]](#page-13-8). Single-layer graphene was even doped beyond its Van Hove singularity [\[74\]](#page-13-9). This promises the possibility to also realise interactioninduced ground states in highly doped graphene systems.

In this work, we perform a comprehensive analysis of the phase diagram of graphene and BBG as modeled by a Hubbard model on the single- or bi-layer honeycomb lattice. We employ unrestricted Hartree Fock calculations in real space, complemented by an instability analysis via a random phase approximation (RPA) in the thermodynamic limit. We complete the phase diagram for the entire range of doping from empty to fully filled bands at zero and finite temperatures. Similar to the square-lattice Hubbard model, we find that a (layered) Neél antiferromagnet transitions into a cascade of stripe phases. However, for larger dopings the phase diagram on the single- and bi-layer honeycomb lattices is qualitatively different due to their Van Hove singularities. We observe a competition between spin density waves with three Fourier modes. This includes the detailed temperature and density dependence of the chiral and uniaxial spin density waves which were previously studied at Van Hove doping. Furthermore, we analyse the effect of unequal layer occupation in BBG, which can arise from asymmetric intercalation or an external displacement field. We note that we focus on density regimes beyond the cascade behavior recently observed in BBG in a displacement field at the lowest densities [\[77–](#page-13-10)[79\]](#page-13-11). We find that for intermediate interaction strengths, the overall field dependence can be well understood based on the phase diagram of two almost decoupled single layers.

The rest of the paper is structured as follows. In Sec. [II,](#page-1-0) we introduce the Hubbard model on a singlelayer and Bernal-stacked bilayer honeycomb lattice, and we describe our unrestricted Hartree Fock and RPA calculations. Furthermore, we provide a classification of the ordered states we find based on their real-space spin and charge patterns, and Fourier modes. In Sec. [III,](#page-6-0) we present the phase diagram, magnetisation, and wave vectors of the ordered states for the single- and bi-layer case. We vary doping, temperature, and for BBG a displacment field. We provide a discussion of our results and a brief outlook about possible further research directions in Sec. [IV.](#page-10-0)

II. MODEL AND METHOD

Motivated by graphene and Bernal bilayer graphene, we consider the Hubbard model on a single- and ABstacked bi-layer honeycomb lattice

$$
H = H_0 + H_{\rm int} = \sum_{j,j',\sigma} t_{jj'} c_{j\sigma}^{\dagger} c_{j'\sigma} + U \sum_j n_{j\uparrow} n_{j\downarrow}, \quad (1)
$$

with local interaction $U > 0$ and hopping amplitudes $t_{jj'}$. Here, $c_{j\sigma}^{\dagger}(c_{j\sigma})$ is the fermion creation (annihilation) operator for an electron with spin σ on site j, and $n_{j\sigma} =$ $c_{j\sigma}^{\dagger}c_{j\sigma}$. The index j runs over all atoms in both layers. The hopping matrix $t_{jj'}$ depends only on the distance of the sites j and j' . We model the single-layer case with only the nearest-neighbor hopping amplitude t being nonzero. In the bilayer case, we include nearest-neighbor hopping within a layer, and vertical $t_{\perp} = 0.121t$ and skew hopping terms $t_3 = 0.120t$, and $t_4 = 0.044t$ between layers $[38]$, see Fig. [1.](#page-1-1)

The unit cell of single-layer graphene contains two atoms (A,B) and that of bilayer graphene four (A_1,B_1,A_2,B_2) (see the green dashed box in Fig. [1i](#page-1-1)). In the sublattice basis and transforming to momentum space, the non-interacting Hamiltonian becomes $H_0 = \sum_{\mathbf{k},\sigma} c_{\mathbf{k}\sigma}^{\dagger} H_{0,\mathbf{k}} c_{\mathbf{k}\sigma}$, where $c_{\mathbf{k}\sigma} = (c_{A\mathbf{k}\sigma}, c_{B\mathbf{k}\sigma})^T$ or $c_{\mathbf{k}\sigma} = (c_{A_1\mathbf{k}\sigma}, c_{B_1\mathbf{k}\sigma}, c_{A_2\mathbf{k}\sigma}, c_{B_2\mathbf{k}\sigma})^T$, and for single-layer graphene

$$
H_{0,\mathbf{k}} = \begin{pmatrix} 0 & -t\delta_{\mathbf{k}} \\ -t\delta_{\mathbf{k}}^* & 0 \end{pmatrix},\tag{2}
$$

Figure 1. Overview of the real-space structure of Bernal bilayer graphene showing i) the top view and ii) a view from the side with an indication of the four different types of hoppings, t, t_{\perp}, t_3 and t_4 . The green dashed box is one possible choice for a BBG unit cell, which contains 4 sites.

while for Bernal bilayer graphene

$$
H_{0,\mathbf{k}} = \begin{pmatrix} 0 & -t\delta_{\mathbf{k}} & t_4\delta_{\mathbf{k}} & -t_3\delta_{\mathbf{k}}^* \\ -t\delta_{\mathbf{k}}^* & 0 & t_\perp & t_4\delta_{\mathbf{k}} \\ t_4\delta_{\mathbf{k}}^* & t_\perp & 0 & -t\delta_{\mathbf{k}} \\ -t_3\delta_{\mathbf{k}} & t_4\delta_{\mathbf{k}}^* & -t\delta_{\mathbf{k}}^* & 0 \end{pmatrix}
$$
(3)

with $\delta_{\mathbf{k}} = e^{\frac{iky}{\sqrt{3}}} + 2e^{\frac{-iky}{2\sqrt{3}}} \cos(k_x/2)$. We show the corresponding energy bands $\epsilon_{\mathbf{k}}$ in Fig [2.](#page-2-0) They feature linear band touchings at half filling at the $\pm K$ points (see Fig. [3](#page-4-0)) for high-symmetry points in the Brillouin zone). BBG has three further linear band touching points very close to the $\pm K$ points. For large enough dopings of 25%, a Van Hove singularity can be reached in single layer graphene. In bilayer graphene, there are two subsequent Van Hove energies of the two conduction/valence bands. The Fermi surface at the Van Hove energy is approximately nested with wave vector M.

In addition, the band structure of bilayer graphene can be tuned by an electric displacement field. For a non-zero displacement field, we add the term

$$
H_D = \frac{D}{2} \sum_j \epsilon_j n_j,\tag{4}
$$

Figure 2. The bandstructure of BBG (colored solid lines) and single layer graphene (grey dashed lines). The bands are shown along the high symmetry path $\Gamma - M - K - \Gamma$.

to the Hamiltonian where $\epsilon_j = 1$ in the upper layer and $\epsilon_j = -1$ in the lower layer. We note that doping of bilayer graphene via intercalation also leads to an asymmetry in the charge carrier density of both layers and can be modeled in an analogous way [\[72,](#page-13-7) [75\]](#page-13-12).

A. Unrestricted Hartree-Fock in real space

For an unbiased analysis of spin and charge orders, we perform a mean-field decoupling of the interaction term of Eq. [\(1\)](#page-1-2) in real space. The resulting mean-field expression is of the form [\[17,](#page-11-5) [32\]](#page-12-2)

$$
H_{\text{int}}^{\text{MF}} = \sum_{j\sigma} \Delta_{j\overline{\sigma}} n_{j\sigma} + \sum_{j} \left(\Delta_{j-} c_{j\uparrow}^{\dagger} c_{j\downarrow} + \Delta_{j+} c_{j\downarrow}^{\dagger} c_{j\uparrow} \right) - \frac{1}{U} \sum_{j} \left(\Delta_{j\uparrow} \Delta_{j\downarrow} - \Delta_{j-} \Delta_{j+} \right), \tag{5}
$$

where we defined $\bar{\uparrow} = \downarrow$ and $\bar{\downarrow} = \uparrow$. We determine the parameters $\Delta_{i\alpha}$ self-consistently by the gap equations

$$
\Delta_{j\sigma} = U \langle n_{j\sigma} \rangle, \n\Delta_{j+} = \Delta_{j-}^{*} = -U \langle c_{j\uparrow}^{\dagger} c_{j\downarrow} \rangle.
$$
\n(6)

The decoupling in Eq. [\(6\)](#page-2-1) captures both the Hartree- $(\Delta_{i,\sigma})$ and Fock $(\Delta_{i,\pm})$ contributions and allows us to describe arbitrary spin and charge ordering patterns. The local charge- and spin expectation values are given by

$$
\langle n_j \rangle = \frac{\Delta_{j\uparrow} + \Delta_{j\downarrow}}{U},
$$

\n
$$
\langle S_j^z \rangle = \frac{\Delta_{j\uparrow} - \Delta_{j\downarrow}}{2U},
$$

\n
$$
\langle S_j^x \rangle = -\frac{\Delta_{j+} + \Delta_{j-}}{2U},
$$

\n
$$
\langle S_j^y \rangle = -\frac{\Delta_{j+} - \Delta_{j-}}{2iU},
$$
\n(7)

with $n_j = n_{j\uparrow} + n_{j\downarrow}$ and $\vec{S}_j = \frac{1}{2}c_j^{\dagger} \vec{\sigma} c_j$, where $\vec{\sigma}$ is the vector of Pauli matrices.

We solve the mean-field equations on a finite lattice consisting of N unit cells and periodic boundary conditions. The lattice is set up with parallel boundaries. The unit cells of single- and bilayer graphene contain two and four atoms, respectively. Thus, in total, the number of sites in our calculation is $\mathcal{N} = 2N$ for single-layer and $\mathcal{N} = 4N$ for bilayer graphene. We typically perform the real space calculations on lattices with 18×18 unit cells for single-layer and 12×12 unit cells for bilayer graphene, i.e., we have 648 and 576 sites, respectively.

With these specifications the mean-field Hamiltonian can be written as

$$
H^{\rm MF} = H_0 + H_{\rm int}^{\rm MF} = \sum_{j,j'} \sum_{\sigma,\sigma'} c_{j\sigma}^{\dagger} \mathcal{H}_{jj'}^{\sigma\sigma'} c_{j'\sigma'} + \text{const}, \tag{8}
$$

where $\mathcal{H}_{jj'}^{\sigma\sigma'} \in \mathbb{C}^{2\mathcal{N}\times 2\mathcal{N}}$ is a square matrix with $4\mathcal{N}$ real parameters to be determined self-consistently $(\Delta_{i\uparrow}, \Delta_{i\downarrow},$ $\text{Re}\Delta_{j+}$, and $\text{Im}\Delta_{j+}$ for each lattice site j). The expectation values of eq. (6) are then given by

$$
\langle c_{j\sigma}^{\dagger} c_{j\sigma'} \rangle = \sum_{\ell=1}^{2\mathcal{N}} (v_{j\sigma}^{\ell})^* v_{j\sigma'}^{\ell} f(\epsilon_{\ell} - \mu), \tag{9}
$$

where $f(x) = 1/(1 + e^{x/T})$ is the Fermi function, T the temperature, ϵ_{ℓ} are the eigenvalues of the matrix $\mathcal{H}_{jj'}^{\sigma\sigma'}$ from Eq. [\(8\)](#page-2-2), and $v_{j\sigma}^{\ell}$ is the normalized eigenvector corresponding to the ℓ -th eigenvalue. This formulation allows us to perform the mean-field approximation also at finite temperatures.

Furthermore, we keep the total average of the electron density n fixed in our calculation by enforcing the constraint

$$
n = \frac{1}{N} \sum_{j\sigma} \langle n_{j\sigma} \rangle = \frac{1}{N} \sum_{\ell=1}^{2N} f(\epsilon_{\ell} - \mu), \quad (10)
$$

To achieve this, we adjust the chemical potential μ in each iteration of the self-consistency loop.

Finally, when we obtain a convergent solution of the self-consistent mean-field equations, we calculate the free energy and determine the lowest-energy state via

$$
F/\mathcal{N} = -\frac{T}{\mathcal{N}} \sum_{\ell} \log \left(1 + e^{-\beta(\epsilon_{\ell} - \mu)} \right)
$$

$$
-\frac{1}{\mathcal{N}U} \sum_{j} \left(\Delta_{j\uparrow} \Delta_{j\downarrow} - \Delta_{j\downarrow} \Delta_{j\downarrow} \right) + \mu n. \tag{11}
$$

We perform this Hartree-Fock procedure for varying temperature, density, and displacement field. To ensure that we do not converge to a local minimum, we repeat each calculation several times from random initial spin and charge patterns and after that from the (converged) states of adjacent points in the phase diagram.

With a few exceptions, we consider calculations on a fixed lattice size. This means that the exact phase boundaries are subject to finite size effects. The influence of these kinds of finite size effects was analyzed in greater detail for the Hubbard model on a square lattice in [\[32,](#page-12-2) [33\]](#page-12-3). For an even more precise picture of the phase diagram, one could repeat the calculations for various lattice sizes comparing their free energies or constrain the spin orders in order to work directly in the thermodynamic limit. For our purposes, we intend to give an overview of the regimes where different phases are dominant without calculating sharp phase boundaries, and leave their exact determination for future study. We still perform checks on 18x18 and 24x24 lattices for several points for BBG to ensure a correct convergence.

B. Random Phase Approximation

We additionally performed calculations using a random phase approximation (RPA) in the thermodynamic limit to compare the mean-field critical temperature T^* for the onset of magnetic order. For this we introduce the Green's function of the non-interacting system and calculate the static spin susceptibility

$$
\chi(\mathbf{q}) = \chi_0(\mathbf{q}) \left[\mathbb{1} - \Gamma_0 \chi_0(\mathbf{q}) \right]^{-1},
$$

\n
$$
\chi_0^{\alpha\beta}(\mathbf{q}) = \int_k G_0^{\alpha\beta} (k+q) G_0^{\beta\alpha}(k),
$$

\n
$$
G_0(k) = \left(i\nu + \mu n - H_{0,\mathbf{k}} \right)^{-1},
$$
\n(12)

where we introduced the shorthand notation \int_k $T \sum_{i\nu} \int_{\mathbf{k}\in BZ} d\mathbf{k} \sqrt{3}/(8\pi^2)$ and $k = (i\nu, \mathbf{k}), q = (0, \mathbf{q})$ contain a fermionic Matsubara frequency ν and a wavevector k or q.

We assume that right below the critical temperature T ∗ , the spin order will be given by a single contributing mode with wave vector \mathbf{Q} [\[33\]](#page-12-3), corresponding to a diverging $\chi(\mathbf{Q})$. To determine T^* and **Q**, we focus on **q** along the high symmetry lines (i.e. $\Gamma - M - K - \Gamma$), and calculate the maximal critical temperature $T_{\mathbf{q}}^*$ where at least one eigenvalue of $\left[\mathbb{1}_4 - \Gamma_0 \chi_0(\mathbf{q})\right]$ becomes 0 so that the denominator of Eq. (12) vanishes. We then determine the mean-field critical temperature as

$$
T^* = \max_{\mathbf{q}} T^*_{\mathbf{q}},\tag{13}
$$

and **Q** as the corresponding **q**, where T_{q}^{*} becomes maximal. Note that the chemical potential needs to be calculated for each set of filling and temperature.

of states based on the pattern of the spin expectation values. This classification is inspired by similar classifications for spin patterns on the square lattice [\[32,](#page-12-2) [80\]](#page-13-13). In agreement with [\[80,](#page-13-13) [81\]](#page-13-14), we generally find that the charge pattern of our states follows the spin pattern according to

$$
\langle \rho_j \rangle \propto \left\langle \vec{S}_j \right\rangle^2 + \text{const.}
$$
 (14)

Note that in general this relation only holds for small spin expectation values, since it was derived from a low-order Landau theory [\[81\]](#page-13-14).

To classify a magnetic state, we consider the Fouriertransformation of the real-space spin pattern

$$
\langle \vec{S}_j \rangle = \langle \vec{S}_{m,\alpha} \rangle = \sum_{\mathbf{q}} \vec{S}_{\mathbf{q},\alpha} e^{i\mathbf{q}\mathbf{r}_m},
$$
 (15)

where we specify a site j by the the unit cell (m) at position r_m and the sublattice (α). Since the real-space spin pattern is real, the Fourier components of the spin expectation values satisfy $\vec{S}_{\mathbf{q},\alpha} = \vec{S}_{-\mathbf{q},\alpha}^*$. We find that the classification is the same for each of the sublattices, so we drop the extra index α . The sum runs over the N allowed momenta q in the Brillouin zone given by the real-space lattice size. The Brillouin zone is discretized based on the 12×12 lattice we used to calculate our phase diagrams, i.e., there are 144 allowed momenta for the spin pattern. In particular, this includes wave vectors for the spin orders at the M - or K -points. In Fig. [3,](#page-4-0) we show the Fourier weight of the four most common types of spin orders we find in our numerical calculations. Generally, we obtain non-zero Fourier components at one, two, or three different **q** and the related $-q$. They can be at highsymmetry points Γ, K , and M or along high-symmetry lines $\Gamma - K$, $\Gamma - M$ or $K - M$. In addition, we determine the relative orientation of the Fourier-spins, since we can not completely classify a state with its Fourier weights only.

This leads us to the following categories for the most common spin orders we find. Note that the actual spin pattern we get in our Hartree-Fock calculations can be related to the states of the categories by a global $SU(2)$ rotation or translations of the spin order. We present example patterns in Fig. [4,](#page-5-0) illustrated by showing the real-space configuration of one graphene layer projected onto the $x - y$ -plane in spin-space.

1. Paramagnetism

Before we discuss the phase diagrams, we give an overview of the types of magnetic states we find and how we categorize them. We perform the classification

C. Classification of real-space states

In the paramagnetic state, the average spin magnetization on every lattice site is zero, $\langle \vec{S}_j \rangle = 0$ and the average electron density is uniform, $\langle n_j \rangle = n$.

Figure 3. The four most common Fourier-patterns we find in our real-space Hartree-Fock calculations. a) The spin order has only a single peak at $\mathbf{Q} = 0$, indicating a resulting Néel or ferromagnetic order depending on the sublattice structure. b) There is a single contributing Fourier mode at $\mathbf{q} = \pm \mathbf{Q}$, corresponding to incommensurate single mode stripe order. c) The spin order consists of two symmetry-related Fourier modes, which we mainly find in the two orthogonal stripe ordered phase. We here show the special case where they have the same amplitude. d) Three symmetry-related Fouriermodes occur with the same amplitude. For example, an order with three orthogonal or collinear stripes shows this Fourier pattern. As a special case, the three Fourier modes can occur at the three M points.

2. Néel or ferromagnetic order

The spin order in each sublattice is given by

$$
\vec{S}_0 = \mathcal{S} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, \qquad \vec{S}_q = \vec{0} \quad \text{for} \quad \mathbf{q} \neq \mathbf{0}, \qquad (16)
$$

with spin amplitude S. This definition entails both ferromagnetism as well as Néel antiferromagnetism, depending on whether the spins on the different sublattices are arranged in a parallel or antiparallel way. Only if the spins are antiparallel, we classify the state as Néel order. In bilayer graphene, we additionally find that spins on the same site in different layers are antiparallel. All spins on each sublattice have the same amplitude and thus we do not find charge modulations. The Fourier weight is shown in Fig. [3](#page-4-0) a) The real-space spin pattern is shown in Fig. $4a$ $4a$).

3. Single mode stripe order

We classify a state as single mode stripe order, if it can be described by only one mode Q in momentum space, so that

$$
\vec{S}_{\mathbf{Q}} = \vec{S}_{-\mathbf{Q}}^* = \mathcal{S} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, \qquad \vec{S}_{\mathbf{q}} = \vec{0} \quad \text{for} \quad \mathbf{q} \neq \pm \mathbf{Q}. \tag{17}
$$

All the spins are pointing collinearly along one axis with their amplitude modulated with wavevector Q. The charge modulation on a sublattice will be to lowest order proportional to $\langle n_m \rangle - n \propto \cos(2\mathbf{Q} \cdot \mathbf{r}_m)$. The Fourier weight of single mode stripe order corresponds to Fig. [3](#page-4-0) b). Its real-space representation is shown in Fig. [4](#page-5-0) b).

4. Two orthogonal stripes

If the spin order is given by

$$
\vec{S}_{\mathbf{Q}_1} = \vec{S}_{-\mathbf{Q}_1}^* = \mathcal{S}_1 \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix},
$$
\n
$$
\vec{S}_{\mathbf{Q}_2} = \vec{S}_{-\mathbf{Q}_2}^* = \mathcal{S}_2 \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix},
$$
\n(18)

we classify a state as two orthogonal stripes. The wavevectors \mathbf{Q}_1 and \mathbf{Q}_2 have to be symmetry-related by a C_3 rotation. We often find a special case of this state where $S_1 = S_2$. We show the Fourier amplitudes of this state in Fig. [3](#page-4-0) c), where we present the common case with $S_1 = S_2$. In this case, the charge modulation follows $\langle n_m \rangle - n \propto \cos(2\mathbf{Q}_1 \cdot \mathbf{r}_m) + \cos(2\mathbf{Q}_2 \cdot \mathbf{r}_m)$. Its real-space representation is shown in Fig. [4](#page-5-0) c).

5. Three modes with same amplitude

We classify a state as three modes with same amplitude, if S_{q} is nonzero only for three symmetry-related modes $\pm \mathbf{Q}_1, \pm \mathbf{Q}_2, \pm \mathbf{Q}_3$, where $\mathbf{Q}_1, \mathbf{Q}_2$ and \mathbf{Q}_3 are again related to each other by a 120[°] rotation and

$$
|\vec{S}_{\mathbf{Q}_1}| = |\vec{S}_{\mathbf{Q}_2}| = |\vec{S}_{\mathbf{Q}_3}|.
$$
 (19)

We show an example in Fig. [3](#page-4-0) d). We find several different types of spin orders in the form [\(19\)](#page-4-1), which are not necessarily coplanar. We show the $x - y -$ projection of one example in Fig. [4](#page-5-0) d). We distinguish general states with three modes of the same amplitude from two special cases where the three spin modes are orthogonal or parallel.

Figure 4. Example representatives of the real-space patterns of the most common spin orders we find. We here show only one layer, but we found that in the case of BBG both layers display the same type of spin pattern for a given parameter set possibly with a relative phase. a) Néel antiferromagnetism, b) single mode stripe order, c) two orthogonal stripes with the same amplitude, d) an order with three modes with same Fourier amplitude, which are neither orthogonal nor parallel stripes e) three orthogonal stripes in the special case of commensurate wave vector $\mathbf{Q}_i = M_i$, f) three collinear stripes, again in the commensurate case $\mathbf{Q}_i = M_i$. Orders in d) and e) are neither collinear nor coplanar and we only depict their projection on a plane.

6. Orthogonal stripes

Orthogonal stripes are a special case of three modes with the same amplitude, where the three spin amplitudes at $\mathbf{Q}_1, \mathbf{Q}_2, \mathbf{Q}_3$ are orthogonal to each other, i.e.

$$
\vec{S}_{\mathbf{Q}_1} = \vec{S}_{-\mathbf{Q}_1}^* = \mathcal{S} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}
$$

$$
\vec{S}_{\mathbf{Q}_2} = \vec{S}_{-\mathbf{Q}_2}^* = \mathcal{S} \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}
$$

$$
\vec{S}_{\mathbf{Q}_3} = \vec{S}_{-\mathbf{Q}_3}^* = \mathcal{S} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} .
$$
(20)

The charge modulation is therefore proportional to $\langle n_m \rangle - n \propto \cos(2\mathbf{Q}_1 \cdot \mathbf{r}_m) + \cos(2\mathbf{Q}_2 \cdot \mathbf{r}_m) + \cos(2\mathbf{Q}_3 \cdot \mathbf{r}_m).$ Its Fourier-weight looks like that of the three same mode order, i.e. Fig. [3](#page-4-0) d). Since this order is not coplanar, we show the projection of the spins to the $x - y$ −plane in Fig. [4](#page-5-0) e). In that panel, we show the special case where $\mathbf{Q}_i = M_i$. This state was previously discussed as a symmetry-broken state of the doped triangular or honeycomb lattice [\[59–](#page-13-3)[62\]](#page-13-4). It forms a four-sublattice state where the spins on each sublattice point into the four corners of a tetrahedron.

7. Collinear stripes

Collinear stripes are a special case of three modes with the same amplitude, where the three spin amplitudes at $\mathbf{Q}_1, \mathbf{Q}_2, \mathbf{Q}_3$ are collinear, i.e.

$$
\vec{S}_{\mathbf{Q}_1} = \vec{S}_{\mathbf{Q}_2} = \vec{S}_{\mathbf{Q}_3} = \mathcal{S} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, \tag{21}
$$

and its conjugate for $\mathbf{Q}_i \leftrightarrow -\mathbf{Q}_i$. The charge modulation is proportional to $\langle n_m \rangle - n \propto (\cos(\mathbf{Q}_1 \cdot \mathbf{r}_m) +$ $\cos(\mathbf{Q}_2 \cdot \mathbf{r}_m) + \cos(\mathbf{Q}_3 \cdot \mathbf{r}_m))^2$. In the special case $\mathbf{Q} = M$, this state is equivalent to the collinearly ordered state proposed in [\[61\]](#page-13-15). Its Fourier weight is thus again represented by Fig. [3](#page-4-0) d). We show the spin order pattern in Fig. [4](#page-5-0) f).

8. Other orders

Any spin order we find which does not fit into one of the aforementioned categories, we classify as "other" spin orders.

Since we are performing our calculations on a finite system and completely unrestricted, there is the risk to converge to a local energy minimum, which is not the true lowest energy state of the system. Generally, the "other" orders tend to disappear when we increase the system size. We therefore believe that the "other" orders are largely artifacts of convergences to local minima and finite size effects, similar to [\[32\]](#page-12-2).

III. RESULTS

A. Single Layer Graphene

For later reference, we perform Hartree-Fock and RPA calculations also for single layer graphene. We vary the temperature between 0 and 0.5t in steps of 0.01 and the density between 0.5 and 1.5 in steps of $\frac{1}{108}$. We choose an interaction strength of $U = 3t$ because, on the one hand, it is big enough to find magnetism along a wide region of dopings and temperature, while on the other hand, it is still small enough for Hartree-Fock theory to provide meaningful results.

Since single layer graphene is particle-hole symmetric, we only consider hole doping. We present the phase diagram as function of doping δ and temperature, as well as the relevant spin ordering wavevectors Q and the magnetization m in Fig. [5.](#page-7-0) In general, we find striking similarities between BBG and single layer graphene, cf. Sec. [III B.](#page-7-1)

The critical temperature as calculated in RPA coincides well with the critical temperature that we find in our real-space calculations, indicating that our system sizes are already big enough to give a good approximation of the thermodynamic limit. Around half-filling, we observe a Néel ordered dome consistent with previous studies, despite the vanishing density of states because the considered interaction $U = 3t$ is above the critical interaction strength needed in mean-field the-ory [\[39,](#page-12-8) [44](#page-12-10)[–47,](#page-12-11) [50](#page-12-12)[–52\]](#page-12-9). The critical temperature T^* is at a relative maximum because of particle-hole symmetry between conduction and valence bands $\epsilon_k^+ = -\epsilon_k^-$ at charge neutrality. The regime of Neél order is followed by an intermediate regime of single mode stripe order. A

secondary dome arises around Van Hove filling because the logarithmic singularity of the density of states together with nesting at wave vector M, i.e., $\epsilon_{k+M} = -\epsilon_k$ boosts the critical temperature T^* . Within the secondary dome, we find an interplay of different types of three same modes, including orthogonal and collinear stripes, at dopings between $\delta = 0.15$ and $\delta = 0.3$. Consistent with previous studies we find orthogonal stripes, i.e., a chiral spin density wave, at Van Hove doping [\[59](#page-13-3)[–62\]](#page-13-4). Their competition with collinear stripes is influenced by temperature [\[61\]](#page-13-15), and more strongly by doping. For higher doping of 0.3 to 0.35, we find a single mode stripe ordered regime and for even higher dopings we see a small region of two orthogonal stripe order.

In the middle panel of Fig. [5,](#page-7-0) we present the Q dependence of the spin patterns as a function of doping and temperature. We color code the Q dependence according to their location in the Brillouin zone (cf. inset). For the real-space Hartree-Fock calculations we use the Q-vector with the biggest weight of the corresponding Fourier-mode of the spin pattern. The color of the outline is given by the Q vector of the divergence in the RPA calculation. The Q dependence of the magnetic orders is largely determined by the evolution of the Fermi surface with doping. For Fermi points and small pockets close to half-filling, we see Néel order with $\mathbf{Q} = 0$. For small dopings with Fermi pockets around K, K' , we find intermediate wave vectors with **Q** moving along the $\Gamma - K$ line or $\Gamma - M$ line. The wave-vector fluctuations in this regime indicate that these states are close in energy. In general, |Q| increases for increasing doping or lower temperatures. In the secondary dome, the spin order reaches the M point approximately at Van Hove doping, which corresponds to the nesting wave vector. Temperature effects slighlty shift the maximum away from Van Hove doping. At very high dopings, Q shifts towards K along the $M - K$ line. This evolution is in agreement with our RPA calculations of single layer graphene.

For each converged state, we calculated the average magnetization per site

$$
m = \frac{1}{\mathcal{N}} \sum_{j} \sqrt{\langle S_j^x \rangle^2 + \langle S_j^y \rangle^2 + \langle S_j^z \rangle^2}, \tag{22}
$$

where the index j runs over all sites of the system. We show our results in the right panel of Fig. [5.](#page-7-0) The magnetization m is highest at half-filling and for small T . The transition from the paramagnetic phase to the magnetically ordered phase is a second order transition within the resolution of our calculations. We also find a smooth magnetization profile for large ranges of doping. In particular, no magnetization jump occurs at the transition from Néel to incommensurate magnetic order, indicating a second order transition. We see weak fluctuations in m between the main and secondary magnetic dome. Since in the thermodynamic limit the magnetization should be stable up to the white RPA line, we believe these m fluctuations are due to finite size effects of our lattice.

Figure 5. The Hartree-Fock phase diagram, main wavevector \bf{Q} (color scale in middle inset) and average magnetization m (right color scale) of single layer graphene for $U = 3t$ as a function of temperature and doping. Calculations were done on 18 × 18 lattices. The grey dashed line at 25% hole doping in the left panel indicates the Van Hove filling of the non-interacting model. The T^* line and its corresponding \bf{Q} (color in the middle double line) were calculated in the thermodynamic limit using RPA.

B. Bernal Bilayer Graphene

In the following we state our results for BBG. In our calculations for BBG, we vary the temperature between $T = 0$ and $T = 0.5t$ in steps of 0.01t and the density between 0.5 and 1.5 in steps of $\frac{1}{144}$. We again choose an interaction strength of $U = 3t$. We are interested in the possible interaction-induced ordered states that meanfield theory provides to get a comprehensive overview as function of filling and temperature.

1. Phase diagram

In Fig. [6,](#page-7-2) we show the phase diagram in hole/electron doping and temperature as obtained by our unrestricted real-space Hartree-Fock calculations. Note that in contrast to single-layer graphene the phase diagram is not perfectly particle-hole symmetric due to a finite t_4 hopping parameter. The RPA critical temperature again coincides well with the critical temperature that we find in the real-space calculations, i.e., the system sizes are a good approximation of the thermodynamic limit. The only exception is a small paramagnetic regime at doping $\delta \approx -0.1$ below the critical temperature. But we identify this as an artifact of the finite system size. When we repeat our calculations in this region on a 24×24 lattice, we find a finite magnetic order parameter. Around

Figure 6. Mean-field phase diagram for the Hubbard model on Bernal bilayer graphene with $U = 3t$ as a function of doping and temperature. Calculations were done on 12×12 lattices. The black T^* line was calculated in the thermodynamic limit using RPA. The grey dotted lines represent Van Hove fillings of the non-interacting model at $n = 0.849, 0.644, 1.211$ and 1.286.

half-filling, we see a magnetic dome with relatively high critical temperatures of up to $T^* \approx 0.40t$ in the phase diagram. As we increase the electron- or hole doping, the critical temperature first shrinks to $T^* \approx 0.08t$. Then, a secondary dome appears where the critical temperature rises again between 13 and 28 percent doping, peaking at $T^* \approx 0.13t$ and finally goes down to 0 at $\delta \approx \pm 0.4$. In highly doped BBG, there are two Van Hove energies from the two conduction (valence) bands. On the electrondoped side $(\delta < 0)$, the occurrence of the secondary dome coincides with a rise of the density of states and approximate nesting at Van Hove doping. On the hole-doped side, the maximum of T^* is strongly shifted away from the individual Van Hove points. We suspect the reason of the strong shift to come from inter-band effects in the particle-hole susceptibility, besides temperature effects and the overlap of the two Van Hove peaks.

The dome around half filling predominantly corresponds to Néel order. At $T = 0$, the Néel order seems to extend over a small doping range, however, this is likely due to the finite size effects, as our system cannot resolve spin orders with very small incommensurabilities. For small dopings and low temperatures, a single mode stripe-ordered region emerges, extending from $\delta \approx 0.02$ to $\delta \approx 0.1$ and from $T = 0$ up to the critical temperature. For larger dopings $\delta \gtrsim 0.1$ in the region between the main magnetic dome and the secondary domes, the system undergoes several transitions between different stripe phases. As we describe below the wave vectors of magnetic orders remain stable when we increase the lattice size in our calculations. However, we attribute the absence of clear phase boundaries to finite size effects.

Within the secondary domes, we see an interplay of the "three-orthogonal-stripe", "three-same-modes", and "three-collinear-stripes" phases with wave vector M similar to single-layer graphene. While this indicates that also in BBG the fermiology at Van Hove doping with approximate nesting is crucial for the order formation, the competition between the three phases is only resolved within a Hartree Fock calculation inside the symmetrybroken phases. In particular, orthogonal stripes, i.e., chiral spin density waves, cover the largest area in the secondary domes. Collinear stripes also cover extended regions for even larger hole- or electron dopings $\delta \approx \pm 0.3$. Generally, when phases extend over such big areas in the phase diagram, it is an indication that they will remain stable in the thermodynamic limit [\[32\]](#page-12-2). On the electrondoped side, we find an additional single mode stripe ordered regime for dopings even smaller than −0.3, which is not present on the hole-doped side. For very high dopings of $\delta \pm 0.4$, we see indications of a two-orthogonal-stripe order. In this area, the two orthogonal stripes have the same amplitude, i.e. $S_1 = S_2$ in Eq. [\(18\)](#page-4-2). Overall, the sequence of magnetic orders is very similar to the one of single-layer graphene, in particular on the electron doped side.

We also repeated the calculations on 18×18 and 24×24 lattices along the $T = 0.04t$ and $T = 0.05t$ lines to estimate how stable the phase diagram will remain in the thermodynamic limit. In both of these lattice sizes, we find collinear stripes, orthogonal stripes and the phase with three same modes in the secondary domes, in quali-

Figure 7. Upper panel: The $\mathbf{Q} = (Q_x, Q_y)^T$, where we find a divergence of the RPA bubble in the thermodynamic limit. When the green line is zero, the divergence occurs at the $\Gamma - M$ line. When the green line equals the red line, the divergence occurs at the $\Gamma - K$ line. Otherwise it is at the $M - K$ line. Lower panel: The main Q of the spin orders in real space. The color of the outline was calculated using RPA and corresponds to the upper panel.

tative agreement with Fig. [6.](#page-7-2) The collinear stripe phases appear stable. The phases of three orthogonal stripes and three same modes have slightly different boundaries for the bigger systems, indicating that their energies are very close and they are competing. We did not find a single mode stripe-ordered phase for dopings $\delta \leq -0.3$ on the electron-doped side for the bigger lattices. Instead the two orthogonal stripes take most of the phase space. Based on these checks, we believe that the overall phase structure will remain stable even for bigger lattices.

2. Q-dependence

In Fig. [7,](#page-8-0) we present the Q dependence of the spin patterns corresponding to the phases in Fig. [6](#page-7-2) as a function of doping and temperature. As before, we show the wave vector **Q** of the divergence of the RPA bubble and the one of the real-space Hartree-Fock calculations given by the Fourier-mode of the spin pattern with the biggest weight. We see that within the resolution allowed by our 12×12 lattice, at the critical temperature the **Q** vectors of the RPA and the real-space Hartree-Fock calculations coincide, as expected.

Close to half-filling, we see a wave vector of $Q = 0$ for the Néel order. Generally, we then see an increase of |Q| as we increase electron or hole doping. Within our resolution, the transition from N'e order to the adjacent single mode stripe phase is consistent with a second-order transition as Q increases by the smallest possible value allowed by the finite-size system. As function of temperature, we note an increase of $|Q|$ as we lower the temperature in this region around half filling. We then have a short doping region ($\delta \approx 0.05$ - $\delta \approx 0.1$) where wave vectors change back and forth between $\Gamma - K$ and $\Gamma - M$ lines indicating that the energies of both magnetic orders are very close together. This reflects the changes between different phases we described above in this region of the phase diagram. While we cannot completely rule out finite-size effects, the **Q** on the $\Gamma - K$ and $\Gamma - M$ lines remain stable in our checks on bigger lattices (18×18) and 24×24).

For dopings $\delta \geq 0.1$, the wave vector settles along the $\Gamma-M$ line corresponding to an instability towards incommensurate spin density waves. At a doping of roughly $\delta \pm 0.25$ in the Van Hove region, **Q** reaches the M point and the magnetic order becomes commensurate. At even larger dopings $\delta \geq 0.35$, the ordering wave vector within RPA becomes again incommensurate close to M along the $M - K$ line. While this agrees with the Hartree-Fock results for electron doping, we find $\mathbf{Q} = \mathbf{0}$ ferromagnetism for hole doping instead. However, when we repeat the calculation on bigger lattices, we obtain $\mathbf{Q} = M$ or close to the $M-K$ line, in agreement with the predictions of the RPA. The reason why we find ferromagnetism in this region of the phase diagram is that a 12×12 lattice can not resolve the $M - K$ line sufficiently well and therefore $\mathbf{Q} = 0$ ferromagnetic order is energetically the next best state. In the thermodynamic limit, we therefore do not expect ferromagnetic order to prevail. This is also why we have classified it as "other" order in the phase diagram.

3. Magnetization

For each converged state, we calculated the average magnetization per site according to Eq. (22) . We show our results in Fig. [8.](#page-9-0) Similar to the single-layer case, the transition between the paramagnetic and the magnetic regime appears like a continuous second order transition within our density and temperature resolution. The magnetization takes its maximum at half-filling. In general, we do not observe jumps in the magnetization as we transition between different magnetic phases. This includes the transition from the N'eel state to the adjacent single mode stripes. However, we do see fluctuations in m in the following doping region between the main magnetic dome and the secondary magnetic domes, particularly on the electron-doped side. Since in the thermodynamic limit the magnetization should be stable up to the white RPA line, we believe these m fluctuations are due to finite size effects.

Figure 8. Average magnetization m per site in Bernal bilayer graphene for $U = 3$ as a function of doping and temperature. The amplitudes are calculated using unrestricted Hartree-Fock and the white outline using RPA.

4. Displacement field

In addition, we also considered the effects of an externally applied displacement field, see Eq. [4.](#page-1-3) We note that we cannot resolve the cascade of transitions observed at smallest density regions as function of gate voltage. Instead, our motivation comes from intercalated BBG, which can lead to different charge densities in both layers. This can effectively be modeled by a term like Eq. [4](#page-1-3) in the Hamiltonian, which translates to different chemical potentials in both layers [\[72,](#page-13-7) [75\]](#page-13-12). We perform calculations at $T = 0.01t$ to work at very low temperatures while having more numerical stability than for $T = 0$. We choose a hole doping range from -0.1 to 0.5. We vary the displacement field from $D = 0$ to $D = 2t$ in steps of $0.02t$ and set $U = 3t$.

In Fig. [9](#page-10-1) we show a phase diagram of BBG as a function of displacement field and doping. We see that now the two layers show qualitatively different behaviours. At half-filling, both layers exhibit Néel order up to displacement fields of $D \approx 1.3t$. We see that the lower layer has a wide region of Néel order in the hole doped regime. In this region, the upper layer instead shows parallel vertical lines of constant phase. These vertical lines of constant phases extend to the $D = 0$ line diagonally. In the lower layer, we also see these lines of constant phases in the electron doped regime. In the hole doped regime outside the N'eel area, we again see diagonal lines of constant phase, this time with the diagonals going towards the top right. We note that the image is fairly pixelated, since we used less convergence time and still face the same finite size effects as we do for the phase diagrams in doping and temperature. Nevertheless, we believe that the phase diagram gives a qualitatively correct picture of the dominant field effects, which can be understood based on the phase diagram of single-layer graphene in Sec. [III A.](#page-6-2)

To this end, we think of the system as two almost de-

Figure 9. Phase diagram of BBG for an applied external magnetic field at $T = 0.01t$ and $U = 3$ as a function of doping and D. The left (right) panel shows the phase diagram for the sites on the upper (lower) layer. We can qualitatively describe the phase diagram by a cartoon picture of non-coupled graphene sheets, as shown in Fig. [10.](#page-10-2)

Figure 10. Cartoon picture of the density of states (DOS) ρ of two non-connected layers of graphene. **Panel a**): DOS of the system without displacement field. The DOS for the upper and the lower layer are degenerate. Both DOSs exhibit a gap Δ_{AFM} due to the Néel order. **Panel b**): DOS after applying a small displacement field $D < \Delta_{AFM}$. The DOS of the upper and lower panel are shifted with respect to each other, but the magnetic gap still remains. Panel c): DOS for $D > \Delta_{\text{AFM}}$. There is now no more magnetic gap remaining.

coupled sheets of graphene which is a good approximation as long as $t \gg t_{\perp}$. The displacement field acts on the two layers like a chemical potential with flipped sign. A single layer of graphene in the Néel ordered state at half-filling and $U = 3t$ has a magnetic gap Δ_{AFM} in the density of states of $\Delta_{\text{AFM}} \approx 1.3t$, see Fig. [10](#page-10-2) (a). At half-filling, we can see that both layers remain in the

Néel state until $D \gtrapprox \Delta_{\text{AFM}}$. The reason is that, as long as $D < \Delta_{\text{AFM}}$, both layers remain half-filled (Fig. [10](#page-10-2) (b)) and thus, exhibit perfect Néel order. When $D > \Delta_{\text{AFM}}$ exceeds the size of the magnetic gap, the different layers start to obtain different fillings. In this case the lower (upper) layer is filled slightly more (less) than half-filling, see Fig. 10 (c). Therefore, the order changes from a Neél pattern to a single mode stripe phase following the phase diagram of BBG, Fig. [6.](#page-7-2)

As we start hole doping the system the upper layer is depleted first, while the lower layer remains half-filled (for sufficiently big D and $T = 0$), see Fig. [10](#page-10-2) (b). Effectively, the upper layer is then doped twice as much as the total system (e.g. when we consider 10% hole doping the upper layer has 20% and the lower layer 0% hole doping). As a consequence, the lower layer remains Neél ordered, while the upper layer shows incommensurate magnetic order. The opposite effect happens as we electron dope the system. All additional electrons populate the lower layer first, while the upper layer remains at half filling. This mechanism is responsible for the extended Néel regions as well as the vertical lines of constant phases in the phase diagram of Fig. [9.](#page-10-1)

As we increase the doping even more, both layers become doped, however, with the lower (upper) layer remaining less doped across all hole (electron) dopings. This results in the diagonal lines of constant phases that can be seen in Fig. [9.](#page-10-1) They follow lines of constant doping of the individual layers. We can also identify a qualitatively similar sequence of phases. There is a fluctuating region of stripe phases with increasing doping, which transitions to larger regions of orders with three same modes, three collinear stripes and three orthogonal stripes.

IV. CONCLUSION

We performed unrestriced Hartree-Fock calculations on graphene and BBG lattice structures at moderate interaction strength $U = 3t$. The calculations were performed mainly on finite lattices with 18×18 unit cells for single layer graphene and 12×12 unit cells for BBG. Bigger lattice sizes were used for several selected points to double check our results and estimate finite size effects. Additionally, we performed RPA calculations directly in the thermodynamic limit for spin orders close to the critical temperature T^* . We classified the resulting states based on their magnetic pattern, calculated their average magnetization and showed the dominant Fourier weight of the spins.

We found that Néel order is the dominant spin order close to half-filling for both single layer and Bernal bilayer graphene consistent with previous studies [\[39–](#page-12-8)[52\]](#page-12-9). Additionally, we studied the full phase diagram as the system gets doped away from half filling. We found that different stripe orders emerge with a wave vectors along $\Gamma - K$ and $\Gamma - M$ lines. In a second magnetic dome at $|\delta| \approx 0.3$, there is a competition of 3 orthogonal stripes, 3 collinear stripes and other phases with 3 Fourier modes with the same amplitude. These correspond to the previously discussed chiral (3 orthogonal stripes) and collinear (3 collinear stripes) spin density waves at Van Hove filling [\[59–](#page-13-3)[62\]](#page-13-4). We showed that they extend away from Van Hove filling and mapped out the regimes in doping and temperature where they appear.

The qualitative shape of the phase diagram of single layer graphene and BBG is very similar, as well as the magnetic incommensurability Q and average magnetizations. We found a smooth magnetization profile and a smooth variation of the incommensurability. A commensurate $\mathbf{Q} = M$ emerges in an extended region in the secondary domes.

We also studied the effect of an external displacement field D on BBG. At the same time, the displacement field can also be understood as modelling unequal potentials in both layers, which is an effect that can occur in intercalation in BBG [\[72,](#page-13-7) [75\]](#page-13-12). Motivated by this, we calculate a phase diagram for high doping levels as function of D, which can qualitatively be explained by modeling BBG as two almost disconnected sheets of single layer graphene.

In future works, it will be interesting to extend the Hartree-Fock analysis of this paper to clarify the exact nature of the phase boundaries, especially in the secondary dome. This can be done by limiting the allowed spin orders to the dominant spin orders that we found here and work directly in momentum space. This can also enable an investigation of the very small doping regime relevant for the recently observed cascade of phase transitions [\[59–](#page-13-3)[62\]](#page-13-4). Finally, spin fluctuations can be taken into account by transforming the (long-range ordered) magnetic state into a fluctuating magnet with short-range (and potentially topological) order. This can be achieved by extending $SU(2)$ gauge theories, incorporating Néeland spiral-ordered chargons [\[34–](#page-12-4)[36\]](#page-12-5), to the new lattice geometry and also considering magnetic stripe order. Experimentally, the different magnetic phases we find can be detected by scanning tunneling measurements, where a direct comparison with the Fourier modes and real space charge patterns, which follow the magnetisation of the local spin patterns, is possible. In this context, it will be interesting to further analyse the effect of extended Van Hove singularities observed in intercalated graphene samples [\[58,](#page-13-2) [73,](#page-13-16) [74,](#page-13-9) [76,](#page-13-8) [82\]](#page-13-17). Our results demonstrate that intercalation of graphene and BBG can lead to interesting interaction-induced phases.

V. ACKNOWLEDGEMENTS

We thank Walter Metzner, Andrey Chubukov and Pietro Bonetti for several interesting and fruitful discussions.
