(The Belle and Belle II Collaborations)

We present the first search for the lepton flavor-violating decay modes $B^0 \to K_S^0 \tau^{\pm} \ell^{\mp}$ ($\ell = \mu, e$) using the 711 fb⁻¹ and 365 fb⁻¹ data samples recorded by the Belle and Belle II detectors, respectively. We use a hadronic *B*-tagging technique, and search for the signal decay in the system recoiling against the fully reconstructed *B* meson. We find no evidence for $B^0 \to K_S^0 \tau^{\pm} \ell^{\mp}$ decays and set 90% confidence level upper limits on the branching fractions in the range of $[0.8, 3.6] \times 10^{-5}$.

Recent anomalies observed in semileptonic B decays, particularly in transitions like $b \to c\tau \nu$ [1], may indicate deviations from lepton flavor universality. According to this principle, the three generations of leptons are expected to interact identically with gauge bosons, except for mass differences. The experimental deviations from the standard model (SM) predictions suggest the potential existence of new heavy particles that couple preferentially to third-generation leptons. Recently, Belle II reported a $b \to s \nu \bar{\nu}$ excess and obtained the branching fraction $\mathcal{B}(B^+ \to K^+ \nu \bar{\nu}) = (2.3 \pm 0.7) \times 10^{-5}$ [2], which is 2.7 standard deviations (σ) larger than the SM expectation. If confirmed, this would not only be physics beyond the standard model (BSM), but could also reflect off-diagonal couplings between leptons of different flavors [3, 4]. Lepton flavor-violating (LFV) decays, which are forbidden in the SM, could then occur in B meson decays at significant rates. Ref.[4], starting from the $B^+ \to K^+ \nu \bar{\nu}$ excess, predicts an enhancement of $\mathcal{B}(B \to K\tau^{\pm}\mu^{\mp})$ to $[2, 3] \times 10^{-6}$, which is close to the current experimental sensitivity. The BSM models in Refs. [3] and [5] predict significant enhancements in the branching fractions (\mathcal{B}) of processes such as $b \to s\tau \ell$, with the effect being enhanced due to the coupling of the third-generation b quark with the heaviest lepton, τ . This results in a notable increase in the branching fractions of $B \to K \tau^{\pm} \ell^{\mp}$ $(\ell = \mu, e)$ decays and provides a potential experimental window into BSM physics.

BaBar performed the first LFV searches in $B^+ \rightarrow K^+ \tau^\pm \ell^\mp$ modes and set upper limits (ULs) on their branching fractions in the range of [1.5, 4.5] × 10⁻⁵ at 90% confidence level (CL) [6]. Belle provided the most stringent UL on the $B^+ \rightarrow K^+ \tau^+ \mu^-$ decay of 6×10^{-6} at 90% CL using 772 × 10⁶ $B\bar{B}$ pairs [7], significantly better than LHCb's limit of 3.9×10^{-5} , obtained with 9 fb⁻¹ of *pp* collision data [8]. Moreover, LHCb set ULs on $B^0 \rightarrow K^{*0} \tau^\pm \mu^\mp$ decays in the range of [0.8, 1.0]×10⁻⁵ at 90% CL [9].

In this Letter, we present the first search for the LFV decays $B^0 \to K_S^0 \tau^{\pm} \ell^{\mp}$ ($\ell = \mu, e$). We employ a hadronic *B*-tagging technique, and then use recoil mass to reconstruct the mass of the τ . Our results are based on a combined analysis of $772 \times 10^6 B\bar{B}$ pairs (711 fb⁻¹) from

Belle and $387 \times 10^6 \ B\bar{B}$ pairs (365 fb⁻¹) from Belle II (2019–2022). The advantage of K_S^0 over K^+ and K^{*0} in $B \to K \tau \ell$ decays is its very pure $K_S^0 \to \pi^+ \pi^-$ signature, which is an additional advantage over pp collision experiments, highlighting the unique strengths of Belle and Belle II.

Belle operated at the KEKB asymmetric-energy collider with electron-(positron-)beam energies of 8.0(3.5) GeV [10]. Belle II operates at the successor, SuperKEKB, designed to deliver forty times higher instantaneous luminosity than KEKB, with electron-(positron-)beam energies of 7(4) GeV [11]. The Belle II detector [13] is a upgraded version of the Belle [12], including a vertex detector (VXD), composed of two inner layers of pixel detectors (PXD) and four outer layers of double-sided strip detectors (SVD), a central drift chamber (CDC), a time-of-propagation (TOP) detector in the central detector volume and an aerogel ring-imaging Cherenkov (ARICH) detector in the forward region, and an electromagnetic calorimeter (ECL). All these sub-detectors are located inside the same solenoid as in Belle, with a K_L^0 -Muon detector (KLM) instrumented in the yoke.

The analysis procedure is first developed using simulation before being applied to data. EvtGen [14] is used to generate $e^+e^- \rightarrow \Upsilon(4S) \rightarrow B\bar{B}$ with final-state radiation simulated by PHOTOS [15]. The $B^0 \rightarrow K_S^0 \tau^{\pm} \ell^{\mp}$ signal channels are modeled using an uniform three-body phase space model. The KKMC [16] and PYTHIA [17] packages are used to simulate the $e^+e^- \rightarrow q\bar{q}$ continuum (q = u, d, s, c). The detector responses are modeled by GEANT3 [18] for Belle and GEANT4 [19] for Belle II. We use the Belle II analysis software framework (basf2) [20] to reconstruct the events for both Belle and Belle II data. The Belle data is converted to the Belle II format for basf2 compatibility using the B2BII framework [21].

In each $B\bar{B}$ pair, if one *B* meson, $B_{\rm sig}$, decays to a final state involving neutrinos, it cannot be fully reconstructed as neutrinos escape the detector. However, the presence of missing energy and momentum can be inferred from the other *B* meson. This process is called tagging, with the other *B* meson referred to as $B_{\rm tag}$. By combining the visible particles from $B_{\rm sig}$, we can kine-

matically constrain the undetected neutrinos as possible products of a τ decay. We require a fully reconstructed B_{tag} using the full-event-interpretation (FEI) algorithm [22], a machine-learning based algorithm developed for *B*-tagging analyses at Belle and Belle II. Each reconstructed B_{tag} candidate is assigned a multivariate classifier output, \mathcal{P}_{FEI} , ranging from zero (backgroundlike) to one (signal-like). To constrain the $B_{\rm tag}$ kinematics, we require the beam-energy-constrained mass $M_{\rm bc} = \sqrt{\left(E_{\rm beam}/c^2\right)^2 - \left(p_{B_{\rm tag}}/c\right)^2} > 5.27 \text{ GeV}/c^2, \text{ and}$ the energy difference $\Delta E = E_{B_{\rm tag}} - E_{\rm beam}$ to satisfy $-0.15 < \Delta E < 0.1 \text{ GeV}.$ Here, $E_{\rm beam}, E_{B_{\rm tag}},$ and $p_{B_{\rm tag}}$ denote the beam energy, and the energy and momentum of the B_{tag} candidate in the e^+e^- center-of-mass (c.m.) frame, respectively. If multiple B_{tag} candidates are reconstructed in a single event, the one with the highest \mathcal{P}_{FEI} is chosen, and candidates satisfying $\mathcal{P}_{\text{FEI}} > 0.001$ are retained. Using these criteria, the B-tagging has an average efficiency of 0.59% and a purity of 44%. Here, purity is the ratio of reconstructed or expected signal events to total events in the signal region.

Tracks and clusters not associated to B_{tag} are used to reconstruct the B_{sig} , whose flavor is assumed to be opposite to that of the B_{tag} candidate. The BSM couplings between $b\tau$ and $b\ell$, or between $s\tau$ and $s\ell$, can be different, leading to an asymmetric differential decay rate between $b \to s\tau^+\ell^-$ and $b \to s\tau^-\ell^+$ (see Eq. 9 in Ref. [3]). To address this and the different background characteristics, we distinguish signal channels by the primary lepton charge and b quark flavor: same-sign SS_ℓ ($B^0 \to K_S^0 \tau^- \ell^+$) and opposite-sign OS_ℓ ($B^0 \to K_S^0 \tau^+ \ell^-$). Due to $B^0 - \overline{B}^0$ mixing, a small fraction (χ_d) [23] of SS_ℓ decays are classified as OS_ℓ decays, and vice versa. The τ candidates are reconstructed via $\tau \to e\nu\bar{\nu}, \mu\nu\bar{\nu}, \pi\nu$, or $\rho(\to \pi\pi^0)\nu$, covering over 70% of τ decays [23]. Signal channels are formed by combining a K_S^0 , a primary lepton (ℓ), and a τ decay track (t_{τ}).

We reconstruct K_S^0 candidates from a pair of oppositely charged tracks assumed to be pions, with a common vertex. We use a standard momentum-binned K_S^0 selection that includes requirements on the K_S^0 flight information [24]. The purity of the K_S^0 candidates exceeds 98%, with backgrounds predominantly containing real K_S^0 candidates.

To select ℓ and t_{τ} , we require the transverse (d_0) and longitudinal (z_0) projection of the distance of closest approach to the origin to be less than 0.5 cm and 5.0 cm to reduce misreconstructed or spurious tracks from beaminduced background. At least 20 hits in the CDC are required. For Belle, we use information from the KLM only to identify muon candidates, while for Belle II, we use information from all sub-detectors except the VXD. Muon candidates are required to have momenta greater than 0.6 GeV/c to sufficiently penetrate the KLM. This selection has an efficiency of 89% with a pion misidentification rate lower than 2.5% for both samples [25]. Electrons are required to have momenta greater than 0.3 GeV/c to lie in the acceptance of the ECL. For Belle, electrons are identified using the information from the ECL, CDC and aerogel threshold Cerenkov counter (ACC), respectively. For Belle II, the electron identification uses a boosted-decision-tree (BDT) classifier trained with information from all sub-detectors except the VXD. The electron identification has an efficiency of 92% (86%) and a pion misidentification rate below 0.3% (0.5%) for Belle (Belle II) [26]. To recover electron candidates with bremsstrahlung, we accept photons with a minimum energy of 50 MeV that are within a 50 mrad angle of an electron track. Pion candidates for t_{τ} reconstruction are selected using PID likelihoods using information from the ACC, CDC, and time-of-flight scintillation counters for Belle. For Belle II, information from all the subdetectors except the VXD is used. This achieves a pion identification efficiency of 85% (83%) and a kaon misidentification rate of 6% (8%) for Belle (Belle II).

The $\tau \to \rho \to \pi \pi^0 \nu$ mode, the most probable τ decay channel ($\mathcal{B} > 20\%$), has never been used in $B \to K\tau\ell$ analyses [6-8]. Understanding this mode is crucial for improving the kinematic properties of t_{τ} and enhancing background rejection strategies. However, its reconstruction is challenging due to contamination from π^0 mesons, which can be misreconstructed using either a fake photon (clusters associated with hadronic deposits) or a photon from beam-background. To reconstruct the clean $\tau \to \rho \nu$ mode, photons are selected with energies above 50(60) MeV, 100(75) MeV, and 150(100) MeV in the barrel, forward, and backward endcaps for Belle (Belle II). We developed classifiers to suppress these backgrounds using BDTs. The common cluster features are energy, polar angle (relative to the beam-pipe), lateral energy distribution [27], distance between the cluster and its nearest track, and fraction of cluster energy detected in the central part. For Belle II classifiers, we include additional features: the time-difference between the collision and reconstructed cluster; outputs of classifiers using eleven Zernike moments [28]; and identifiers for electromagnetic or hadronic showers using pulse shape discrimination [29]. For Belle, additional features include azimuthal angle, number of crystals in the cluster, and energy in the most energetic crystal. On average, the classifiers reduce backgrounds by 90% with a π^0 efficiency of 70%, including the selection 0.125 < $M_{\pi^0} < 0.145 \text{ GeV}/c^2$. The ρ candidates are selected with $0.60 < M_{\pi\pi^0} < 0.94 \text{ GeV}/c^2$, with one candidate randomly chosen due to the multiplicity of 1.07.

The rest-of-event (ROE) consists of the tracks and clusters not used in B_{tag} and B_{sig} . We select events without any track in the ROE having $|d_0| < 10$ cm and $|z_0| < 20$ cm. The ROE clusters are required to satisfy the same selection criteria as the photons used for π^0 reconstruction. If the t_{τ} candidate is identified with multiple particle hypotheses, we assign a single one according to the following priority order (based on the purity of the modes): muon, electron, and pion. We require the $\tau \to \pi \nu$ mode to have no additional π^0 candidate in the ROE to avoid double counting with the $\tau \to \rho \nu$ mode. The $B_{\rm sig}$ momentum is equal in magnitude and opposite in direction to that of $B_{\rm tag}$, $\vec{p}_{B_{\rm tag}}$, and the $B_{\rm sig}$ energy is equal to $E_{\rm beam}$ in the c.m. frame. Therefore, the τ momentum and energy are given by,

$$\begin{split} \vec{p}_\tau &= -\vec{p}_{B_{\text{tag}}} - \vec{p}_{K_S^0} - \vec{p}_\ell, \\ E_\tau &= E_{\text{beam}} - E_{K_S^0} - E_\ell \end{split}$$

from which we reconstruct the recoiling M_{τ} according to Eq. 1. The signal yields are then extracted from M_{τ} , as signal events peak at the known τ mass [23], while the background remains flat without any peaking structures in the simulation. When t_{τ} is μ or e (i.e. when there are two leptons in B_{sig}), it is possible to form both SS_{ℓ} and OS_{ℓ} candidates, but this does not bias the signal yield as misassigned candidates do not peak in M_{τ} .

$$M_{\text{recoil}} = M_{\tau} = \left[m_B^2 + M_{K_S^0 \ell}^2 - 2 \left(E_{\text{beam}} E_{K_S^0 \ell} + |\vec{p}_{B_{\text{tag}}}| |\vec{p}_{K_S^0 \ell}| \cos \theta \right) \right]^{\frac{1}{2}}$$
(1)

Here, m_B is the known B^0 mass [23]; $M_{K_S^0\ell}$, $E_{K_S^0\ell}$, $\vec{p}_{K_S^0\ell}$ are the mass, energy, and momentum of the system composed of the K_S^0 and ℓ , respectively; θ is the angle between $\vec{p}_{B_{\text{tag}}}$ and $\vec{p}_{K_S^0\ell}$. The M_{τ} resolution is approximately 25 MeV/ c^2 for both Belle and Belle II simulations.

The background after the pre-selection is mainly decays arising from $b \to c$ transitions. Events with $B^0 \to c$ $D^{(*)-}(\to K^0_S t^- X) \ell^+ \nu$ decays, where the reconstructed primary lepton originates from semileptonic B^0 decay and a track t^- from $D^{(*)-}$ is misinterpreted as coming from the τ decay, with X representing any other particles, constitute the dominant source of background in SS_{ℓ} modes. If $B^0 \to D^{(*)-\ell+\nu}$ undergoes a flavor transformation due to $B^0-\bar{B}^0$ mixing, this results in a change in the signs of the final states $(\bar{B}^0 \to D^{(*)+} \ell^- \bar{\nu})$ and provides the appropriate sign configuration for the final state in OS_{ℓ} modes. Additionally, the reconstruction of the primary lepton from $B_{\rm sig}$ tends to favor a higher momentum lepton originating from the B^0 meson. Consequently, semileptonic B decays are the primary background in both SS_{ℓ} and OS_{ℓ} modes. As the K_S^0 and t_τ come from a D meson, we require the invariant mass of K_S^0 and t_{τ} to be greater than 1.91 GeV/ c^2 , i.e., greater than the D meson mass accounting for resolution. For $\tau \to \rho \nu$ decay, we require $M_{K^0_s \rho}$ to be greater than 2.1 GeV/c^2 due to the poor mass resolution resulting from the presence of a π^0 candidate. Because $B^0 \rightarrow$ $K_S^0 J/\psi(\to \ell^+ \ell^-)$ background can pass our selection criteria, events in the range $3.00 < M_{t_{\tau}\ell} < 3.14 \text{ GeV}/c^2$ are rejected when ℓ is an electron (muon) for the $\tau \to e(\mu)\nu\bar{\nu}$ mode. To suppress the photon conversion background, we require $M_{t_{\tau}\ell}$, in this case $M_{e^+e^-}$, to be greater than $0.15 \text{ GeV}/c^2$.

Continuum $q\bar{q}$ events can be distinguished from $B\bar{B}$ events by exploiting their difference in event topologies.

We use sphericity-related variables [30] and require the cosine of the angle between the thrust axis of B_{tag} and the other particles not used in B_{tag} (cos θ_{T}) to be less than 0.9. These selections reduce the $q\bar{q}$ background by 86% and retain 88% of the signal for both samples.

After the above selection criteria, the background consists of charm meson semileptonic decays with a K_S^0 and ℓ in their final state, other $B\bar{B}$ decays, and $q\bar{q}$ events. For each signal mode, BDT classifiers are trained with 11 features to suppress the residual backgrounds. These features include $M_{K_c^0\ell}$, which helps to suppress the background from charm meson semileptonic decays, the sum of ECL cluster energies in the ROE, energies of the ℓ and t_{τ} , event-shape variables and modified Fox-Wolfram moments [31], which help to reduce the $q\bar{q}$ background. The same BDT output criterion are used for Belle and Belle II because of the similar performance, determined using figure of merit $\epsilon_{\rm sig}/(\frac{a}{2} + \sqrt{N_{\rm bkg}})$ [32]. Here, $\epsilon_{\rm sig}$ is the signal efficiency, $N_{\rm bkg}$ is the expected background yield and a = 3 represents the target significance in terms of standard deviations. The BDT selection results in an average signal efficiency of about 75% and rejects 90% of the remaining background.

The purity in the simulations is similar in Belle and Belle II for every channel after applying all selection criteria, so the two datasets are merged. To extract the signal yield, we do a single unbinned-maximum-likelihood fit to the M_{τ} distribution of the combined dataset. The probability density function (PDF) used to model the M_{τ} signal distribution is a Johnson function [33]. The parameters that describe the signal shape are fixed to the values obtained from the fit to the simulated samples. Background events have a smooth distribution in the M_{τ} fit region, modeled using a second-order polynomial. To validate the fitting procedure, we generate large ensembles of simulated experiments, in which the M_{τ} distributions are produced from the PDFs used for fitting. Comparisons of the simulated and measured signal yields indicate no obvious bias.

The $B^0 \to D^-\pi^+$ sample is used to calibrate B_{tag} efficiency. We reconstruct B_{tag} using the FEI and a high momentum π^+ , then compute M_{recoil} to observe the D signal using Eq. 1. The yield ratio $\mathcal{R}_{\text{FEI}} = N_{\text{data}}/N_{\text{simulation}} = 0.74 \pm 0.04 \ (0.81 \pm 0.04)$ is taken as the calibration factor for the B_{tag} efficiency in Belle (Belle II).

The $B^0 \to D_s^+ D^-$ sample is used to calibrate the signal PDF and BDT selections. The D^- mass is reconstructed similarly to the τ mass in the signal decays. We reconstruct neutral B_{tag} candidates using the FEI algorithm and D_s^+ , sharing the same momentum range as $K_S^0 \ell$, through the decays $\phi(\to K^+ K^-)\pi^+$ and $K_S^0 K^+$ and a charged track from D as t_{τ} . The distribution of the mass recoiling against the B_{tag} and D_s^+ system is shown in Fig. 1 and clear signals for D^- and D^{*-} are visible. The $B^0 \to D_s^+ D^{*-}$ component is also fitted but we do not use it due to its lower purity. The $B^0 \to D_s^+ D^-$ signal PDF is modeled by the Johnson function and the parameters are fixed in the fits, except the mean, while

the background is described by an exponential function with floating yield and shape parameters. We introduce a scale factor f to account for data-simulation difference on the width from signal simulation. The f ratio, determined to be 1.04 ± 0.15 , is used as a correction factor for the width. The value of $\mathcal{B}(B^0 \to D_s^+ D^-)$ is measured to be $(10.1 \pm 1.2) \times 10^{-3}$, consistent with the world-average value [23] within 2σ , and serves as a closure test of the entire analysis chain. To validate the BDT performance, we apply $B^0 \to K_S^0 \tau^{\pm} \ell^{\mp}$ weights to $B^0 \to D_s^+ D^-$ events. The efficiency is derived from $B^0 \to D_s^+ D^-$ yields before and after BDT selection using M_{recoil} fits. The data-simulation efficiency ratios (\mathcal{R}_{BDT}) are 0.93 ± 0.17 , 0.96 ± 0.16 , 0.92 ± 0.16 , and 0.96 ± 0.18 for the OS_{μ} , SS_{μ} , OS_e , and SS_e modes, respectively.

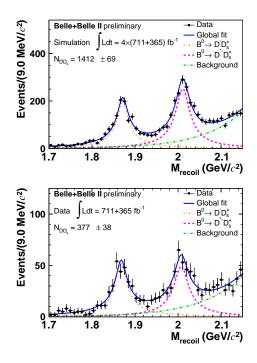

FIG. 1. Fit to the recoil mass of the B_{tag} and D_s^+ system for simulation (upper) and data (lower) with the combined Belle and Belle II samples.

Figure 2 shows the M_{τ} fits to data for $B^0 \to K_S^0 \tau^{\pm} \ell^{\mp}$ decays. There is no significant signal in any of the fit channels. We translate the number of observed events N_{sig} into a branching fraction \mathcal{B} using the expression

$$\mathcal{B} = \frac{N_{\rm sig}}{\epsilon \times 2N_{B\bar{B}} \times (1 + f_{+-}/f_{00})^{-1}},\tag{2}$$

where ϵ is the efficiency after $\mathcal{R}_{\rm BDT}$ and $\mathcal{R}_{\rm FEI}$ calibrations. The efficiency also includes the branching fractions of K_S^0 , τ , ρ , π^0 , and the effect of B^0 - \bar{B}^0 mixing (i.e. signal loss in mixed events) in the simulation. In the case where the true branching fractions are zero, the resulting estimates are unbiased. We use $N_{B\bar{B}} = 1159 \times 10^6$, which is the total number of *BB* pairs for the combined datasets; and $f_{+-}/f_{00} = 1.052 \pm 0.031$, which is the ratio

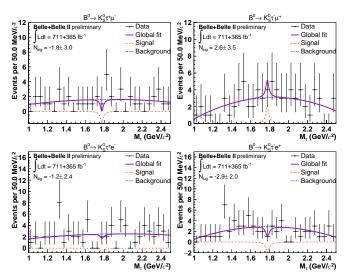

FIG. 2. The M_{τ} distributions and fits for the combined Belle and Belle II datasets. The black dots with error bars show the data, the red dash-dotted curve shows the signal component, the blue dashed curve shows the background component, and the purple solid curve shows the global fit.

We obtain ULs on the signal yields using pseudoexperiments. They are generated using background and signal PDFs for different values of the signal branching fractions, performing 10,000 fits for each value. We then define $N_{\text{sig}}^{\text{UL}}$ at 90% CL as the signal yield for which 10% of the experiments have fit yields less than the observed $N_{\rm sig}$ in data. Systematic uncertainties are included by smearing the $N_{\rm sig}$ distribution obtained from the pseudoexperiments with the fractional systematic uncertainty, which has an effect of less than 1% on the mean $N_{\rm sig}$. The ULs on the branching fractions \mathcal{B}^{UL} are then ob-tained from $N_{\text{sig}}^{\text{UL}}$ using Eq. 2. Including the effect of $B^0 - \overline{B}^0$ mixing in the efficiency (Eq. 2) ensures ULs correctly cover the case of zero true branching fractions and are conservative otherwise. Table I summarizes the efficiency, fit results, and observed ULs at 90% CL for the four channels. Expected ULs, derived from the no-signal assumption, are in the range $[2.1, 2.2] \times 10^{-5}$.

TABLE I. Efficiencies (ϵ), signal yields ($N_{\rm sig}$) of the data fit, central value of the branching fractions and the observed $\mathcal{B}^{\rm UL}$ at 90% CL. The first uncertainty of the central value is statistical and the second is systematic.

			$\mathcal{B}(10^{-5})$	
Channels	$\epsilon(10^{-4})$	$N_{ m sig}$	Central value	UL
$B^0 \to K^0_S \tau^+ \mu^-$	1.7	-1.8 ± 3.0	$-1.0 \pm 1.6 \pm 0.2$	1.1
$B^0 \to K^0_S \tau^- \mu^+$	2.1	2.6 ± 3.5	$1.1\pm1.6\pm0.3$	3.6
$B^0 \to K^0_S \tau^+ e^-$	2.0	-1.2 ± 2.4	$-0.5\pm1.1\pm0.1$	1.5
$B^0 \to K^0_S \tau^- e^+$	2.1	-2.9 ± 2.0	$-1.2\pm0.9\pm0.3$	0.8

The primary source of systematic uncertainty arises

from the BDT selections, which is 16–18%, based on the uncertainty in \mathcal{R}_{BDT} using the $B^0 \to D_s^+ D^-$ sample. Using the same sample, the uncertainty from the signal PDF is 15%. This includes the uncertainties in width (uncertainty of the width correction factor), mean (deviation from nominal D mass in the data fit), skewness, and Gaussian component strength of the Johnson function, estimated using a new PDF reweighted by modedependent calibration factors for the dominant B-tagging modes. The uncertainty in the B_{tag} efficiency is taken from the uncertainty of \mathcal{R}_{FEI} (4%). The small difference (0.8-1.6%) in the validation of the fitting procedure is treated as the associated uncertainty. The uncertainty in K_S^0 reconstruction is estimated to be 1.1% using a $D^{*+} \to \pi^+ D^0, D^0 \to K_S^0 \pi^+ \pi^-$ sample. The Belle PID uncertainties are evaluated using $J/\psi \to \ell^+ \ell^-$ and $D^{*+} \to D^0 (\to K^- \pi^+) \pi^+$ samples to be 0.3%, 0.4% and 1.0% for muons, electrons, and pions, respectively. The Belle II PID uncertainties for muon, electron and pion are 0.5%, 1.0% and 1.0%, respectively, which are obtained using the samples described in Ref. [35]. The uncertainty from the π^0 reconstruction is 1.3% using $B^+ \to K^{*+}(\to$ $K^+\pi^0)J/\psi$ and $D^{*-} \rightarrow \bar{D}^0(\rightarrow K^+\pi^-\pi^0)\pi^-$ samples. The uncertainty for the requirement that there is no additional π^0 candidate in the ROE in the $\tau \to \pi \nu$ mode is 1.0% using $B_{\text{tag}}B(\to K_S^0 J/\psi)$ events. The uncertainties arising from $N_{B\bar{B}}$, f_{+-}/f_{00} , and the branching fractions of K_S^0, τ, ρ and π^0 decays [23] are 1.1%, 1.5% and 0.7%, respectively. For sources with different systematic uncertainties in Belle and Belle II, we calculate the total multiplicative values by weighting the individual uncertainties according to the integrated luminosities of the two samples. The total systematic uncertainties are 24%, 22%, 23%, and 24% for OS_{μ} , SS_{μ} , OS_{e} , and SS_{e} modes, respectively.

In summary, we have searched for $B^0 \to K_S^0 \tau^{\pm} \ell^{\mp}$ for the first time using Belle and Belle II datasets. This is also the first direct search for LFV in *B* decays using the Belle II dataset. The ULs on the branching fractions at 90% CL are:

$$\begin{split} \mathcal{B}(B^0 \to K^0_S \tau^+ \mu^-) &< 1.1 \times 10^{-5} \\ \mathcal{B}(B^0 \to K^0_S \tau^- \mu^+) &< 3.6 \times 10^{-5} \\ \mathcal{B}(B^0 \to K^0_S \tau^+ e^-) &< 1.5 \times 10^{-5} \\ \mathcal{B}(B^0 \to K^0_S \tau^- e^+) &< 0.8 \times 10^{-5} \end{split}$$

The results for $B^0 \to K_S^0 \tau^{\pm} e^{\mp}$ are the most stringent ULs on $b \to s\tau e$ transitions, and those for $B^0 \to K_S^0 \tau^{\pm} \mu^{\mp}$ are among the best limits on $b \to s\tau \mu$ transitions achieved to date. These results are approaching the potential BSM enhancement level of $\mathcal{O}(10^{-6})$. Additionally, we provide the selection efficiency as a function of $(M_{\tau\ell}^2, M_{K_S^0\ell}^2)$ in the Supplemental Material, to allow these results to be reinterpreted in specific BSM models.

Supplemental material

SUPPLEMENTAL FIGURES

Figure 1 presents the selection efficiencies for the four signal modes: $B^0 \to K^0_S \tau^+ \mu^-$, $B^0 \to K^0_S \tau^- \mu^+$, $B^0 \to K^0_S \tau^- e^+$. The efficiency is shown as a function of two kinematic variables, $M^2_{\tau\ell}$ and $M^2_{K^0_S \ell}$, where the 4-momentum of the τ lepton is inferred using the $B_{\rm tag}$ reconstruction. These distributions can be utilized to reinterpret the results for different models and kinematics, extending beyond the uniform phase space distribution assumed in the signal simulation and upper limit estimation.

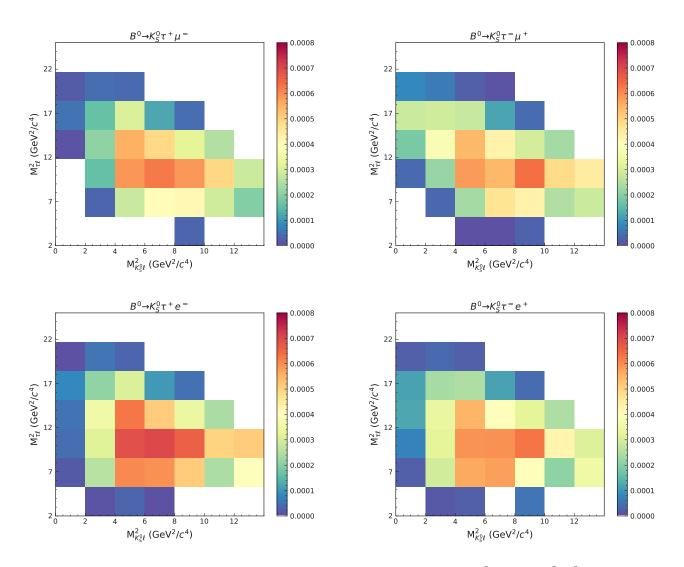

FIG. 1: Selection efficiency as a function of the kinematic variables $M^2(\tau \ell)$ and $M^2(K_S^0 \ell)$.
