# ABSTRACT

arXiv:2412.16485v1 [cs.DS] 21 Dec 2024

Counting the number of (p, q)-bicliques (complete bipartite subgraphs) in a bipartite graph is a fundamental problem which plays a crucial role in numerous bipartite graph analysis applications. However, existing algorithms for counting (p, q)-bicliques often face significant computational challenges, particularly on large real-world networks. In this paper, we propose a general biclique counting framework, called NPivoter, based on a novel concept of node-pivot. We show that previous methods can be viewed as specific implementations of this general framework. More importantly, we propose a novel implementation of NPivoter based on a carefully-designed minimum non-neighbor candidate partition strategy. We prove that our new implementation of NPivoter has lower worst-case time complexity than the state-of-the-art methods. Beyond basic biclique counting, a nice feature of NPivoter is that it also supports local counting (computing bicliques per node) and range counting (simultaneously counting bicliques within a size range). Extensive experiments on 12 real-world large datasets demonstrate that our proposed NPivoter substantially outperforms state-of-the-art algorithms by up to two orders of magnitude.

# **1** INTRODUCTION

A bipartite graph is a special type of graph where the node set can be divided into two disjoint sets, typically denoted as U and V, such that every edge in the graph connects a node from U to a node from V, with no edges within U or V. If  $X \subseteq U$  and  $Y \subseteq V$ , the pair (X, Y) forms a (p, q)-biclique if |X| = p, |Y| = q, and every node in X is connected to every node in Y.

The count of (p, q)-biclique is a key structural measure in bipartite graphs. In graph database query optimization, this count helps predict query processing costs by estimating the result set size in join operations, improving query planning and execution efficiency [1, 29]. In graph neural networks (GNNs), counting (p, q)-bicliques for each node captures higher-order graph structural properties, which are crucial for improving model performance [3, 6, 35, 49, 54].

(p,q)-biclique counts are also essential in various real-life applications, such as social network analysis [5, 17, 41] and bioinformatics [34], where they help identify dense substructures representing highly connected clusters of users, entities, or data items.

The state-of-the-art (SOTA) methods for (p, q)-biclique counting are BCList++ [50] and EPivoter [52]. BCList++ is a listing-based algorithm that works by enumerating all *p*-node subsets of U (denoted as L) and finding their common neighbors in V, represented as *R*. The count of (p, q)-bicliques is then calculated as  $\binom{|R|}{q}$ , where the pruning techniques in BCList++ help avoid unnecessary searches. EPivoter, on the other hand, observes that (p, q)-bicliques are often subsets of larger bicliques. It uses edge enumeration to build a tree-like data structure, where each node in the tree represents an edge, and each root-to-leaf path corresponds to a large biclique. This search tree ensures that each (p, q)-biclique appears in exactly one large biclique, allowing EPivoter to count (p, q)-bicliques by enumerating the larger ones. Both BCList++ and EPivoter split the bipartite graph into smaller subgraphs before counting the bicliques, but they employ different graph-split strategies. BCList++, focusing on node enumeration, splits the graph based on the neighbors of nodes (namely node-split), whereas EPivoter, through edge enumeration, splits the graph based on edge neighbors (namely edge-split). This difference in strategy leads to varying efficiencies in counting (p, q)-bicliques depending on the graph structure and parameter values of p and q.

Despite the success, existing algorithms for (p, q)-biclique counting still have several significant limitations. For example, BCList++ performs well only when p and q are small, but its efficiency diminishes sharply as these values increase [50, 52]. On the other hand, EPivoter is more suited for larger *p* and *q* and can handle **range counting**, i.e., counting (p, q)-bicliques for different p and q in a range simultaneously. However, EPivoter suffers from high constant factors in its time complexity, primarily due to its edge-based enumeration approach. This method leads to more frequent set intersection operations, which increases computational overhead and makes it less efficient for smaller values of p and q [52]. Additionally, both BCList++ and EPivoter are limited by their high time complexity and reliance on a single graph-split strategy, which restricts their flexibility and scalability across various graph structures. Moreover, many applications, such as graph neural networks and graph clustering, require local counting, which involves computing the count of (p, q)-bicliques for individual nodes as an important property. Unfortunately, neither BCList++ nor EPivoter is well-suited for efficient local counting, further limiting their applicability in real-world scenarios.

To overcome the above limitations, we propose NPivoter, a versatile and general framework for biclique counting, which provides a theoretically and practically efficient algorithm. The NPivoter framework is general in two ways. First, it offers a unified perspective on biclique counting, where both BCList++ and EPivoter can be

regarded as specific implementations within this framework. This not only establishes NPivoter as a significant advancement over existing methods but also highlights its flexibility in addressing a wider range of cases. Second, NPivoter extends beyond traditional (p, q)-biclique counting to support both local counting and range counting. These extensions make NPivoter applicable to numerous real-world applications while ensuring greater efficiency and adaptability.

The core idea of the NPivoter framework is the concept of nodepivot. A set of nodes are called node-pivots if they connect to all the nodes on the opposite side. In NPivoter, these node-pivots simplify the enumeration process by eliminating the need for further exploration and building a unique representation for all bicliques. This unique representation allows NPivoter to efficiently count bicliques in a combinatoric way. On top of that, we develop an advanced implementation of the NPivoter framework by the candidate set partition strategy called the minimum non-neighbor candidate partition. This candidate partition makes the search tree of the NPivoter as small as possible. With this candidate partition strategy, we prove that our implementation achieves lower worst-case time complexity than the previous SOTA algorithms. For example, the time complexity of BCList++ depends on the result size, whereas EPivoter has a time complexity of  $O(|E|3|^{E_{max}|/3})$ , which is independent of the result size. In contrast, our new implementation of NPivoter has a result-size-free time complexity of  $O(|E|2^{n'/2})$ , where  $2^{1/2} < 3^{1/3}$  and  $n' < |E_{max}|$ , making it more efficient in the worst case. Furthermore, we enhance the efficiency of NPivoter with a carefully-designed cost estimator, which dynamically selects the node-split and edge-split strategies. This hybrid approach adapts to the specific structure of the graph, taking advantage of both node-split and edge-split to reduce computational overhead and improve scalability. In a nutshell, our main contributions are briefly summarized as follows:

A General Counting Framework: We propose NPivoter, a versatile and general framework for (p, q)-biclique counting, built upon the novel node-pivot technique. This framework not only unifies existing algorithms like BCList++ and EPivoter as special cases but also extends beyond them by supporting local and range biclique counting.

A Powerful Candidate Partition Strategy: We develop a powerful candidate partitioning technique—minimum non-neighbor candidate partition—which optimizes the search tree and achieves lower worst-case time complexity than SOTA approaches.

An Adaptive Splitting Technique: Our framework integrates a cost estimator that dynamically switches between node-split and edge-split strategies. This adaptive approach tailors the biclique counting process to the graph's structure, reducing computational overhead and improving practical performance.

**Extensive Experimental Evaluation:** Through comprehensive experiments on 12 real-world datasets, we demonstrate that the proposed NPivoter outperforms SOTA algorithms by up to two orders of magnitude in both basic and extended biclique counting tasks, underscoring the high efficiency and scalability of our solutions.

# 2 PRELIMINARIES

Let G = (U, V, E) be a bipartite graph, where U and V are disjoint sets of nodes, and  $E \subseteq U \times V$  is the set of edges. For each node  $u \in U$ , its neighbor set in V is  $N(u, V) = \{v \in V \mid (u, v) \in E\}$ . For a set of vertices  $S \subseteq U$ , the common neighbors of S in V are defined as  $N(S, V) = \bigcap_{u \in S} N(u, V)$ . The degree of a node u in V, denoted by d(u, V), is the size of its neighbor set: d(u, V) = |N(u, V)|. When the context is clear, we abbreviate N(u, V), N(S, V), and d(u, V) as N(u), N(S), and d(u), respectively. The 2-hop neighbors of a node  $u \in U$  are given by  $\bigcup_{v \in N(u,V)} N(v, U)$ . For all the above concepts, we have symmetrical definitions for vertices in V. A rank R of a set of nodes S is a vector that assigns each node in S a distinct number from the range [1, |S|]. Below, we give the definition of (p, q)-biclique.

Definition 2.1. Given a bipartite graph G(U, V, E), a (p, q)-biclique in G is a complete subgraph with a pair of vertex sets (X, Y) where |X| = p, |Y| = q.

**Problem Definition.** Given a bipartite graph G(U, V, E) and two integers p and q, the task is to compute the number of (p, q)-bicliques in G.

The (p, q)-biclique counting problem is NP-hard [50], which implies that no known polynomial-time algorithm can efficiently solve all instances of the problem.

*Example 2.2.* Figure 1 is a synthetic graph with 10 (3, 3)-bicliques. For example,  $(\{u_0, u_2, u_3, u_4\}_3, \{v_1, v_2, v_3\})$  is a (3, 3)-biclique, where  $\{u_0, u_2, u_3, u_4\}_3$  indicates choose arbitrary 3 nodes from  $\{u_0, u_2, u_3, u_4\}$ . The rest of (3, 3)-bicliques are  $(\{u_1, u_2, u_3, u_4\}_3, \{v_1, v_2, v_4\})$ ,  $(\{u_2, u_3, u_4\}, \{v_1, v_3, v_4\})$ , and  $(\{u_2, u_3, u_4\}, \{v_2, v_3, v_4\})$ .

# **3 EXISTING SOLUTIONS AND THEIR DEFECTS**

### 3.1 BCList++ [50]

BCList++ is a listing-based algorithm, which lists the *p*-node complete subgraphs in a data structure called the "2-hop graph". Specifically, given a bipartite graph G(U, V, E), the 2-hop graph H(U, E') is a directed acyclic graph (DAG) with the node set U, where two nodes are connected by an edge if they have at least q common neighbors in V. Namely, for all  $(u_0, u_1) \in E'$ ,  $|N(\{u_0, u_1\}, V)| \ge q$ . Thus, for any (p, q)-biclique (X, Y), the set X must form a complete subgraph in H(U, E'), as each pair of nodes in X has at least q common neighbors in  $Y \subseteq V$ . BCList++ counts the number of (p, q)-bicliques by listing all p-node complete subgraphs in H(U, E'). For each complete subgraph  $X \subseteq U$  where |X| = p, the number of (p, q)-bicliques is  $\binom{|N(X,V)|}{q}$ .

Fast Biclique Counting on Bipartite Graphs: A Node Pivot-based Approach

The first search layer of BCList++ divides the network into smaller subgraphs based on a ranking of nodes and then counts (p,q)-bicliques in these subgraphs. Specifically, for each node  $u \in U$ , BCList++ counts the (p-1,q)-bicliques in the subgraph induced by the neighbors and higher-ranked 2-hop neighbors of u. We refer to this method as the *node-split* strategy.

Given the bipartite graph G(U, V, E) and its 2-hop graph H(U, E'), the time complexity of BCList++ is  $O(\alpha(H)^{p-2}|E'|d_{\max}+\Delta)$ , where  $\alpha(H)$  is the arboricity of H [12],  $d_{\max}$  is the maximum degree in U(G) and  $\Delta$  is the size of result. BCList++ can also construct a 2-hop graph on V and enumerate q-cliques. Additionally, BCList++ employs an estimation model to determine which side of the graph (either U or V) is more efficient for enumeration.

BCList++ is efficient for large, sparse bipartite graphs when p or q is small. However, its performance degrades as p, q, or the graph size increases. For instance, on the Twitter dataset (|U| = 175, 214, |V| = 530, 418, |E| = 1, 890, 661), the count of (5, 5)-biclique reaches  $10^{13}$ , thereby the listing-based algorithms are doomed to fail. Another limitation is that BCList++ requires p and q as input parameters, meaning that it can only count (p, q)-bicliques for a specific pair of values. To count bicliques across a range of sizes, the algorithm must run multiple times for each pair of (p, q), which is inefficient. A third drawback is that BCList++ does not support local counting per node, which is essential for certain applications, such as graph neural networks and higher-order graph clustering, where local biclique counts serve as important node properties [3, 6, 35, 49, 54].

# 3.2 EPivoter [52]

Unlike BCList++, which counts (p, q)-bicliques by listing, EPivoter counts them using a combinatorial approach. A straightforward combinatorial method would first enumerate maximal bicliques and then count the (p, q)-bicliques within them. However, due to significantly overlapping maximal bicliques, a (p, q)-biclique might be counted multiple times. To address this, EPivoter introduces an edge-pivot technique that encodes large bicliques into a unique representation for each (p, q)-biclique. Specifically, EPivoter constructs a search tree where each tree vertex represents an edge, and each path from the root to a leaf corresponds to a large biclique. Each large biclique encodes a set of (p, q)-bicliques, and each (p, q)-biclique is uniquely represented by one large biclique. With this unique encoding, EPivoter can count (p, q)-bicliques combinatorially without listing them one by one.

As discussed above, BCList++ counts the (p-1, q)-bicliques with the *node-split* strategy. Differently, for each edge (u, v), EPivoter counts the (p - 1, q - 1)-bicliques in the subgraphs induced by the higher-ranked neighbors of both u and v. This method is termed the *edge-split* strategy. Deciding which strategy is more efficient is complex and depends on both the algorithm and the graph structure. Different algorithms and graph structures are better suited to different strategies, and even different parts of a single graph may benefit from various approaches. In this paper, we will propose a novel cost estimator to leverage the advantages of both the node-split and edge-split strategies (Section 4.3).

Given the bipartite graph G(U, V, E), the time complexity of EPivoter is  $O(|E|3^{|E_{\max}|/3})$ , where  $|E_{\max}|=\max_{(u,v)\in E}|E\cap (N(u)\times$ 

N(v))|. Unlike BCList++, EPivoter has a time complexity free from the result size (the (p, q)-biclique counts). EPivoter is more efficient than BCList++ when p and q are relatively large (e.g.,  $p \ge$  $6, q \ge 6$ ), and can count bicliques across a range of sizes simultaneously, thanks for the edge-pivot based unique encoding [52]. However, EPivoter is less efficient when p and q are very small (e.g., p < 6, q < 6). The key difference is in the enumeration process: BCList++ enumerates nodes from one side (i.e., selecting a node from a fixed side during backtracking), while EPivoter enumerates edges (each search tree vertex represents an edge), selecting two nodes-one from each side-during backtracking. This approach leads to higher constant factors in its time complexity for EPivoter, as edge enumeration requires more set intersection operations, which are computationally intensive. As a result, EPivoter is not as efficient when p and q are very small. Moreover, the time complexity of EPivoter can be high, as it depends on the parameter  $|E_{max}|$ , which can significantly affect performance.

### **4 NOVEL NODE-PIVOT BASED FRAMEWORK**

As previously discussed, the BCList++ algorithm enumerates nodes on only one side, which constitutes a straightforward and lightweight approach. On the other hand, EPivoter constructs a unique representation for all (p, q)-bicliques, proving more efficient for relatively larger p and q. However, EPivoter is hindered by a high time complexity, with an exponential component that is contingent upon  $|E_{max}|$ . On top of that, EPivoter incurs high constant factors due to its edge enumeration process. A pertinent question arises: is it possible to devise an algorithm that (1) maintains simplicity and lightweightness, (2) is efficient for counting (p, q)-biclique whether p and q is large or small, (3) facilitates both local counting and range counting, and (4) exhibits an improved worst-case time complexity?

To achieve these goals, we propose a novel node-pivot based framework NPivoter. Firstly, NPivoter employs the proposed powerful node-pivot technique to build a unique representation for all (p, q)-bicliques, while the previous work EPivoter utilizes edgepivot. Our node-pivot differs significantly from edge-pivot. Our node-pivot is a set of nodes which connect to all the opposite nodes, while edge-pivot is an edge with the maximum number of neighbors. Secondly, since NPivoter can construct a unique representation for all (p, q)-bicliques, we can use a combinatorial counting approach to significantly reduce redundant calculations. Thirdly, NPivoter is a general framework for counting bicliques. We show that both the previous methods BCList++ and EPivoter are special implementations of our framework. Further, we propose a specific candidate partition strategy to boost the efficiency and achieve a lower worstcase time complexity (details in Section 4.2). At last, in Section 4.3, we develop a novel cost estimator to judge whether node-split or edge-split is more efficient under different graph structures.

# 4.1 The Proposed NPivoter Framework

The key idea of the NPivoter framework is the following node-pivot.

Definition 4.1 (node-pivot). For any  $C_U \subseteq U$ ,  $C_V \subseteq V$ , let  $P_U = \{u | u \in C_U, N(u, C_V) = C_V\}$  and  $P_V = \{v | v \in C_V, N(v, C_U) = C_U\}$ . We refer to the nodes in  $P_U$  and  $P_V$  as node-pivots.

26	$ cnt \leftarrow cnt + \binom{p_0 + c_0}{p - h_0} \binom{p_1}{q - h_1} + \binom{p_0}{p - h_0} \binom{p_1 + \hat{c}_1}{q - h_1} - \binom{p_0}{p - h_0} \binom{p_1}{q - h_1}; $							

**An In-depth Observation.** Given that  $C'_U = C_U \setminus P_U$  and  $C'_V =$  $C_V \setminus P_V$ , any biclique extended by a node-pivot preserves its biclique structure since node-pivots are connected to all nodes in the opposite set. For instance, an (x, y)-biclique in  $(C'_U, C'_V)$  becomes an (x + 1, y)-biclique if extended by a node in  $P_U$  and an (x, y + 1)-biclique if extended by a node in  $P_V$ . Furthermore, an (x, y)-biclique can evolve into an (x + a, y + b)-biclique by extending it with a nodes from  $P_{U}$  and b nodes from  $P_{V}$ . This important characteristic of node-pivots enables the NPivoter framework to significantly reduce the size of the candidate sets by shrinking  $C_U$ and  $C_V$  to  $C'_U$  and  $C'_V$ , respectively. If there are c(x, y)-bicliques in  $(C'_U, C'_V)$ , the total number of (p, q)-bicliques in  $(C_U, C_V)$  can be computed by  $c\binom{|P_U|}{p-x}\binom{|P_V|}{q-y}$ , in a combinatorial way. To calculate the bicliques in  $(C'_U, C'_V)$ , NPivoter divides  $(C'_U, C'_V)$  into multiple smaller subsets. Each of these small subsets has its own node-pivots, and the NPivoter framework recursively processes them to build down the problem. Through this recursive approach, NPivoter efficiently represents and counts all (p, q)-bicliques combinatorially.

The process of dividing  $(C'_U, C'_V)$  into smaller subsets, referred to as the candidate partition problem, has a significant impact on the performance of the NPivoter framework. Given four node sets  $L_U \subseteq C_U \subseteq U$  and  $L_V \subseteq C_V \subseteq V$ , the bicliques in the bipartite graph  $G(C_U, C_V)$  can be classified into two main categories: those that include nodes from  $L_U$  and  $L_V$ , and those that do not. The NPivoter framework enumerates  $L_U$  and  $L_V$  to break the candidate sets into multiple subsets. Each subset counts the bicliques that include nodes from  $L_U$  and  $L_V$ . The final subset,  $C_U \setminus L_U$  and  $C_V \setminus L_V$ , is used to count the bicliques that do not include nodes from either  $L_U$  or  $L_V$ . We propose a specific candidate partition strategy that ensures NPivoter operates within a worst-case time complexity (details in Section 4.3).

**Remark.** We will show later that both BCList++ and EPivoter can be viewed as specific implementations of the broader NPivoter framework, each with distinct strategies for selecting node-pivots. BCList++ processes the graph without leveraging node-pivot based pruning. On the other hand, EPivoter prunes an edge (u, v) where  $u \in P_U$  and  $v \in P_V$ . In contrast, the NPivoter framework prunes all node-pivots, which enables it to prune a greater number of candidate sets compared to BCList++ and EPivoter. As demonstrated in the experiments discussed in Section 6, over 85% of (10, 10)bicliques across the tested graphs are counted using this combinatorial method, showcasing the effectiveness of the NPivoter approach.

**Implementation Details.** Algorithms 1 shows the pseudo-code of NPivoter. NPivoter inputs G(U, V, E), p, q and outputs the count of (p, q)-biclique in G. Let R be the rank of nodes (line 1). NPivoter splits the bipartite graph into smaller subgraphs and counts the (p, q)-bicliques within them. There are two splitting strategies. The first is the edge-split, where an edge (u, v) is chosen, and the algorithm counts (p - 1, q - 1)-bicliques in the subgraph induced by nodes of higher rank (lines 5-8 of Algorithm 1). The second is the node-split, where a node u is chosen, and the algorithm counts (p - 1, q)-bicliques in the subgraph induced by N(u) and higher-ranked 2-hop nodes (lines 10-11 of Algorithm 1). To determine which strategy is more efficient (line 4), we provide a cost estimation technique, detailed in Section 4.3.

The NPC procedure is central to the NPivoter framework (line 13). It takes six parameters:  $C_U$ ,  $C_V$ ,  $P_U$ ,  $P_V$ ,  $H_U$ , and  $H_V$ . Here,  $C_U$  and  $C_V$  represent the candidate sets, where the nodes are common neighbors of  $P_V \cup H_V$  and  $P_U \cup H_U$ , respectively. The sets  $P_U$ ,  $P_V$ ,  $H_U$ , and  $H_V$  form a partial biclique, where  $(P_U \cup H_U, P_V \cup H_V)$  is already a biclique, and  $|H_{U}| < p$  and  $|H_{V}| < q$ . The goal of NPC is to count the (p, q)-bicliques that contain all of  $H_U$  and  $H_V$ , and partially include nodes from  $C_U$ ,  $C_V$ ,  $P_U$ , and  $P_V$ . Importantly,  $P_U$ and  $P_V$  serve as the node-pivots. Since node-pivots connect to all candidate nodes, any biclique extended by node-pivots remains a biclique. Therefore, after moving node-pivots from  $C_U$  and  $C_V$  to  $P_U$  and  $P_V$  (lines 16-17), the task reduces to counting bicliques in the remaining  $C_{U}$  and  $C_{V}$ . For example, if a node *u* is moved from  $C_U$  to  $P_U$  as a node-pivot and there are x (p - 1, q)-bicliques in the remaining candidate sets, there will be x(p,q)-bicliques directly. Thus, the algorithm focuses on counting bicliques in the remaining candidate sets (lines 18-23).

After removing node-pivots, NPC processes the remaining candidate sets. Instead of enumerating one node at a time, NPC splits the sets into  $L_U$ ,  $L_V$  and their complements  $C_U \setminus L_U$  and  $C_V \setminus L_V$  (line 18). The bicliques in  $(C_U, C_V)$  are categorized based on whether they include nodes from  $L_U$  and  $L_V$ . For each node in  $L_U$  and  $L_V$ , NPC recursively counts bicliques that include the node and exclude the nodes preceding it (lines 19-22). The nodes are removed from the candidate sets to avoid double-counting (line 20), and the nodes that must be included are placed in  $H_U$  and  $H_V$  (line 21). For instance, if  $u_0$ ,  $u_1$ , and  $u_2$  are three nodes considered in line 19, the recursive call in line 21 counts bicliques that must include  $u_0$  and may include  $u_1$  and  $u_2$ . The next recursive call counts bicliques that exclude  $u_0$ , must include  $u_1$ , and may include  $u_2$ . Finally, after removing  $L_U$ and  $L_V$  from  $C_U$  and  $C_V$  (lines 20 and 22), NPC recursively counts the bicliques in the remaining candidate sets (line 23).

Thanks to the node-pivots, the large biclique  $(P_U \cup H_U, P_V \cup H_V)$ encodes a unique representation of the set of bicliques  $\{(P'_U \cup H_U, P'_V \cup H_V) \mid P'_U \subseteq P_U, P'_V \subseteq P_V\}$ . In this framework,  $H_U$  and  $H_V$  are required to be chosen, while  $P_U$  and  $P_V$  are optional. This leads to the derivation of Theorem 4.2.

THEOREM 4.2. There are  $\binom{|P_U|}{p-|H_U|} \times \binom{|P_V|}{q-|H_V|}$  (p,q)-bicliques encoded in a large biclique  $(P_U \cup H_U, P_V \cup H_V)$ .

The NPC procedure terminates when either there is no edge left or the number of required nodes reaches the maximum size (lines 14-15). The following four cases, based on Theorem 4.2, describe the scenarios of the count procedure (lines 14-15 and 24-26).

- Case 1:  $(C_U \times C_V) \cap E = \emptyset$ , with  $C_U \neq \emptyset$  and  $C_V \neq \emptyset$ . Here,  $C_U$  represents the common neighbors of  $P_V \cup H_V$ , so all nodes in  $C_U$  can be moved into  $P_U$ . The (p,q)-biclique in  $((P_U \cup C_U) \cup H_U, P_V \cup H_V)$  is counted as  $\binom{p_0+c_0}{p-h_0}\binom{p_1}{q-h_1}$  (line 26). Similarly,  $C_V$ , being the common neighbors of  $P_U \cup H_U$ , gives the item  $\binom{p_0}{p-h_0}\binom{p_1+c_1}{q-h_1}$ . However, directly adding  $C_V$  to  $P_V$  would result in double-counting the pair  $(P_U \cup H_U, P_V \cup H_V)$ , so we subtract  $\binom{p_0}{p-h_0}\binom{p_1}{q-h_1}$ . Case 2:  $(C_U \times C_V) \cap E = \emptyset$ , with  $C_U = \emptyset$ . In this case, all nodes in
- Case 2:  $(C_U \times C_V) \cap E = \emptyset$ , with  $C_U = \emptyset$ . In this case, all nodes in  $C_V$  are moved to  $P_V$ , and the (p, q)-biclique in  $((P_U \cup C_U) \cup H_U, (P_V \cup C_V) \cup H_V)$  is counted (line 25).
- Case 3:  $(C_U \times C_V) \cap E = \emptyset$ , with  $C_V = \emptyset$ . This case mirrors Case 2.
- Case 4:  $|H_U| = p$  or  $|H_V| = q$ . When  $|H_U| = p$  or  $|H_V| = q$ , we have  $p h_0 = 0$  or  $q h_1 = 0$ , and the counts on lines 25-26 are correct, as they account for the completed bicliques.

THEOREM 4.3. NPivoter can count (p, q)-bicliques correctly.

PROOF. To prove Theorem 4.3, it is sufficient to show that each (p, q)-biclique is counted exactly once. Consider the recursive search process of the NPC procedure as a search tree. At each search tree vertex, every biclique is counted in exactly one root to leaf path. At each vertex in the search tree, if a biclique contains nodes from  $L_U \cup L_V$ , it will be counted in lines 21 or 22. Since the nodes in  $L_U \cup L_V$  are removed from the candidate sets (line 20), no repeated counting occurs for those nodes. If a biclique does not contain nodes from  $L_U \cup L_V$ , it will be counted in the child tree vertex generated from line 23. Thus, each biclique belongs to only one path in the search tree and is counted exactly once. This ensures that the algorithm correctly counts all (p, q)-bicliques without duplication.  $\Box$ 

BCList++ as a Special Implementation of NPivoter. BCList++ can be viewed as a specialized implementation of the NPivoter framework. While BCList++ processes the entire graph, its initial layer mirrors the node-split strategy [50]. The enumeration process in BCList++ is a simplified version of the NPC procedure. Specifically, BCList++ does not utilize node-pivots, as seen in lines 16-17

11	$range_{p,q} \leftarrow range_{p,q} + \binom{p_0}{p-h_0}\binom{p_1+c_1}{q-h_1}, \forall p \in$
	$[l_0, \min(p_0 + h_0, p_u)], q \in l_1, \min(p_1 + c_1 + h_1, q_u)];$
12	$range_{p,q} \leftarrow range_{p,q} - \binom{p_0}{p-h_0}\binom{p_1}{q-h_1}, \forall p \in$
	$[l_0, \min(p_0 + h_0, p_u)], q \in [l_1, \min(p_1 + h_1, q_u)];$

of Algorithm 1. It sets  $L_U = C_U$  and  $L_V = \emptyset$  in line 18, and there are no remaining candidate sets in line 23 for further enumeration. BCList++ only terminates when  $|H_U| = p$  (line 14). During the count procedure (line 24), BCList++ simplifies the process with  $c_0 = p_0 = p_1 = h_1 = 0$ ,  $h_0 = p$ , and  $c_1 = |C_V|$ .

EPivoter **as a Special Implementation of NPivoter.** EPivoter follows a different approach by using the edge-split strategy (lines 5-8 of Algorithm 1). Its enumeration process is also a variant of the NPC procedure. EPivoter selects the edge (u, v) with the maximum number of neighbors and sets  $L_U = C_U \setminus N(v) \setminus \{u\}$  and  $L_V = C_V \setminus N(u) \setminus \{v\}$ . The edge (u, v) will be moved into  $P_U$  and  $P_V$  as an edge-pivot in the next recursive search layer (line 23). In the count procedure, NPivoter uses a constant-time inclusion-exclusion principle to avoid duplicate-counting (line 26), whereas EPivoter uses an enumeration method with linear time complexity [52].

**Local Counting.** Theorem 4.2 can be extended to perform local counting. Each node in  $H_U \cup H_V$  is involved in  $\binom{|P_U|}{p-|H_U|} \times \binom{|P_V|}{q-|H_V|}$

Algorithm	4:	Minimum	non-neighbor	candidate	partition

1 **Procedure** NPC  $(C_U, C_V, P_U, P_V, H_U, H_V)$ 

- 4  $L_U \leftarrow C_U \setminus N(w); L_V \leftarrow C_V \setminus N(w);$
- 5 | if  $|L_U| < |L_V|$  then  $L_V \leftarrow \emptyset$ ; else  $L_U \leftarrow \emptyset$ ;
- 6 lines 19-22 of Algorithm 1;
- 7 NPC  $(C_U, C_V, P_U, P_V, H_U, H_V)$

(p,q)-bicliques. A node in  $P_U$  contributes to  $\binom{|P_U|-1}{p-|H_U|-1} \times \binom{|P_V|}{q-|H_V|}$  (p,q)-bicliques, while a node in  $P_V$  contributes to  $\binom{|P_U|}{p-|H_U|} \times \binom{|P_V|-1}{q-|H_V|-1}$  (p,q)-bicliques. By modifying the count procedure to perform local counting, NPivoter can efficiently handle this task. Algorithm 2 is the pseudo-code for local counting. When  $c_0 > 0$  and  $c_1 > 0$  (line 4), localcount firstly insert  $C_U$  into  $P_U$  to count the bicliques in  $(C_U \cup P_U \cup H_U, P_V \cup H_V)$ , i.e. the bicliques without nodes in  $C_V$  (line 5), and then count the bicliques containing nodes in  $C_V$  (lines 6-9). When  $c_0 = 0$  or  $c_1 = 0$ , insert the cadidate sets into the node-pivots (line 11), and count the bicliques for each kind of nodes (lines 12-14).

**Range Counting.** Given a large biclique  $(P_U \cup H_U, P_V \cup H_V)$ , Theorem 4.2 applies to all  $p \in [|H_U|, |P_U \cup H_U|]$  and  $q \in [|H_V|, |P_V \cup H_V|]$ . The current count procedure in NPivoter only counts bicliques for a specific pair of p and q. To handle range counting with specified ranges  $[p_l, p_u]$  and  $[q_l, q_u]$ , NPivoter can execute the count procedure  $(p_u - p_l)(q_u - q_l)$  times, enabling it to count bicliques within the given size range simultaneously. Algorithm 3 is the pseudo-code.  $l_0$  and  $l_1$  are the minimum number of nodes to contain, which is the lower bound of p and q (line 4). When  $c_0 = 0$  or  $c_1 = 0$ , min $(p_0 + c_0 + h_0, p_u)$  and min $(p_1 + c_1 + h_1, q_u)$  are the upper bound of p and q (line 6 and 7). When  $c_0 > 0$  and  $c_1 > 0$ , lines 10 counts the bicliques in  $((C_U \cup P_U) \cup H_U, P_V \cup H_V)$ , line 11 counts the bicliques in  $(P_U \cup H_U, (C_V \cup P_V) \cup H_V)$ , and line 12 subtract the double-counting part  $(P_U \cup H_U, P_V \cup H_V)$ .

# 4.2 A Novel Minimum Non-neighbor Candidate Partition Strategy

As a general framework, NPivoter does not inherently possess a specific time complexity. The time complexity depends on the specific design of the candidate partition strategy, i.e. how to choose  $L_U$  and  $L_V$  (line 18 of Algorithm 1). In this subsection, we propose the minimum non-neighbor candidate partition strategy, with which NPivoter can achieve a lower worst-case time complexity than the previous SOTA works, as proven in Theorem 4.6 and Theorem 4.7.

We start with the definition of the minimum non-neighbor candidate partition. The minimum non-neighbor candidate partition selects  $L_U$  and  $L_V$  based on the non-neighbors of the node with the fewest non-neighbors. The core idea behind the minimum nonneighbor candidate partition is to minimize the sizes of the sets  $L_U$  and  $L_V$  during the recursive calls in the NPC procedure. Each recursive node in the NPC search tree has  $|L_U| + |L_V| + 1$  child nodes, so reducing the sizes of  $L_U$  and  $L_V$  leads to a smaller overall search tree and more efficient computation. Definition 4.4 (Minimum non-neighbor candidate partition). For the sets  $C_U$  and  $C_V$ , the node with minimum non-neighbor is

$$w \leftarrow \arg\min_{u \in C_U \cup C_V} (\min(|C_U \setminus N(u)|, |C_V \setminus N(u)|)).$$

The partitioning is done as follows:

$$\begin{cases} L_U \leftarrow C_U \setminus N(w), L_V \leftarrow \emptyset, & |C_U \setminus N(w)| \le |C_V \setminus N(w)| \\ L_U \leftarrow \emptyset, L_V \leftarrow C_V \setminus N(w), & |C_U \setminus N(w)| > |C_V \setminus N(w)| \end{cases}$$

In Definition 4.4, w may be in  $C_U$  or  $C_V$ . We mainly discuss the cases when  $w \in C_U$ , and the following result also holds when  $w \in C_V$ . When  $w \in C_U$ , it is true that  $C_U \setminus N(w) = C_U$  because N(w) refers to the set of nodes on the opposite side of the bipartite graph connected to w. If  $|C_U| = |C_U \setminus N(w)| \le |C_V \setminus N(w)|$ , we can conclude that  $L_U = C_U$ , meaning that we can enumerate the nodes on the U-side directly. This condition suggests that when the size of  $C_U$  is small enough, it becomes efficient to enumerate the nodes in  $C_U$ . On the other hand, if  $|C_U| = |C_U \setminus N(w)| \ge |C_V \setminus N(w)|$ , the more efficient strategy is to enumerate the non-neighbors of w on the V-side, meaning  $L_V = C_V \setminus N(w)$ . The partition optimizes the process by leveraging the smaller subset of nodes, ensuring that either side of the bipartite graph is efficiently handled depending on their relative sizes. Algorithm 4 is the pseudo-code of the implementation with the minimum non-neighbor candidate partition strategy. The following example illustrates how our algorithm works.

Example 4.5. Figure 2 illustrates the process of NPivoter for counting (3,3)-biclique. The example graph and the associated icon description are presented in Figure 2(a). Figure 2(b), (c), and (d) are running processes of the NPC procedure, with the node-split strategy. For clarity, edges connected to the already selected nodes  $P_U$ ,  $P_V$ ,  $H_U$ , and  $H_V$ (within the blue and green boxes) are omitted, as  $(P_U \cup H_U, P_V \cup H_V)$ already forms a biclique, and  $C_U$  and  $C_V$  represent the sets of common neighbors of  $P_U \cup H_U$  and  $P_V \cup H_V$ , respectively. The upper nodes are labeled from  $u_0$  to  $u_4$ , and the lower nodes are labeled from  $v_0$  to  $v_4$ . In Figure 2(b), NPivoter counts the (3,3)-bicliques that contain  $u_0$ . So  $u_0$  is in  $H_U$ . The candidate sets are now  $C_U = \{u_1, u_2, u_3, u_4\}$ and  $C_V = \{v_0, v_1, v_2, v_3\}$ . Since  $v_1$  and  $v_2$  connect to all nodes in  $C_U$ , they are moved into the node-pivots (represented by dotted cycles, moving from the red box to the blue box, as indicated in lines 16-17 of Algorithm 1). In the remaining candidate sets  $C_{II} = \{u_1, u_2, u_3, u_4\}$ and  $C_V = \{v_0, v_3\}, u_1$  has the minimum number of non-neighbors, and let  $L_U = \emptyset$ ,  $L_V = \{v_3\}$  (lines 3-5 of Algorithm 4). Put  $v_3$  into  $H_V$  and recursively call NPC to count the bicliques containing  $v_3$ (line 23 of Algorithm 1). There is no edge between the candidate sets  $C_U = \{u_2, u_3, u_4\}$  and  $C_V = \{v_0\}$  (line 14 of Algorithm 1) and the count procedure will add three (3,3)-bicliques. Then backtrack to the previous layer and recursively call the NPC procedure (line 23 of Algorithm 1). After moving  $u_1$  into  $P_U$ , there is no edge between the candidate sets. In this case, there is no  $L_U$  and  $L_V$ , and just recursively call the NPC procedure to count the result (line 23 and 14 of Algorithm 1). Figure 2(c) is running process of counting the (3, 3)-bicliques that contain  $u_1$ , which has 3 (3,3)-bicliques. Figure 2(d) is running process of counting the (3,3)-bicliques that contain  $u_2$ , which has 4 (3,3)-bicliques.

Fast Biclique Counting on Bipartite Graphs: A Node Pivot-based Approach

Figure 2: A running example of our proposed NPivoter

**Time Complexity of** NPC **and** NPivoter. The time complexity of the NPC procedure and the entire NPivoter framework, when equipped with the minimum non-neighbor candidate partition strategy, is detailed in Theorem 4.6 and Theorem 4.7.

THEOREM 4.6. With the minimum non-neighbor candidate partition strategy, the NPC procedure has time complexity of  $O(2^{\frac{n'}{2}})$  where  $n' = |C_U| + |C_V|$ .

**PROOF.** The time complexity of finding the node-pivot in each recursive search vertex of NPC is  $O(n'^2)$ , which is equal to compute the degree of each node. For simplicity, we use *n* instead of *n'* in the following context.

Let T(n) be the time complexity of NPC with input  $C_U, C_V$ . Let k be the number of the minimum non-neighbors and  $c_3$  be constant. We can derive that

$$T(n) \le \sum_{i=1}^{k} T(n-k-i) + T(n-k-1) + c_3 n^2,$$
(1)

where  $\sum_{i=1}^{k} T(n - k - i)$  is the time complexity of lines 19-22 of Algorithm 1, T(n - k - 1) is the time complexity of line 23 of Algorithm 1 and  $c_3 n^2$  is the time complexity of finding the nodepivots. Define constant numbers  $c_1, c_2, c_3$  that satisfy  $c_1 \ge 4.5(c_2 + c_3)$ . We can prove that

$$T(n) \le c_1 2^{n/2} - c_2 n^2.$$
 (2)

When n = 1, we have  $T(1) \le c_1\sqrt{2} - c_2$  from inequality (2) and  $T(1) \le c_3$  from inequality (1). inequality (2) holds because  $c_1 \ge 4.5(c_2 + c_3) > \frac{c_2 + c_3}{\sqrt{2}}$ .

Let *N* be a positive integer. We assume that inequality (2) holds for all integers  $n \in [1, N-1]$ , and prove that it also holds for n = N. **Case** k = 2. inequality (1) becomes  $T(n) \le 2T(n-3)+T(n-4)+c_3n^2$ . According to the assumption, we have

$$T(n) \leq 2T(n-3) + T(n-4) + c_3 n^2$$
  

$$\leq 2c_1 2^{\frac{n-3}{2}} - c_2(n-3)^2 + c_1 2^{\frac{n-4}{2}} - c_2(n-4)^2 + c_3 n^2$$
  

$$\leq (2^{-\frac{1}{2}} + 2^{-2})c_1 2^{\frac{n}{2}} + c_3 n^2$$
  

$$\leq c_1 2^{\frac{n}{2}} - c_2 n^2.$$
(3)

The last inequality equals to prove

$$\frac{n^2}{2^{n/2}} \le \frac{(1-2^{-\frac{1}{2}}-2^{-2})c_1}{c_2+c_3} \le \frac{c_1}{c_2+c_3} \tag{4}$$

Table 1: Time complexity comparison ( $2^{\frac{1}{2}} \approx 1.414, 3^{\frac{1}{3}} \approx 1.442$ )

NPivoter (Our)	EPivoter [52]	BCList++ [50]
$O( E 2^{n_{max}/2})$	$O( E 3^{ E_{max} /3})$	$O(\alpha(H)^{p-2} E' d_{max}+\triangle)$

holds for all *n*. Since  $\frac{n^2}{2^{n/2}} \le 4.5$  ( $\frac{n^2}{2^{n/2}} = 4.5$  when n = 6) and  $\frac{c_1}{c_2+c_3} \ge 4.5$ , the mathematical induction is proved.

**Case**  $k \neq 2$ . A scaled inequality (1) is

$$T(n) \le (k+1)T(n - (k+1)) + c_3 n^2,$$
(5)

from which we have

$$T(n) \leq (k+1)c_1 2^{(n-(k+1))/2} - c_2(k+1)(n-(k+1))^2 + c_3 n^2$$
  
$$\leq (k+1)2^{-\frac{k+1}{2}} \cdot c_1 2^{n/2} + c_3 n^2$$
  
$$\leq c_1 2^{\frac{n}{2}} - c_2 n^2.$$
 (6)

The last inequality comes from (1)  $(k + 1)2^{-\frac{k+1}{2}}$  is always no larger than 1; (2) the following inequality is always true

$$\frac{n^2}{2^{n/2}} \le \frac{(1 - (k+1)2^{-\frac{k+1}{2}})c_1}{c_2 + c_3} \le \frac{c_1}{c_2 + c_3} \tag{7}$$

Since  $\frac{n^2}{2^{n/2}} \le 4.5$  ( $\frac{n^2}{2^{n/2}} = 4.5$  when n = 6) and  $\frac{c_1}{c_2+c_3} \ge 4.5$ , the mathematical induction is proved.

As a result, the time complexity of NPC is  $O(2^{n'/2})$ .

THEOREM 4.7. With the minimum non-neighbor candidate partition strategy, the time complexity of Algorithm 1 is  $O(|E|2^{n_{max}/2})$ , where  $n_{max} = \max_{u \in U} |N(u, V)| + \max_{v \in V} |N(v, U)|$ .

PROOF. The number of calling NPC is bounded by |E|, and the size of  $|C_U| + |C_V|$  is bounded by  $n_{max}$ . Thus, according to Theorem 4.6, the time complexity of Algorithm 1 is  $O(|E|2^{n_{max}/2})$ .

The Superiority of NPivoter on the Time Complexity. Table 1 summarizes the time complexity of the proposed NPivoter and SOTA methods. The time complexity of EPivoter is  $O(|E|3|^{E_{max}|/3})$ , where  $|E_{max}|$  is bounded by the maximum number of edge among all candidate sets of edge-split strategy. Since  $2^{\frac{1}{2}} \approx 1.414$ ,  $3^{\frac{1}{3}} \approx 1.442$  and  $|E_{max}| > n_{max}$ , our NPivoter has a lower worst-case time complexity. The time complexity of BCList++ is  $O(\alpha(H)^{p-2}|E'|d_{max} + \Delta)$ , as outlined in Section 3.1. Here,  $\alpha(H)$  represents the arboricity

in the 2-hop graph H, and in the worst case,  $\alpha(H)$  is on the order of  $n_{\max}$  [30, 32, 50]. |E'| is in the order of  $d_{\max}|E|$ .  $\triangle$  is the result size, which can be quite large for large real-world networks. Therefore, NPivoter also outperforms BCList++.

### 4.3 The Proposed Cost Estimator

The BCList++ algorithm employs a node-split strategy, while EPivoter uses an edge-split strategy (Section 3). Intuitively, the node-split strategy tends to be more efficient for dense graphs with more connections. In such graphs, the subgraphs generated from edgesplitting can be nearly as large as the entire graph, resulting in minimal reduction in problem size and inefficiency. Conversely, in sparse graphs, the edge-split strategy becomes more efficient. In this case, the subgraphs created by splitting edges are much smaller, allowing EPivoter to perform faster due to the reduced search space. Thus, node-split excels in handling dense structures, whereas edge-split is more suited for sparse graph scenarios.

To leverage the advantages of both the node-split and edge-split strategies, we propose a novel cost estimator that helps determine when to use the node-split (lines 10-11) or edge-split (lines 5-8) strategy in line 4 of Algorithm 1. The goal of this estimator is to predict which graph-split strategy will be more efficient. Specifically, let the variables *l*, *r*, and *e* be the sizes of the candidate sets and the number of edges as follows:  $l = |C_U|$  (the size of the candidate

set  $C_U$ ),  $r = |C_V|$  (the size of the candidate set  $C_V$ ),  $e = |(C_U \times C_V) \cap E|$  (the number of edges between  $C_U$  and  $C_V$ ). Theorem 4.6 initially suggests using  $2^{\frac{l+r}{2}}$  as a measure of the running cost for the recursive process. However, this measure has two main drawbacks: **1. Imbalance Between** l and r: When the sizes of l and r differ significantly, the smaller value dominates the computation cost, rather than their sum. To account for this, we replace  $2^{\frac{l+r}{2}}$  with  $2^{\frac{\min(l,r)}{2}}$ , focusing on the smaller of the two sets. **2. Edge Density Consideration**: The initial measure only accounts for the number of nodes and ignores the number of edges, which can significantly impact the algorithm can still run efficiently even if the combined size of l and r is large.

To address these limitations, we propose a new metric that incorporates both the number of nodes and edges. This new metric is based on the observation that the complexity of the algorithm increases as we process more edges between  $C_U$  and  $C_V$ . The refined metric is defined as follows:

$$\left(\frac{e}{\min(l,r)}\right)^{\min(l,r)}.$$
(8)

This term reflects the idea that if a set contains *a* items, the number of subsets of size *b* is proportional to  $\binom{a}{b}$ , which is bounded by  $a^b$ . In this case,  $a = \frac{e}{\min(l,r)}$  and  $b = \min(l,r)$ . Here,  $\frac{e}{\min(l,r)}$  represents the average number of neighbors for a node in the smaller of the two sets, while  $\left(\frac{e}{\min(l,r)}\right)^{\min(l,r)}$  estimates the complexity of processing all possible subsets of neighbors of size  $\min(l,r)$ . The final running cost estimation of the NPC procedure combines both node and edge considerations:

$$\min\left(\left(\frac{e}{\min(l,r)}\right)^{\min(l,r)}, 2^{\frac{\min(l,r)}{2}}\right) \tag{9}$$

This metric balances the trade-offs between node size and edge density, effectively estimating the computational cost. As demonstrated in our experiments, this cost estimation provides reliable guidance for choosing the most efficient graph-split strategy.

The cost estimator computes two values  $cost_{node}$  and  $cost_{edge}$ , which represent the computation cost of the two strategies respectively. For  $cost_{node}$ , we compute the value of l, r, e and let  $cost_{node} = \min((\frac{e}{\min(l,r)})^{\min(l,r)}, 2^{\frac{\min(l,r)}{2}})$ . The computation of  $cost_{edge}$  is more complex. In Algorithm 1, the edge-split has multiple calls of NPC (line 8). Hence, we compute cost estimation for each edge and sum them together as the final value of  $cost_{edge}$ .

Algorithm 5 outlines the pseudo-code of the cost estimator. Algorithm 5 inputs a node u and two integers x, y, and returns whether node-split or edge-split is more efficient to count (p, q)biclique with  $p \ge x, q \ge y$ . The costEs procedure (lines 1-3 of Algorithm 5) returns the cost estimation of a NPC procedure with input  $l = |C_U|, r = |C_V|, e = |(C_U \times C_V) \cap E|$ . For approximating  $cost_{node}$ , Algorithm 5 maintains l, r, e (line 5). l is the number of nodes in U that have larger rank than u and has more than y neighbors in N(u) (lines 7-10). r is the number of nodes in N(u) that have more than x - 1 neighbors in the previous l nodes (lines 13-17). e is the number of edges between the l and r nodes (lines 13-16). At last,  $cost_{node} = \min((\frac{e}{\min(l,r)})^{\min(l,r)}, 2^{\frac{l+r}{2}})$  (line 25). For approximating  $cost_{edge}$ , Algorithm 5 approximates l', r', e' for each edge (line 19-24). Consider an edge  $(u, v_i)$ . l' is the number of nodes in U that has larger rank than u and has more than y neighbors in  $S_{u,v_i} = \{v|v \in N(u), R(v) > R(v_i)\}$  (lines 19-22). r' is the number of nodes in  $S_{u,v_i}$  that has more than x - 1 neighbors (line , 17, 18, 20). Label the nodes in N(u) by  $\{v_1, v_1, v_2, ... v_{d(u)}\}$  (line 11). Instead of computing r' for each edge, Algorithm 5 records a suffix summary vector ss where  $ss_i$  is the number of nodes in  $\{v|v \in N(u), R(v) > R(v_i)\}$  that has more than x - 1 neighbors (lines 17-18). Thus, we can use  $ss_i$  to approximate r' directly (line 20). Due to the edges before  $v_i$  being removed already (line 23),  $cnt_w$  is the number of neighbors of w with rank larger than  $v_i$ . Thus, sum all the  $sum_w$  together is the number of edges e' (line 22). At last,  $cost_{edge} = \min((\frac{e'}{\min(l',r')})^{\min(l',r')}, 2^{\frac{l'+r'}{2}})$  (line 24).

THEOREM 4.8. Given a bipartite graph G(U, V, E), in Algorithm 1 (line 4), the total time complexity of Algorithm 5 is  $O(\alpha(G)|E|)$ , where  $\alpha(G)$  is the arboricity of G.

PROOF. For each node u (i.e., line 3 of Algorithm 1), lines 7, 13 and 19 of Algorithm 5 scan the neighbors of u, which has complexity of O(|E|). Each line of lines 8, 15, and 21 of Algorithm 5 scan the neighbors of a neighbor of u, which has a total time complexity of  $O(\sum_{(u,v) \in E} d(v))$ . According to the definition of  $\alpha(G)$  [12], E can be partitioned into  $\alpha(G)$  edge-disjoint spanning forests, and let these trees be  $F_i$ ,  $1 \le i \le \alpha(G)$ , where  $|F_i| \le |V|$ . We have  $\sum_{(u,v) \in E} d(v) = \sum_i^{\alpha(G)} \sum_{(u,v) \in F_i} d(v) \le$  $\sum_i^{\alpha(G)} \sum_{v \in V} d(v) = 2\alpha(G)|E|$ . Thus, the complexity of Algorithm 5 is  $O(\alpha(G)|E|)$ .

Theorem 4.8 demonstrates that the cost estimator has a polynomial time complexity, which is significantly smaller compared to the complexity of the biclique counting algorithm. By efficiently estimating the cost of various candidate sets, the cost estimator allows the algorithm to choose the most optimal strategy dynamically. Our empirical results confirm that the proposed algorithm, when equipped with the cost estimator, outperforms approaches relying on a single fixed graph-split strategy (Section 6).

**Cost Estimator based Index.** When counting (p, q)-bicliques, the parameters x and y should not exceed p and q. To optimize this process, we can build an index for x and y. Specifically, the index is a vector of length |U|, storing the results of Algorithm 5 for each node in U. Equipped with the pre-computed index, when  $p \ge x$  and  $q \ge y$ , Algorithm 1 can determine whether a node-split or edge-split is more efficient in constant time complexity for each node. The time complexity of building the index is Theorem 4.8.

# **5 FURTHER OPTIMIZATIONS**

In this section, we devise several optimization tricks to further improve the efficiency of our proposed algorithm.

 $(\alpha, \beta)$ -core Based Graph Reduction [50]. For the bipartite graph G(U, V, E) and any (p, q)-biclique (X, Y), every node  $u \in X$  must have at least q neighbors in V, and every node  $v \in Y$  must have at least p neighbors in U. This allows us to simplify the graph by reducing it to its (p, q)-core, which retains only the nodes and

edges that are essential for potential (p, q)-bicliques [50]. The most efficient algorithm for computing the (p, q)-core of a bipartite graph G(U, V, E) operates in linear time with a complexity of O(|E|) [14].

Definition 5.1 ((p, q)-core [14, 28]). For a bipartite graph G(U, V, E) and two integers p and q, the (p, q)-core of G is a maximal subgraph  $G_c(U_c, V_c, E_c)$  where every node in  $U_c$  has at least q neighbors in  $V_c$ , and every node in  $V_c$  has at least p neighbors in  $U_c$ .

**Core Value-Based Node Ranking.** The core ordering method [4] is a commonly used strategy in graph mining tasks to enhance the algorithm efficiency [16, 22, 39, 50]. The core value of a node u is defined as the highest degree that u holds in a subgraph where u has the smallest degree within that subgraph [11]. In this optimization, nodes are ranked according to their core values, where higher-ranked nodes correspond to those with larger core values. For any node, the number of the nodes with larger core values is bounded by the *degeneracy* of the graph [11], which is often a small number for real-world networks [27]. This ranking ensures that only nodes with larger core values are included in the candidate sets during key steps of the NPC procedure (lines 6, 7, 10 of Algorithm 1), optimizing the search space and improving computational performance.

**Early Termination.** The NPC procedure can be terminated early under the following conditions:

(1) Lower bounds on biclique size: If  $|H_U| > p$  or  $|H_V| > q$ , the biclique is guaranteed to exceed the desired (p, q)-biclique size, as the nodes in  $H_U$  and  $H_V$  must be part of the solution (Theorem 4.2).

(2) Upper bounds on biclique size: If  $|C_U \cup P_U \cup H_U| < p$  or  $|C_V \cup P_V \cup H_V| < q$ , the search can be terminated since these sets represent the upper bounds on the biclique size, making it impossible to reach a valid (p, q)-biclique.

(3) Single node in  $C_U$ : When  $|C_U| = 1$ , meaning that  $C_U$  contains only one node u, instead of branching into further recursive calls, the biclique count can be computed directly as  $\binom{p_0}{p-h_0}\binom{p_1+c_1}{q-h_1} + \binom{p_0}{p-h_0-1}\binom{p_1+n_u}{q-h_1}$ , where  $n_u = |N(u) \cap C_V|$ . The first term represents the bicliques that do not include u, while the second term counts bicliques containing u.

(4) Single node in  $C_V$ : Similarly, when  $|C_V| = 1$  (i.e.,  $C_V$  contains only one node v), the biclique count is  $\binom{p_0+n_v}{p-h_0}\binom{p_1}{q-h_1-1} + \binom{p_0+c_0}{p-h_0}\binom{p_1}{q-h_1}$ . The first term corresponds to bicliques that include v, and the second term counts bicliques that do not include v.

**Efficient Maintenance of the Non-neighbor Count.** During the NPC procedure in Algorithm 1, instead of recalculating the non-neighbor count from scratch at each recursive step, the algorithm reuses the non-neighbor counts from the parent search vertex. Specifically, for a node  $w \in C_U$ , let  $C'_U = C_U \setminus \{w\}$ . The non-neighbor set of any neighbor  $u \in N(w, C_V)$  remains unchanged, i.e.,  $C_U \setminus N(u) = C'_U \setminus N(u)$ . For non-neighbors  $u \in C_V \setminus N(w)$ , the non-neighbor set decreases by exactly one, i.e.,  $C_U \setminus N(u) \setminus \{w\} = C'_U \setminus N(u)$ . Leveraging this observation, the optimization effectively manages and updates non-neighbor counts without redundant recalculations.

### 6.1 Experimental Setup

We evaluate all algorithms on a server with an AMD 3990X CPU and 256GB memory running Linux CentOS 7 operating system. We run algorithms against a single core. We terminate an algorithm if the running time is more than  $10^6$  mile-seconds (ms).

**Datasets.** We evaluate our algorithms on 12 real-world bipartite networks drawn from various domains, covering a wide range of applications and structural characteristics. These datasets, listed in Table 2, are downloaded from the KONECT project (http://konect. cc/networks/), which compiles diverse network datasets for research purposes. These datasets vary widely in terms of size and density, with node counts ranging from thousands to millions, and edge counts reflecting the number of connections between the two sets of entities. The average degrees for both sets of nodes, denoted as  $\overline{d}_U$  and  $\overline{d}_V$ , provide insight into the density of graph, highlighting the diversity in structure across different domains. These characteristics make the datasets an excellent test bed for evaluating the performance of biclique counting algorithms [50, 52].

**Algorithms.** We compare BCList++ [50] and EPivoter [52] with our NPivoter. Both EPivoter and NPivoter apply to the range counting problem. NPivoter can also locally count the (p, q)-biclique for each node. All the algorithms are implemented in C++. The code of BCList++ and EPivoter are from the open-source repository [50, 52]. In default, NPivoter uses the cost estimator index with  $x = y = \min(p, q)$ . The index building time is not included in our NPivoter because the computation time of the cost estimator index is negligible (compared to the biclique counting time) as shown in Exp-5, and the index creation can be treated as a preprocessing step. To be more reliable, we report the average running time and quality of 10 runs per algorithm.

# 6.2 Empirical Results

**Exp-1: Running Time of Various Algorithms.** Figure 3 shows the running time of BCList++, EPivoter, and NPivoter with varying p and q on 12 real-world networks. Across almost all cases, NPivoter consistently demonstrates superior performance, significantly outperforming both BCList++ and EPivoter. For instance, on the Twit network for (10, 10)-biclique counting, NPivoter is two orders of magnitude faster than EPivoter. Similarly, on the Stac network for (10, 10)-biclique counting, NPivoter is two orders of magnitude faster than BCList++. These results highlight the high efficiency of NPivoter compared to other methods.

A notable and somewhat counter-intuitive observation is that the running time of NPivoter decreases as the values of p and q increase. For example, on the Kos network, the running time decreases when moving from (6, 6) to (6, 12)-biclique counting. Likewise, counting (12, 12)-bicliques takes less time than counting (9, 9)-bicliques or (6, 6)-bicliques. This phenomenon is primarily due to two reasons: (1) larger values of (p, q) enable more aggressive pruning of small-degree nodes according to the  $(\alpha, \beta)$ -core optimization (Section 5), reducing the search space; (2) the impact of p and q on the search tree's size is minimal. Observe the NPC procedure in Algorithm 1, and we can find that p and q almost do not affect the search process except line 14. In effect, line 14 of Algorithm 1 often terminates

Figure 3: Running time of various algorithms

due to empty edges instead of  $H_U$  or  $H_V$  reaching the maximum value, as shown in the following experiments. At last, this behavior demonstrates that NPivoter is well-suited for efficiently counting (p, q)-bicliques, even for large values of p and q.

**Exp-2: Effectiveness of the Proposed Node-pivot Technique.** Table 3 presents the percentage of bicliques counting combinatorially across all datasets. A biclique is not counted combinatorially when it is handled in line 15 of Algorithm 1 due to the condition  $|H_u| = p$  or  $|H_v| = q$  in line 14. As shown in Table 3, the majority of bicliques are counted in a combinatorial way. Furthermore, as the values of p and q increase, the percentage of combinatorially counted bicliques also increases. This is because larger values of p and q make it less likely to satisfy the condition  $|H_u| = p$  or  $|H_v| = q$  in line 14, demonstrating the growing effectiveness of the node-pivot technique with increasing biclique size. The results

Figure 4: Memory overhead of all algorithms

underscore the efficiency of the node-pivot method in reducing enumeration overhead and facilitating more efficient counting.

Figure 5: Effect of the cost estimator

Exp-3: Memory Overhead. Figure 4 depicts the memory overheads of the evaluated algorithms: NPivoter, EPivoter, and BCList++. The memory consumption was tracked using the "ps -aux" command on the Linux system. As can be seen, we can observe that the three algorithms exhibit similar magnitudes of memory usage across the datasets. For instance, on the Amazon (Ama) dataset, NPivoter consumes 1,048 MB of memory, while EPivoter and BCList++ consume 546 MB and 1,578 MB, respectively. Across all datasets, NPivoter demonstrates memory efficiency, never using more than twice the memory of EPivoter. In many cases, the difference in memory usage between the algorithms is even smaller. This indicates that although NPivoter achieves significant performance improvements in terms of speed, it does not incur a significant increase in memory consumption. The results highlight that NPivoter strikes a balanced trade-off between computational efficiency and memory overhead, making it well-suited for large-scale applications where both memory and time are critical factors.

Exp-4: Effect of the Cost Estimator. Figure 5 shows the impact of the cost estimator on the performance of NPivoter. To analyze this, we compare NPivoter with two versions that exclusively employ either the node-split or the edge-split strategy: NPivoter-N (node-split only) and NPivoter-E (edge-split only). We conducted experiments on two representative datasets, the Stac and Genre datasets, though the results were consistent across other networks as well. Specifically, on the Stac dataset, NPivoter-E-using only the edge-split strategy-proves to be more efficient than NPivoter-N, which exclusively applies the node-split strategy. This suggests that in sparser networks like Stac, edge-split is generally more effective due to the structure of the graph. Conversely, on the Genre network, NPivoter-N performs significantly better than NPivoter-E. This is due to the graph's smaller size and denser connections, where node-split is better suited to handle dense subgraphs. Despite the differences in performance between NPivoter-N and NPivoter-E across these graphs, NPivoter, which uses the cost estimator to

dynamically choose between the two strategies, consistently outperforms both. This clearly demonstrates the effectiveness of our cost estimator, which intelligently selects the more efficient split strategy based on the graph structure, leading to improved overall performance.

**Exp-5: The Performance of Cost Estimator Index.** Table 4 shows two key aspects: the time required to build the cost estimator index and the proportion of nodes that employ the node-split strategy. The results show that building the index consumes quite less time than counting (p, q)-biclique, ensuring that building the index is not a major bottleneck in the algorithm. For instance, on the You dataset, counting takes 1989 ms, while building the index only takes 20 ms. First, the results indicate that the time taken to build the index is not significantly affected by the parameter values (x, y). As (x, y) increases, the variation in index construction time is minimal. For example, on the You dataset, the index construction for (10, 10) is only 1.6 times faster than that for (4, 4). This indicates that the index construction time remains stable across different parameter settings.

Second, the results show that in most real-world datasets, a relatively small proportion of nodes use the node-split strategy. This is because real-world networks typically follow a power-law distribution, where a small subset of nodes (the "dense part") have a disproportionately high degree, while the majority of nodes (the "sparse part") have fewer connections. Consequently, the denser nodes tend to benefit from the node-split strategy, whereas the sparser nodes are better suited for the edge-split strategy. The exception is the Genre network, where most of the nodes employ the node-split strategy. This is due to the fact that Genre has only 15 nodes on one side of the bipartite graph, most of which are densely connected (as shown in Table 2). Therefore, in this case, the node-split strategy dominates.

These findings reinforce the practical utility of the cost estimator, which adapts well to varying network structures by efficiently deciding whether to use node-split or edge-split based on the local graph characteristics. This flexibility contributes to the strong performance of NPivoter across diverse real-world datasets. Fast Biclique Counting on Bipartite Graphs: A Node Pivot-based Approach

**Exp-6: Local Counting.** Table 5 reports the time taken for local counting of (p, q)-bicliques for each node, alongside the time required for global counting in the entire network. The columns labeled 'Local' correspond to the time spent in performing local counting, i.e., counting (p, q)-bicliques that involve each individual node. In contrast, the 'Global' columns show the time taken for counting all (p, q)-bicliques across the entire graph. As demonstrated in Table 5, local counting proves to be highly efficient, as it requires only marginally more time than global counting—at most 1.2× longer. This is an important observation, as one might expect local counting to be significantly slower, given that it isolates the counting process for each node individually. However, the results indicate that our NPivoter algorithm handles local counting with minimal overhead, even when compared to the time needed for global counting over the entire graph.

The high efficiency of local counting is crucial in applications where the focus is on understanding the role or influence of specific nodes within the graph. For example, in social networks, it may be important to locally analyze the influence of certain users or groups. In recommendation systems, local counting allows for examining how particular items or users contribute to specific biclique patterns. Similarly, in citation networks, local counting helps analyze the impact of individual authors or papers on collaboration patterns. Deleted in the full version.

**Exp-7: Range Counting.** Table 6 provides a comparative analysis of the time required for two different counting scenarios: counting only (4, 4)-bicliques versus counting all (p, q)-bicliques where  $p \in [4, 10]$  and  $q \in [4, 10]$  simultaneously. In Table 6 , we observe that range counting with NPivoter takes an order of magnitude longer than counting a single (4, 4)-biclique. For instance, on the You network, NPivoter requires 298 ms to count (4, 4)-bicliques but takes 2244 ms to perform range counting. This increase in computation time is expected due to the additional complexity involved in managing multiple parameters across a range of values, which inherently requires more extensive processing. Despite this, NPivoter's performance in range counting remains significantly superior to that of the state-of-the-art algorithm EPivoter. On the IMDB network, for example, NPivoter is 14.6 times faster than EPivoter for range counting tasks. This substantial efficiency

Figure 6: Scalability test

advantage highlights NPivoter's effectiveness and scalability in handling complex counting scenarios where multiple (p, q)-biclique sizes need to be evaluated simultaneously.

**Exp-8: Scalability Test.** In Figure 6, we evaluate the scalability of NPivoter by adjusting the size of datasets. We sample either the edges or nodes, varying the percentage from 50% to 100%. In this experiment, we use the DBLP dataset, which has the highest number of edges among the tested datasets. We set p = 6, q = 6. The results obtained on the other datasets and with other p, q values show similar trends. From Figure 6, we can see that all three algorithms—NPivoter, BCList++, and EPivoter — exhibit a good scalability with respect to graph size. Furthermore, NPivoter outperforms both BCList++ and EPivoter significantly, showcasing its superior efficiency and capacity to handle large-scale datasets.

**Exp-9: The Effect of the Optimization Tricks.** Table 7 reports the impact of four key optimizations (presented in Section 5) applied to the NPivoter algorithm on several datasets: You, Kos, DBLP, and Ama. The results on the other datasets are similar. The optimizations include:  $(\alpha, \beta)$ -core based graph reduction  $(O_1)$ , core value-based node ranking  $(O_2)$ , early termination  $(O_3)$ , and non-neighbor count maintenance  $(O_4)$ . With each additional optimization, the running time consistently decreases. For instance, on the Ama dataset, the running time reduces by 57.3% when applying  $O_1$ , followed by

Table 7: The effect of further optimizations (ms);  $O_1: (\alpha, \beta)$ core based graph reduction;  $O_2$ : core value-based node ranking,  $O_3$ : early termination,  $O_4$ : maintenance of non-neighbor count

Datasets	You	Kos	DBLP	Ama
No Optimization	13181	1138038	92856	4622
$O_1$	10851	1130167	15823	1971
$O_1 + O_2$	1793	392365	4195	1157
$O_1 + O_2 + O_3$	1341	319504	3043	1127
$O_1 + O_2 + O_3 + O_4$	1325	303924	2948	1050

Figure 7: The impact of graph density (ms)

a further 41.6% decrease when adding  $O_2$ , a 2.6% reduction with  $O_3$ , and an additional 6.8% improvement with  $O_4$ . The full set of optimizations  $(O_1 + O_2 + O_3 + O_4)$  yields the best performance, with the runtime for all datasets minimized, indicating the effectiveness of these optimizations in enhancing algorithm efficiency.

**Exp-10: The Impact of Graph Density.** To evaluate the scalability of NPivoter, we generate a set of random graphs under varying density. Specifically, we fix the number of edges at |E| = 8000 and generate random bipartite graphs with varying average degrees. For each combination of  $\overline{d}_U \in [20, 70]$  and  $\overline{d}_V \in [20, 70]$ , we create 20 random graphs, leading to a total of 50,000 experiments. The goal is to assess how NPivoter behaves as the density of the graph changes.

Each color grid in Figure 7 represents the average running time for the 20 random graphs corresponding to a particular combination of  $\overline{d}_U$  and  $\overline{d}_V$ . Notably, the running time remains under 1000 ms when  $\overline{d}_U < 60$  or  $\overline{d}_V < 60$ . This pattern indicates that NPivoter scales well with the sparsity of the graph, making it a highly effective solution for real-world networks that tend to exhibit a power-law distribution with a majority of nodes having low degrees. As  $\overline{d}_U$  and  $\overline{d}_V$  increase, the computational complexity naturally rises due to the increase in possible connections between the two sets. However, the results show that NPivoter handles this increase in density in a controlled manner. Even at the higher end of the degree spectrum, where both  $\overline{d}_U$  and  $\overline{d}_V$  approach 70, the algorithm still performs efficiently, although the running time does begin to rise sharply. These findings show the high scalability of NPivoter, particularly for handling sparse networks. Since realworld networks are often sparse, these results further validate the practical applicability of NPivoter in real-world scenarios.

### 7 RELATED WORK

Subgraph Counting. Biclique counting is a specific case of the broader problem of subgraph counting, which has been extensively studied in graph theory and its applications. The subgraph counting problem can be categorized based on several dimensions: Exact subgraph counting aims to compute the precise number of occurrences of a specific subgraph within a graph [19, 31, 33, 36], while approximate methods trade accuracy for scalability in large networks [7, 24, 42, 44]. Learning-based approaches also exist as approximate methods [20, 54]. Exact counting problems are closely related to enumeration problems, and algorithms that performs exact counting can often be used for enumeration. Global counting involves determining the number of subgraphs across the entire graph [19, 33], while local counting focuses on computing subgraph counts for specific nodes or edges [25]. In this work, biclique counting falls under both categories, as applications may require global counts or local counts per node, as seen in social networks or graph neural networks. While some algorithms are designed for counting specific subgraph patterns like cliques, cycles, or bicliques [15, 18, 22, 50, 52], others focus on counting a wide variety of subgraph types [2, 8, 33, 54]. Biclique counting is a prominent problem in specific subgraph counting, where general counting algorithms are often not as efficient as specific methods. When p = 2 and q = 2, the (p,q)-biclique is referred to as a butterfly. As a special case of general biclique counting, efficient butterfly counting plays a critical role in the development of advanced algorithms that can handle larger graphs and subgraph patterns. Various algorithms have been introduced to efficiently count butterflies in large bipartite graphs, taking advantage of the bipartite structure to reduce computational complexity [37, 43]. Recent research has focused on optimizing both memory and time complexity by employing parallel computing techniques [46-48], as well as I/O-efficient methods [45] and approximation strategies [38]. Other efforts have been made to extend butterfly counting to uncertain graphs [55, 56] and temporal graphs [10].

*k*-Clique Counting. Our work is closely related to the *k*-clique counting problem in traditional graphs. The first exact algorithm for k-clique counting, introduced by Chiba and Nishizeki [12], relies on a backtracking enumeration method. More recent advances have refined this technique using ordering-based optimizations, such as degeneracy ordering by Danisch et al. [13], and color ordering by Li et al. [26]. These algorithms efficiently list k-cliques for small values of k, but their performance degrades as k increases due to the exhaustive enumeration process. To address the inefficiencies for larger k, Jain and Seshadhri [22] proposed PIVOTER, an algorithm that leverages pivoting techniques for maximal clique enumeration [9, 40]. Instead of enumerating all possible k-cliques, PIVOTER counts them combinatorially, offering significant performance gains over enumeration-based methods. However, the algorithm may still struggle when applied to large, dense graphs [22]. To address this, several sampling-based methods have been developed to improve scalability, including the TuranShadow algorithm and its optimized version [21, 23], as well as color-based sampling techniques by Ye et al. [51, 53]. Despite these efforts, sampling methods tend to become inefficient for larger values of k. Our approach fundamentally differs from these k-clique counting studies as we focus on counting bicliques in bipartite graphs, a problem that cannot be directly tackled by the existing k-clique counting techniques.

### 8 CONCLUSION

In this paper, we propose NPivoter, a novel and general framework for biclique counting. The NPivoter framework not only unifies existing approaches like BCList++ and EPivoter but also extends their capabilities by supporting both local and range counting. Our implementation of NPivoter leverages a novel minimum nonneighbor candidate partition strategy, which significantly improves the worst-case time complexity compared to previous methods. Furthermore, the inclusion of a novel cost estimator enables the framework to adaptively switch between node-split and edge-split strategies, further enhancing its performance and scalability across different graph structures. Extensive experiments conducted on realworld datasets have demonstrated the efficiency and versatility of NPivoter, achieving up to two orders of magnitude improvements over state-of-the-art algorithms.
