(Dated: December 24, 2024)

Heavy neutron stars may contain solid quark cores as motivated by, e.g. the crystalline color superconducting phase, forming *elastic hybrid stars* (HSs). Many previous studies assumed an elastic core to be unsheared for the background, static and spherically symmetric configuration, and introduced shear deformation only at a perturbative level. This study relaxes this assumption and explores the influence of nonlinear elasticity on the static, spherically symmetric structure of elastic HSs within a fully relativistic elasticity framework. Such a framework effectively introduces anisotropic pressure within the quark matter core due to elasticity. The quark core is modeled using a quasi-Hookean equation of state (EOS) with shear contributions, while the nuclear matter envelope is treated as a perfect fluid. We find that including elasticity increases the maximum mass of HSs by approximately 10%. This enhancement allows some soft EOSs to satisfy current observational constraints. However, since the effects of elasticity are primarily concentrated in the high-mass regime, the current observational constraints are insufficient to distinguish whether an elastic anisotropic quark core exists within these stars. Additionally, we show that the compactness of stable stars can exceed the critical value of $1/3$ due to the inclusion of elasticity, making them potential candidates for black hole mimickers. Furthermore, we found that common phenomenological anisotropy models fail to accurately describe the anisotropy of the elastic core and propose a new parametrized anisotropy model that can accurately capture physically-motivated profiles with an error of 10% across a wide parameter space. This work not only bridges the gap between elastic EOSs and parametrized anisotropic models but also provides a foundation for interesting applications such as studying nonradial perturbations, tidal deformability, and pulsation modes for elastic HSs.

I. INTRODUCTION

The internal structure of neutron stars (NSs) remains an open question in astrophysics. One of the candidates for the inner core composition is quark matter (QM), which is predicted to exist at extreme densities where the quarks become asymptotically free. If the core consists of QM while the outer layers remain composed of hadronic matter and there is a phase transition in between, the object is referred to as a hybrid star (HS) to distinguish it from the typical NSs with a hadronic core.

Although typical NSs and HSs have been modeled as isotropic perfect fluids, they may contain stress anisotropy of various astrophysical origins. One such possibility is the existence of elastic layers within the stars. An NS crust can have a shear modulus of 10^{29} erg cm⁻³ [1, 2], and is crucial to explain pulsar glitches. Since this value is much smaller than the bulk modulus, it is not expected to have a significant impact on the NS structure. Meanwhile, the QM component of an HS can be in a crystalline solid state, such as the crystalline color superconducting (CCS) phase, due to the formation of Cooper pairs with non-vanishing momenta via a non-BCS mechanism [3–5] or the formation of quark clusters [6]. The

shear modulus of the QM in the HS core is predicted to be on the order 10^{32} erg cm⁻³ or higher. This can potentially cause the HS structure to be substantially different from ones with an isotropic fluid core when the shear strain is non-vanishing, even in the spherically symmetric configuration. Moreover, the large shear modulus can also influence HS astrophysical properties, such as tidal deformability [7, 8], rotational frequency [9], or oscillation modes [10, 11]. To investigate these properties, an elastic theory compatible with relativity is necessary.

An early reference for relativistic elasticity is given by Carter and Quintana [12]. In particular, their formalism covers elasticity in the finite-strain regime applicable to the high-pressure environment of the compact star interior. While there are various studies of self-gravitating elastic spheres in the context of relativity [13–17], they are rarely linked to the possible elastic phases within an HS. Interestingly, Alho *et al.* [17] demonstrated, by introducing a polytropic model extended to include elasticity, that some elastic stars with a radius within the (unstable) light ring can be dynamically stable against radial perturbations and thus are potential black hole mimickers. However, they might still be subject to nonlinear instabilities [18, 19]. On the other hand, many other astrophysically relevant studies on the elastic properties of NSs or HSs usually assume that the spherically symmetric structure is unsheared and elasticity enters only when the star is non-radially deformed [20–23]. This assumption does not hold, in general, and can lead to a significant offset in the background structure of the star

if the shear modulus is large.

Elasticity introduces modifications to the properties of NSs and HSs, particularly in systems with crystalline QM cores. The core’s resistance to shear deformation, quantified by its shear modulus $\tilde{\mu}$, ranges from 20 to 1000 times greater than that of the nuclear matter crust [24]. This enhanced rigidity affects the mass, radius, and tidal deformability of HSs compared to their fluid counterparts [25]. Such effects become particularly relevant in analyzing observations like GW170817 [26–29], which provide direct constraints on tidal deformability, and the electromagnetic measurements of mass-radius (M – R) relations [30–34]. For a detailed overview of recent progress, see e.g. [35].

Instead of focusing on the anisotropic stress from elasticity, anisotropic compact stars are also constructed using parametrized models for the pressure anisotropy as a function of the energy density. This approach, similar to the equation of state (EOS) relating fluid pressure and energy density in isotropic perfect-fluid stars, was first taken by Bowers and Liang [36] and was followed by various studies [37–44]. These models assume dependence not only on the thermodynamic state variables but also explicitly on other quantities, such as the radial coordinate r or the mass $m(r)$ enclosed within a sphere of radius “ r ”. Such dependence is necessary to make the anisotropy vanish at the stellar center and avoid a singularity [36]. Since they involve dependence other than the state variables, they cannot be considered as EOSs in the strict sense. Furthermore, these models are somewhat unsatisfactory in that the “cure” to the singularity is enforced by hand without fundamental connections to matter properties. They also do not inform us of the change in anisotropy when the star is perturbed from the spherically symmetric configuration. Moreover, the connections between these effective models and the underlying origin of anisotropy are unclear [45].

The main goal of this study to advance our understanding of anisotropic effects in HSs is two-fold. The first one is to relax the assumption in previous literature and include the effect of elasticity within the spherically symmetric configuration to see how it affects global stellar quantities, such as the mass and radius. The second one is to establish connections between the parametrized model of anisotropy and realistic elastic EOSs. We construct static spherically symmetric HS models with an elastic QM core from the Einstein field equations, assuming the solid QM follows a specific form of *quasi-Hookean* EOS first introduced in [13]. The models are thus consistent with both general relativity and a specific class of elastic material properties¹. We call these types of HSs *elastic* HSs, while those composed entirely of isotropic fluid as *fluid* HSs. Using these results, we introduce a

parametrized model that can approximate well the pressure anisotropy in the elastic QM core. This provides a direct relation between the free model parameters with the physical quantities of an elastic solid.

Our main findings can be summarized as follows:

1. Figure 1 presents the mass-radius relation for elastic HSs for various shear modulus coefficients κ that is defined as the ratio between the shear modulus $\tilde{\mu}$ and the square root of the energy density. Observe that the presence of an elastic core can increase the maximum mass of HSs. However, it remains insufficient to distinguish whether HSs possess an elastic core from LIGO/Virgo and NICER/XMM-Newton.

FIG. 1. Mass-radius relations for HS models constructed with EOS HS-A (blue), HS-B (red), and HS-C (green), whose base nuclear matter EOS is the APR EOS. The shear modulus coefficient κ varies among $2.8 \times 10^{25} \text{cm}^{1/2} \text{g}^{1/2} \text{s}^{-2}$ (dotted), $1.1 \times 10^{26} \text{cm}^{1/2} \text{g}^{1/2} \text{s}^{-2}$ (dashed), and $7 \times 10^{26} \text{cm}^{1/2} \text{g}^{1/2} \text{s}^{-2}$ (solid). The isotropic fluid HSs are represented by light-color dots. The cross symbols mark stars with $p_c = 1.2 \times 10^{35} \text{dyn cm}^{-2}$. Various observational bounds are shown with shaded regions, including the mass and radius measurement of GW170817 [28] (90% confidence interval, light blue and blue regions), J0030+0451 with NICER (95% confidence interval, maroon region) [34], J0740+6620 with NICER and XMM-Newton (95% confidence interval, orange region) [32], J0437-4715 with NICER (95% confidence interval, violet region) [33], and the mass measurement of J0740+6620 from pulsar timing [48] (68.3% confidence interval, grey horizontal band).

2. Figure 2 compares the pressure anisotropy profile for the core of an elastic HS, obtained numerically, against various phenomenological anisotropy models. Observe that common models like the ones proposed by Bowers and Liang (BL model) [36] and Horvat *et al.* (H model) [41] fail to

¹ Cadogan and Poisson [45–47] recently established a different, relativistic framework for self-gravitating anisotropic fluids based on a theory of liquid crystals.

accurately capture the numerical data from a physically-motivated elastic HS configuration (see Appendix A for more details on the comparison). We thus provide the following new phenomenological model to more accurately describe the realistic profile:

$$\sigma_{\text{fit}} = \lambda p_c \left(\frac{\rho}{\rho_c} \right)^{\frac{N}{\lambda} - 1} \frac{m}{r} \left(1 - \frac{2m}{r} \right)^{-1}, \quad (1)$$

where ρ is the energy density while λ and N are dimensionless values that can be expressed in terms of the shear modulus coefficient κ and the central pressure p_c . This fitting achieves an accuracy with an error of 10%, as shown in the bottom panel of Fig. 2.

FIG. 2. (Top) The σ profile of the HS-A model (brown crosses) is fitted by our model (green solid), H model (purple dot-dashed), and BL model (blue dashed). We fix $(p_c, \kappa) = (2.1 \times 10^{35} \text{ dyn cm}^{-2}, 7 \times 10^{26} \text{ cm}^{1/2} \text{ g}^{1/2} \text{ s}^{-2})$. The fitted anisotropy parameters for the H and BL models are given by $\lambda_H = -0.459354$ and $\lambda_{BL} = -1.08352$, respectively. (Bottom) Fractional difference between analytical models and the numerical results.

The remainder of this paper is structured as follows. In Section II, we review the formulation to construct elastic HSs derived by [13]. Section III is dedicated to exploring the effect of elasticity on the stellar structure. Section IV introduces a new parametrized model to capture the nature of anisotropy in the elastic core. Finally, in Section V, we summarize our findings and discuss the broader implications of our results for understanding anisotropic HSs. Unless otherwise stated, we adopt the geometric units $c = G = 1$ throughout the paper.

II. FORMULATION OF ANISOTROPIC HYBRID STARS

The elastic core of the HS is under high pressure and, in general, has a non-negligible shear deformation from the relaxed state. In many previous studies, the solid component of a static spherically symmetric star is assumed to be unsheared, and a linear strain-stress relation (i.e., the Hookean relation [12, 23]) is assumed to hold when the star is perturbed (e.g., [7, 8, 20–22, 25, 49–51]). The validity of this assumption relies heavily on the small deviation of the background configuration from the true unsheared state of the solid, which, in general, does not hold. As a result, this treatment has ignored the background shear that can impact the stellar structure. Here, we focus on the effect of elasticity on the static structure of HSs by employing a fully relativistic nonlinear elasticity theory developed in [12]. We further assume the elastic core can be described by the quasi-Hookean EOS studied in [12, 13], which we shall give a brief review in this section.

A. Equation of State

In terms of notation, we use an overhead tilde to represent the unsheared components, depending only on the particle number density n . Relations among these unsheared quantities correspond to what is typically referred to as the fluid EOS, which depends only on volume changes.

For elastic matter, the EOS should also account for shear deformation. We use the quasi-Hookean EOS, which relates to a shear scalar, describing how the energy density depends on the magnitude of shear deformation [13]

$$\rho = \tilde{\rho} + \tilde{\mu} \mathcal{S}^2, \quad (2)$$

where ρ is the energy density, $\tilde{\mu}$ is the shear modulus, and \mathcal{S}^2 is the shear scalar, obtained from the contractions of the shear tensor², s_{ab} , that quantifies the shear deformation (see, e.g., Eq. (5.17) of [12] for its definition³). There are many proposed choices of \mathcal{S}^2 , and its actual form depends on the material (see [52] for more examples). Here, we adopt the form introduced in [13] as explained in the following paragraph.

The shear scalar \mathcal{S}^2 of a quasi-Hookean material measures the deformation that goes beyond simple volume

² The contraction can be quadratic between the shear strain tensor itself, e.g., by $s_{ab}s^{ab}$, or with the tensor representing the unsheared state (see Eq. (5.1) of [12] for definition), or even a cubic contraction as the one we employ here [13].

³ In linear elasticity, the shear strain tensor is simply the traceless part of the infinitesimal strain tensor. In nonlinear cases, the shear strain is no longer traceless.

changes. It remains zero for pure volume changes from the relaxed state but takes nonzero values when shear strain is introduced. We follow the formalism derived in [13], where the shear scalar \mathcal{S}^2 is defined as

$$\mathcal{S}^2 = \frac{1}{12} \left[\left(\frac{n_1}{n_2} - \frac{n_2}{n_1} \right)^2 + \left(\frac{n_2}{n_3} - \frac{n_3}{n_2} \right)^2 + \left(\frac{n_3}{n_1} - \frac{n_1}{n_3} \right)^2 \right]. \quad (3)$$

Here n_1 , n_2 , and n_3 are the linear particle densities in the three orthogonal principle directions, i.e., the number of particles contained in a small unit volume divided by the unit length in that direction (see [13] for the precise definition), which represent how the material is stretched or compressed along their principal axes when compared to the relaxed state. If $n_1 = n_2 = n_3$, the material is unsheared, meaning it deforms equally in all directions relative to the relaxed state. Specifically, the shear scalar should meet criteria that include consistency with the quadratic invariant of the shear tensor in the linear elasticity regime, as well as ensuring that \mathcal{S}^2 remains a non-negative invariant under coordinate transformations. As a result, we can recover the linear Hookean relation (the linear stress-strain relation or Hooke's law) from Eq. (2) for small deformations about the unsheared state. The definition in Eq. (3) is somewhat simpler than the one used by Carter and Quintana [12] in the sense that it does not contain fractional power in the linear number densities.

Let us further rewrite the above shear scalar \mathcal{S}^2 . We introduce the linear particle densities in the radial direction n_r and the tangential direction n_t to describe spherically symmetric solids. In such cases, we can substitute $n_1 = n_r$ and $n_2 = n_3 = n_t$ in Eq. (3) since we assume the deformation along the tangential directions is degenerate. Here, following [13], we define $z = n_r/n_t$, and the shear scalar simplifies to

$$\mathcal{S}^2 = \frac{1}{6} (z^{-1} - z)^2. \quad (4)$$

In our study, the fluid EOS, the relation between un-sheared pressure \tilde{p} and un-sheared energy density $\tilde{\rho}$, incorporates both the nuclear matter (NM) and QM regions, connected by a sharp phase transition at a transition pressure p_{trans} . We use the tabulated APR [53] to describe the NM component, denoted as $\tilde{\rho}_{\text{NM}}(\tilde{p})$. The QM core is described using the Constant Speed of Sound (CSS) template. The resulting EOS is given by [54]

$$\tilde{\rho}(\tilde{p}) = \begin{cases} \frac{\tilde{p} - p_{\text{trans}}}{\tilde{v}^2} + \tilde{\rho}_{\text{NM}}(p_{\text{trans}}) + \Delta\tilde{\rho}, & \text{if } p_r > p_{\text{trans}} \\ \tilde{\rho}_{\text{NM}}(\tilde{p}), & \text{if } p_r \leq p_{\text{trans}} \end{cases} \quad (5)$$

where the fluid sound speed \tilde{v} is assumed to be a constant while $\Delta\tilde{\rho}$ is the energy density gap between the QM and NM. Note that the condition distinguishing these two regions is defined in terms of the radial pressure $p_r = m_r \partial(\rho/n)/\partial n_r$, because the core region is

anisotropic while p_r reduces to \tilde{p} in the fluid envelope region. Since p_{trans} represents a specific value at the boundary of the EOS, we do not distinguish it with or without a tilde notation. We will discuss the boundary conditions, including the one at the QM-NM interface, in Sec. III C. Figure 3 provides examples of the HS model for different values of p_{trans} , $\Delta\tilde{\rho}$, and \tilde{v} . The un-sheared energy density for NM in APR EOS exhibits a log-linear relation with un-sheared pressure.

FIG. 3. The EOSs for NSs and HSs with various EOS parameters. The APR EOS, shown by the black line, serves as a reference to NM EOS. For the HS models, the blue line represents the baseline configuration with $(p_{\text{trans}}, \tilde{v}, \Delta\tilde{\rho}) = (2 \times 10^{33} \text{ dyn cm}^{-2}, 0.33, 1 \times 10^{14} \text{ g cm}^{-3})$. The effects of varying the fluid sound speed to 0.11 (red), the energy density gap to $3 \times 10^{12} \text{ g cm}^{-3}$ (green), and the transition pressure to $2 \times 10^{34} \text{ dyn cm}^{-2}$ (violet) are illustrated in comparison to this baseline. We will use the legends introduced here (i.e., HS-A) to denote the HS models used in our analysis.

The CSS serves as a parameterization template and was developed to avoid model dependence and to offer flexibility in describing various configurations of QM (the well-known MIT Bag model [55] is a good example of this template). Its parameters, such as $\Delta\tilde{\rho}$, p_{trans} , and \tilde{v} , are designed as convenient tools for describing stellar properties rather than representing any direct physical quantities. It allows for flexibility in modeling stars where \tilde{v} changes gently, making it versatile for different types of compact stars, including those undergoing first-order phase transitions. However, since all wave speeds in the solid must satisfy the causality limit, there are further restrictions on the fluid sound speed. We choose 0.8 as an upper bound for \tilde{v}^2 , and the details will be discussed in Appendix B.

A key property distinguishing elastic HSs from fluid HSs is the shear modulus of the QM phase in the core. The shear modulus quantifies the rigidity of the elastic core, allowing it to sustain anisotropic stress and thereby influencing the star's overall structure and observable properties. To model this effect, we adopt a shear mod-

ulus $\tilde{\mu}$ that depends on the energy density as follows:

$$\tilde{\mu} = \kappa \sqrt{\tilde{\rho}}, \quad (6)$$

with a constant κ . Such a simple form is inspired by the calculation of the shear modulus of the CCS phase derived in [24]:

$$\tilde{\mu}_{\text{CCS}} = 2.47 \text{MeV fm}^{-3} \left(\frac{\Delta}{10 \text{MeV}} \right)^2 \left(\frac{\mu_q}{400 \text{MeV}} \right)^2, \quad (7)$$

where Δ is the gap parameter and μ_q represents the chemical potential of QM. In the high-density limit, $\tilde{\mu}_{\text{CCS}} \propto \mu_q^2$, and $\tilde{\rho} \propto \mu_q^4$ as for the ultrarelativistic free Fermi gas. Hence, we have $\tilde{\mu}_{\text{CCS}} \propto \sqrt{\tilde{\rho}}$ and $\kappa \propto \Delta^2$. Mannarelli *et al.* [24] placed constraints on the gap parameter Δ in the CCS phase, suggesting a range of approximately 5 MeV to 25 MeV. Therefore, in our approximation, κ is set to lie within the range $2.8 \times 10^{25} \text{ cm}^{1/2} \text{ g}^{1/2} \text{ s}^{-2}$ to $7 \times 10^{26} \text{ cm}^{1/2} \text{ g}^{1/2} \text{ s}^{-2}$ ⁴, ensuring that the quark core's rigidity is accounted for in line with the current theoretical understanding.

Although the range of these parameters is rather broad, certain choices are made in this paper for illustrative purposes. A smaller p_{trans} implies a larger elastic core with more pronounced effects of anisotropy. Hence, for the remainder of this work, we adopt $p_{\text{trans}} = 2 \times 10^{33} \text{ dyn cm}^{-2}$. To maintain reasonable HS models (i.e., not too low in maximum mass, see [25] for constraints for isotropic cases), we choose intermediate values for the energy density gap and fluid sound speed. The energy density gap affects the stiffness of the EOS. For larger $\Delta\tilde{\rho}$, the pressure is lower for the same energy density, resulting in a very soft EOS. Therefore, we restrict our consideration of the energy density gap to values up to the $10^{14} \text{ g cm}^{-3}$ range to ensure physically plausible stellar models. Furthermore, the fluid sound speed \tilde{v} indicates the stiffness of the core because it mathematically represents the slope of the QM portion of the EOS function on a linear scale. To avoid overly soft models, we set a lower limit for \tilde{v}^2 as 0.11.

B. Structural Equations

We now turn our attention to the sheared part. We describe the spacetime of a static and spherically symmetric configuration using the following line element in Schwarzschild coordinates (t, r, θ, ϕ) :

$$ds^2 = -e^{2\nu(r)} dt^2 + e^{2\lambda(r)} dr^2 + r^2 (d\theta^2 + \sin^2 \theta d\phi^2). \quad (8)$$

The function $e^{2\lambda}$ can be rewritten as

$$e^{2\lambda} = \left(1 - \frac{2m}{r} \right)^{-1}, \quad (9)$$

where m describes the amount of mass contained within a sphere of radius r . Meanwhile, the function ν is related to the gravitational potential.

The spacetime geometry, described by the above metric, is influenced by the distribution of matter and energy, encapsulated in the stress-energy tensor:

$$T_{\alpha\beta} = \rho u_\alpha u_\beta + p_r k_\alpha k_\beta + p_t \Omega_{\alpha\beta}. \quad (10)$$

Here ρ is the energy density, p_r is the radial pressure, p_t is the tangential pressure, u^α is the four-velocity, k^α is the unit normal vector in the radial direction orthogonal to u^α , and $\Omega_{\alpha\beta} = g_{\alpha\beta} + u_\alpha u_\beta - k_\alpha k_\beta$ is the transverse metric on a 2D sphere orthogonal to both u^α and k^α .

Using the above metric and the stress-energy tensor, one finds, through the Einstein equations, the relativistic hydrostatic equilibrium equations (Tolman-Oppenheimer-Volkoff (TOV) equations) for anisotropic fluids [36]:

$$\frac{dm}{dr} = 4\pi r^2 \rho, \quad (11)$$

$$\frac{dp_r}{dr} = -(\rho + p_r) \frac{m + 4\pi r^3 p_r}{r(r - 2m)} - \frac{2\sigma}{r}. \quad (12)$$

Here σ represents the pressure anisotropy, defined as the difference between radial and tangential pressure:

$$\sigma \equiv p_r - p_t. \quad (13)$$

The stellar configuration reduces to the isotropic one in the $\sigma \rightarrow 0$ limit. Within the framework of the quasi-Hookean material defined by Eqs. (2)–(4), the anisotropic TOV equations can be reformulated into a system of differential equations involving m , \tilde{p} , and z as independent variables. The system of differential equations becomes [13]

$$\frac{dm}{dr} = 4\pi r^2 \rho, \quad (14)$$

$$\frac{d\tilde{p}}{dr} = \frac{\tilde{\beta}}{r\beta_r} \left\{ -(\rho + p_r) \frac{m + 4\pi r^3 p_r}{r - 2m} - 2\sigma + 4(e^\lambda z - 1) \left[\tilde{\mu} + 3\tilde{\mu} \mathcal{S}^2 - \frac{\sigma}{2}(1 - \tilde{\Omega}) \right] \right\}, \quad (15)$$

$$\frac{dz}{dr} = \frac{z}{r} \left[\frac{r}{\tilde{\beta}} \frac{d\tilde{p}}{dr} - 3(e^\lambda z - 1) \right], \quad (16)$$

where

$$\sigma = -\frac{\tilde{\mu}}{2} (z^{-2} - z^2), \quad (17)$$

$$p_r = \tilde{p} + (\tilde{\Omega} - 1)\tilde{\mu} \mathcal{S}^2 + \frac{2}{3}\sigma, \quad (18)$$

$$\tilde{\beta} = (\tilde{\rho} + \tilde{p}) \frac{d\tilde{p}}{d\tilde{\rho}}, \quad \tilde{\Omega} = \frac{\tilde{\beta}}{\tilde{\mu}} \frac{d\tilde{\mu}}{d\tilde{p}}, \quad (19)$$

$$\beta_r = \tilde{\beta} + \frac{4}{3}\tilde{\mu} + \left[\tilde{\Omega}(\tilde{\Omega} - 1) + \tilde{\beta} \frac{d\tilde{\Omega}}{d\tilde{p}} \right] \tilde{\mu} \mathcal{S}^2 + 4 \left[\tilde{\mu} \mathcal{S}^2 - \frac{\sigma}{3} \left(\tilde{\Omega} - \frac{1}{2} \right) \right]. \quad (20)$$

⁴ See Eqs. (12)–(16) in [56] for the derivation of the range for κ .

We define β_r as the longitudinal modulus in the radial direction, which characterizes the longitudinal wave speeds in that direction. The above set of equations reduces to the isotropic fluid case when $\tilde{\mu}$ is zero⁵. Besides, z always remains less than or equal to 1 because, at the unshered point (where $\tilde{\mu} = \sigma = 0$ and $z = 1$), the derivative dz/dr is always negative, which prevents z from exceeding 1. This ensures that the radial pressure can never exceed the tangential pressure, and thus σ always remains negative.

In short, Eqs. (14)–(16) describe the same structural framework as Eqs. (11)–(12), where the thermodynamic quantities are governed by a two-parameter EOS involving the number density and the shear scalar (see Eq. (2)). To fully describe the system, it is necessary to solve for the shear profile, which is determined by the differential equation for z . Thus, the results of the structural equations can be recovered by solving the anisotropic TOV equations (Eqs. (11)–(12)) if one uses the anisotropy profile computed from the solution for the z equation. Alternatively, one can construct a phenomenological model for σ , similar to that in [36] or [41], that effectively captures the σ profile obtained by solving z , and uses that to solve for the anisotropic TOV equations. In Sec. IV, we further demonstrate how to construct such a phenomenological model for σ .

C. Boundary Conditions

We now discuss the necessary boundary conditions to solve the above set of equations. Equations (14)–(16) should be integrated from a point relatively close to $r = 0$. The initial conditions at this point are as follows [13]:

$$m = \frac{4}{3}\pi\rho_c r^3 + \mathcal{O}(r^4), \quad (21)$$

$$\tilde{p} = p_c - 2\pi\tilde{\beta}_c \frac{(\rho_c + p_c)(\rho_c + 3p_c) - 4\tilde{\mu}_c\rho_c}{3\left(\tilde{\beta}_c + \frac{4}{3}\tilde{\mu}_c\right)} r^2 + \mathcal{O}(r^3), \quad (22)$$

$$z = 1 - 4\pi \frac{(\rho_c + p_c)(\rho_c + 3p_c) + 3\tilde{\beta}_c\rho_c}{15\left(\tilde{\beta}_c + \frac{4}{3}\tilde{\mu}_c\right)} r^2 + \mathcal{O}(r^3). \quad (23)$$

All variables with the subscript c represent values at the center.

The stellar surface is determined by the condition $p_r/p_c < 10^{-14}$. At the surface, the interior solutions are smoothly matched to the Schwarzschild solution valid in the exterior region.

Furthermore, since we are considering an HS with a phase transition, the following junction condition on \tilde{p} is

needed to integrate Eq. (15) from the solid core to the fluid envelope [13]:

$$\tilde{p}_+ = \tilde{p}_- - \frac{\tilde{\mu}_-}{6} [(1 - \tilde{\Omega}_-)(z_-^{-1} - z_-)^2 + 2(z_-^{-2} - z_-^2)], \quad (24)$$

which is equivalent to the continuity of p_r at the phase transition. The subscripts $+$ and $-$ represent the quantities evaluated at the outer side and the inner side of the interface, respectively. We also have $\tilde{p}_+ = p_{\text{trans}}$ for the perfect fluid envelope. This approach ensures that, for cases where p_c exceeds p_{trans} , the star remains an HS (further discussion is provided in Appendix C).

III. STELLAR STRUCTURE

In previous studies, shear deformation has typically been introduced at the perturbative level. However, in this work, we consider a more realistic scenario for HSs with a crystallized core within a fully relativistic elasticity framework, where shear stress is nonvanishing, even at the background (static and spherically symmetric) level. With the help of structural equations assuming the quasi-Hookean EOS described in Sec. II A, we can now examine how the inclusion of anisotropy impacts the results for elastic HSs by comparing them with the typical isotropic models.

For a better comparison, we use the three elastic HS models (HS-A, HS-B, and HS-C) in Fig. 3, with the same color scheme in other related figures for consistency. We show that the elasticity induces a pressure anisotropy with $\sigma < 0$, which causes an increase in the maximum mass compared to the unshered models.

A. Anisotropy Profile of the Core

To visualize how anisotropy manifests within the core of the star, we present the anisotropy profile for elastic HS models with different shear modulus coefficients κ in Fig. 4. At the stellar center, both radial and tangential pressures are effectively equal due to the symmetric environment and minimal deformation, resulting in vanishing anisotropy. Moving outward from the core, the symmetry is gradually broken as shear strain develops, as indicated by \mathcal{S}^2 in Fig. 5. This leads to the emergence of pressure anisotropy, which monotonically increases in magnitude with radius.

Comparing the same model with different shear modulus coefficients κ (as seen in the same colored lines with different line styles in Fig. 4), we observe that for larger values of κ , the anisotropy increases more significantly with increasing radius. Since $\sigma \propto \kappa$ (from Eq. (17)), a more rigid material (with a higher κ) leads to a more pronounced increase in anisotropy because the material can resist shear deformation more effectively.

⁵ The typos mentioned in [57] have been corrected here.

FIG. 4. The anisotropy profile for elastic HS models (HS-A, HS-B, and HS-C) is shown with varying shear modulus coefficients κ and a fixed central pressure $p_c = 1.2 \times 10^{35} \text{ dyn cm}^{-2}$, corresponding to the crosses in Fig. 1. Three different values of κ are represented: $(0.28, 1.1, 7.0) \times 10^{25} \text{ cm}^{1/2} \text{ g}^{1/2} \text{ s}^{-2}$ depicted by dotted, dashed, and solid lines, respectively. We regard HS-A (blue) as the baseline model, with HS-B (red) having a lower fluid sound speed and HS-C (green) featuring a smaller energy density gap.

FIG. 5. The radial profile of the shear scalar S^2 for elastic HS models corresponding to the configurations in Fig. 4.

In comparing different EOS models (as shown by the different colored lines with the same line style in Fig. 4), we observe that the energy density gap has a minimal impact on the anisotropy profile because it does not affect the magnitude of the shear part contribution of these models, as demonstrated in Fig. 6. In contrast, the speed of the fluid sound speed \tilde{v} associated with the un-sheared part plays a more significant role in determining the anisotropic behavior (the red curves have a smaller \tilde{v} compared to the blue and green curves). Since the overall

anisotropy arises from contributions of the sheared term, if the un-sheared part dominates, the resulting anisotropy will be smaller as the shear strain is reduced in such configurations.

The sheared contribution to the energy density is shown in Fig. 6. The results illustrate a trend of increasing the shear contribution with the radius, which aligns with the anisotropy profile discussed before. As the radius increases, the shear scalar S^2 increases, leading to a progressively larger contribution of the shear term to the overall energy density. This trend highlights the growing role of shear deformation in the outer regions of the elastic core. Furthermore, the magnitude of the shear contribution is strongly dependent on the shear modulus coefficient κ . For larger values of κ , the shear term contribution to the energy density is significantly enhanced. This behavior reflects the higher rigidity of the material, allowing it to maintain greater shear stress and deformation, thus amplifying its impact on the energy density profile.

FIG. 6. The radial profile of the contribution of the shear term $\tilde{\mu}S^2$ on the energy density of elastic HS models corresponding to the configurations in Fig. 4.

B. Effects on the Macroscopic Properties

We next examine how pressure anisotropy σ influences HS properties, such as mass, radius, and compactness, providing a comprehensive understanding of how anisotropy alters the behavior of elastic HSs compared to isotropic models.

In Fig. 1, we show the effects of different shear moduli on the mass and radius of elastic HSs. We observe that the maximum mass of elastic HS increases with κ . Among the three groups shown, the maximum mass of the models with the largest κ increases by up to 6.5% (HS-A, blue), 13.4% (HS-B, red), and 7.6% (HS-C, green). This conclusion differs from the findings presented in [13]. A detailed discussion of this discrep-

ancy is provided in Appendix D. We also observe that the differences in the M – R curves arise from variations in \tilde{v} and $\Delta\tilde{\rho}$. The red curves have a smaller \tilde{v} compared to the blue and green curves, meaning that the material in the red model is less resistant to pressure change. This reduced stiffness results in smaller radii and lower maximum masses, shifting the M – R curve down and to the left. Meanwhile, the green models have a smaller energy density gap than the red and blue models, which increases the stability of higher-mass configurations by making it favorable for the star to support greater masses. This effect shifts the green M – R curve up and to the right, allowing for higher maximum masses and larger radii compared to the blue curve.

Some observational constraints are overlaid on the M – R relations, including the mass measurement of PSR J0740+6620 [48], as well as the inferred mass and radius constraints from the binary NS merger event GW170817 [28] (see similar constraint in [58, 59]), and the latest constraints from NICER observations of PSR J0030+0451 [34], PSR J0740+6620 (combined with XMM-Newton data) [32], and PSR J0437–4715 [33]. Due to the increase in the maximum mass caused by the elasticity, we can expect that some stars that previously could not satisfy the mass constraints of J0740+6620 may become viable. However, the effects of elasticity cannot be distinguished by current observational constraints. For example, the HS-A model can satisfy all constraints, regardless of whether elasticity is taken into account or not.

As demonstrated in [17], elastic stars can have high compactness while maintaining radial stability due to anisotropy. A stable configuration with compactness $> 1/3$ can potentially be a black hole mimicker, i.e., a horizonless object with a photon sphere. Here, we observe a similar behavior with the particular quasi-Hookean EOS (Eqs. (2)–(3)) rather than the extended polytropic EOS⁶ in [17]. Figure 7 illustrates the relation between compactness and central pressure under different shear moduli for various elastic HSs. We observed that the compactness of the elastic HS is greater than that of the fluid HS, and this feature becomes more significant as the central pressure increases. For a fixed central pressure, the compactness increases as one increases κ . For the maximum mass star, the increase in compactness is 0.0152 (HS-A, blue), 0.0216 (HS-B, red), and 0.0186 (HS-C, green), respectively.

Additionally, we present results for an extra set of HS models (brown) in Fig. 7, demonstrating that with the inclusion of anisotropy, the stellar compactness can approach or even exceed $1/3$ before reaching the maximum mass, resulting in ultra-compact HSs [60]. It is expected that these ultra-compact stars within the unstable light ring ($R < 3M$) possess a second stable light ring with a

smaller radius. This causes their perturbations to be unstable either in the nonlinear regime or at the linear level with small rotations, suggesting that the ultra-compact star will eventually become a black hole or a compact star without a photon sphere [18, 19]. However, these results are obtained by analyzing geodesics. The actual fate of these stars requires studying the elastodynamics in the perturbed configurations, which is beyond the scope of this work.

FIG. 7. The relation between compactness and central pressure with different shear modulus (represented by κ) for elastic HSs (HS-A, HS-B, and HS-C; same color coding as in Fig. 3). The brown curves correspond to the results obtained by taking HS-C as the baseline and increasing \tilde{v}^2 to 0.8. The cross points on the curves represent the maximum-mass stars, where their compactness exceeds the critical value of $1/3$. For comparison, the light-color dots represent the isotropic fluid HSs. The grey line indicates the stability boundary for the star.

IV. ANISOTROPIC PROFILE MODELLING

We next construct a new phenomenological model for pressure anisotropy. Our parameterized model (Eq. (1)) is a function of both the thermodynamic variables and the local curvature. The model is derived by fitting the numerical anisotropy profiles in Sec. III, obtained with the quasi-Hookean EOS that guarantees the σ to vanish at $r = 0$. We stress that Eq. (1) is valid in the core region, and the core surface is determined by the phase transition between the core and the envelope, as detailed in Sec. II C.

Notice the following properties for σ_{fit} : (i) At the stellar center, the equality between p_r and p_t is automatically satisfied. This is because the mass function $m(r)$ behaves as $m \sim r^3$ near $r = 0$ (see Eq. (21)), ensuring that $(1 - 2m/r)^{-1}$ remains well-behaved and does not introduce any singularities. Moreover, thanks to the

⁶ A generalization of the fluid polytropic EOS to include elasticity by adding a term quadratic in shear deformation (see [17, 52]).

quasi-Hookean EOS, the energy density ρ and pressure p are expressed as the sum of a relaxed state and a term accounting for shear deformation. This formulation leads to the absence of shear at the stellar center. (ii) σ_{fit} is discontinuous at the interface as it remains finite there while $\sigma = 0$ in the outer fluid envelope.

Let us further analyze the implicit relation between λ and N with respect to p_c and κ . These parameters obviously depend on κ because the shear modulus clearly impacts the stellar structure, as discussed in the previous section. They also depend on p_c because the solution to the set of structural equations depends on this quantity through the boundary condition at the center.

For each specific HS model with defined parameters (p_{trans} , \tilde{v} , $\Delta\bar{\rho}$), we also need to determine the ranges of p_c and κ to complete the fitting. For example, for the results plotted in this work, we evaluate a range of p_c from 2.42×10^{34} dyn cm $^{-2}$ to 6.66×10^{35} dyn cm $^{-2}$ and a range of κ from 2.8×10^{25} cm $^{1/2}$ g $^{1/2}$ s $^{-2}$ to 7×10^{26} cm $^{1/2}$ g $^{1/2}$ s $^{-2}$. We construct the relation in two steps, as explained below:

1. For a specific HS model with a fixed κ , fit the functional forms of λ and N using various $\bar{p}_c = p_c/(1 \text{ dyn cm}^{-2})$. The result is given as follows, where \mathcal{Y} symbolizes $-\lambda$ or $-N$:

$$\ln(\mathcal{Y}) = \sum_{i=0}^4 a_i [\ln(\bar{p}_c)]^i. \quad (25)$$

Here, each coefficient a_i is a fitting parameter but is also a function of κ .

2. Fit the coefficients a_i ($i = 0, 1, 2, 3, 4$) with the corresponding κ . Note that $\bar{\kappa}$ is defined as a dimensionless quantity, $\bar{\kappa} = \kappa/(10^{26} \text{ cm}^{1/2} \text{ g}^{1/2} \text{ s}^{-2})$. The coefficients can be expressed as follows:

$$a_i = \sum_{j=0}^4 b_j [\bar{\kappa}]^j + \frac{c_1}{\bar{\kappa}} + c_2 \exp\left[-\frac{(\bar{\kappa} - c_3)^2}{2c_4^2}\right]. \quad (26)$$

Again, all b_j , c_1 , c_2 , c_3 and c_4 are fitting parameters for a specific a_i in Eq. (25).

In Appendix A, we provide tables of fitted parameters for the HS-A model as an example. We also provide a Mathematica notebook for this fitting process with examples shown in Fig. 8 in the GitHub repository [61].

Figure 8 presents the numerical results and our parameterized model of the anisotropy for different HS models (top in each sub-figure), along with the fractional differences between them (bottom in each sub-figure). We observe that our new model matches the numerical results closely, with the error maintained below 10%. This indicates that the new analytical form of σ is valid across a broad parameter space. Notice also that σ_{fit} (and also λ) are always negative because the tangential stresses always dominate over the radial ones (see Sec. II B).

While the new model achieves agreement with the numerical results, it is still necessary to compare it with other commonly used anisotropy models, such as the BL model [36] and the H model [41] (see Appendix A for more details on these models). Figure 2 illustrates that these widely used models are not suitable for describing the anisotropic behavior of the elastic core in HSs because of their significant deviations from the realistic profile.

V. CONCLUSION

In this work, we studied the effects of nonlinear elasticity on the static, spherically symmetric structures of HSs with a solid core. The most important distinction of this work compared to our previous work [25] lies in the inclusion of shear deformation into the background structure. The formulation is based on the fully relativistic nonlinear elasticity theory in [12]. We modeled the QM core as a solid described by the quasi-Hookean EOS (Eq. (2)), where the unsheared component follows the CSS template (Eq. (5)), and the sheared component is modeled by the shear scalar defined in Eq. (3), originally proposed in [13]. The NM envelope, meanwhile, is treated as a perfect fluid layer described by the APR EOS.

Next, we examined the anisotropic profiles of HSs to understand the qualitative effects of elasticity. Shear stress introduces anisotropy in the pressure distribution within the core. Specifically, the tangential pressure p_t consistently exceeds the radial pressure p_r , indicating an asymmetry driven by the shear deformation. At the center of the star, anisotropy vanishes because of the symmetric environment and the minimal deformation. However, the magnitude of anisotropy, $|\sigma|$, increases monotonically with the radius from the core's center. This trend highlights the critical role of shear deformation in determining the anisotropy profiles of elastic HSs.

We found that the anisotropy significantly affects the maximum mass and compactness of HSs. For stars with a large shear modulus, the maximum mass increases by around 10%, and the compactness shows a marked enhancement compared to isotropic models. Under the current observational constraint, the increased maximum mass allows for the inclusion of softer EOSs. However, it remains unrealistic to distinguish whether elastic HSs exist in the stellar interior with the current observations, as the effects of elasticity are mainly concentrated in the high-mass region. Additionally, for some EOS parameters, the HS models along the M - R relation before reaching the maximum mass can have compactness exceeding 1/3. These objects can be black hole mimickers that are stable against linear radial perturbations if the turning point of the M - R curve implies a change in radial stability as in the homogeneous fluid models [62, 63]. This has been shown to hold for a solid star following the quasi-Hookean EOS, but may not apply to a star with a den-

FIG. 8. (Top) The anisotropy profile for HSs at the maximum mass with three different values of κ for numerical results (dots) and the fitting formula in Eq. (1) (lines). We fix p_{trans} at 2×10^{33} dyn cm $^{-2}$. For the fluid sound speed, we choose three values: 0.11, 0.33, and 0.8. The energy density gap ($\Delta\bar{\rho}$) is categorized into two distinct segments: a low-density gap at 3×10^{12} g cm $^{-3}$ (top row) and a high-density gap at 1×10^{14} g cm $^{-3}$ (bottom row). (Bottom) Fractional difference between numerical results and the fitting formula.

sity discontinuity⁷ [64]. Even being stable against linear radial pulsations, whether these ultra-compact HSs can exist without being prone to nonlinear instabilities still requires detailed perturbation studies involving elastodynamics. Therefore, shear effects play a critical role in refining EOS models and accurately capturing the structural properties of HSs.

Lastly, we show that phenomenological anisotropy models that are commonly used in literature (BL and H models) cannot accurately capture the anisotropy profile for elastic HS cores and propose a new parametrized model of anisotropy that can capture the realistic profile with an error of $\sim 10\%$. This new model bridges

the gap between microphysical EOSs and parametrized anisotropic models, offering a practical tool for exploring the effects of elasticity in astrophysical contexts.

Future work can focus on extending this model to study nonradial perturbations using the quasi-Hookean framework, including the formulation and calculation of tidal deformability and pulsation modes. Our subsequent work [66] will explore the potential universality of HS properties by using this quasi-Hookean EOS. One can also compare the quasi-Hookean approach with other elastic EOSs, such as those recently discussed in [52].

⁷ It is known that for HS models with a sharp phase transition, the turning point of the M - R curve does not necessarily imply a change in stability even for fluid stars. Depending on the rate of the phase conversion, there can be an extended stable region passing the turning point (see, e.g., [64, 65]).

Appendix A: Examples for σ model

In this appendix, we provide some examples of anisotropic model. First, we list two phenomenological models that are commonly used in literature that we also use in Fig. 2. The first model is the H model, originally introduced by Horvat *et al.* [41], given by

$$\sigma = 2\lambda_{\text{H}} p_r \frac{m}{r}. \quad (\text{A1})$$

The second model is the BL model, originally proposed by Bowers and Liang [36] (the BL mode), defined by

$$\sigma = \frac{\lambda_{\text{BL}}}{3} r^2 (\rho + 3p_r) (\rho + p_r) \left(1 - \frac{2m}{r}\right)^{-1}. \quad (\text{A2})$$

For both models, the constant parameters λ_{H} and λ_{BL} quantify the degree of anisotropy with $\lambda_{\text{H}} \rightarrow 0$ or $\lambda_{\text{BL}} \rightarrow 0$ corresponding to the isotropic limit.

Next, we present a set of fitted parameters for our new phenomenological anisotropy model using the HS-A model in Tables I & II. This fitting is applicable across the full range of κ and p_c for the stable star. A Mathematica notebook detailing the fitting process for this model has been made available at the GitHub repository [61], allowing readers to better understand our method and generate parameters using some input values of p_{trans} , \tilde{v}^2 , and $\Delta\tilde{\rho}$.

Appendix B: Wave Speeds

The fluid sound speed is constrained by the causality limit, meaning that it cannot exceed the speed of light ($\tilde{v} \leq 1$). However, in elastic materials, the situation becomes more complex due to the presence of multiple wave speeds associated with different modes of deformation. To ensure the physical validity of the model, we must ensure that all of these wave speeds remain below the speed of light. In this appendix, we provide an approximate constraint on the fluid sound speed using Eq. (B3) below and present a numerical analysis of wave speeds, resulting in a parameter space depiction of regions where causality is satisfied (or broken) across various HS models.

1. Wave Speeds in Elastic Matter

Within isotropic elastic matter in the linear (Hookean) regime [67], there are two distinct wave speeds corresponding to the longitudinal wave and transverse wave,

respectively. The wave speeds are given by

$$v_{\parallel}^2 = \tilde{v}^2 + \frac{4}{3} \frac{\tilde{\mu}}{\tilde{\rho} + \tilde{p}}, \quad (\text{B1})$$

$$v_{\perp}^2 = \frac{\tilde{\mu}}{\tilde{\rho} + \tilde{p}}, \quad (\text{B2})$$

where v_{\parallel} is the longitudinal wave speed and v_{\perp} is the transverse wave speed. Due to the fact that $\tilde{\mu}$ is proportional to $\sqrt{\tilde{\rho}}$, it is straightforward to deduce that both v_{\parallel} and v_{\perp} reach their maximum values at the core surface. We use this expression to establish an approximate upper bound for the fluid sound speed within the solid cores of HSs:

$$\tilde{v}^2 \leq 1 - \frac{4}{3} \frac{\kappa \sqrt{\tilde{\rho}_{\text{NM}}(p_{\text{trans}}) + \Delta\tilde{\rho}}}{\tilde{\rho}_{\text{NM}}(p_{\text{trans}}) + \Delta\tilde{\rho} + p_{\text{trans}}}. \quad (\text{B3})$$

For the specific EOS model, we expect that the upper bound of fluid sound speed will reach a minimum limit when κ is at its maximum value. This behavior will be discussed later.

Moreover, due to the anisotropy, the above two wave modes for isotropic elastic matter exhibit directional dependence as we move away from the center, resulting in the emergence of five distinct wave speeds (see also Eq. (159) in [13]):

$$\begin{aligned} v_{r\parallel}^2 &= \frac{\beta_r}{\rho + p_r}, \\ v_{t\parallel}^2 &= \frac{\beta_t}{\rho + p_t}, \\ v_{r\perp}^2 &= \frac{\tilde{\mu} + \frac{3}{2}(\tilde{\mu}\mathcal{S}^2 - \frac{\sigma}{3})}{\rho + p_t}, \\ v_{t\perp r}^2 &= \frac{\tilde{\mu} + \frac{3}{2}(\tilde{\mu}\mathcal{S}^2 + \frac{\sigma}{3})}{\rho + p_r}, \\ v_{t\perp t}^2 &= \frac{\tilde{\mu}(1 + \mathcal{S}^2)}{\rho + p_t}, \end{aligned} \quad (\text{B4})$$

where β_t is the tangential longitudinal modulus

$$\begin{aligned} \beta_t &= \tilde{\beta} + \frac{4}{3}\tilde{\mu} + \left[\tilde{\Omega}(\tilde{\Omega} - 1) + \tilde{\beta} \frac{d\tilde{\Omega}}{d\tilde{p}} \right] \tilde{\mu}\mathcal{S}^2 \\ &+ 2 \left[\tilde{\mu}\mathcal{S}^2 - \frac{\sigma}{3} \left(\tilde{\Omega} - \frac{1}{2} \right) \right]. \end{aligned} \quad (\text{B5})$$

Here, both β_r (see Eq. (20)) and β_t reduce to $\tilde{\beta} + 4\tilde{\mu}/3$ in linear elasticity regime (i.e., $z \rightarrow 1$). The longitudinal speeds $v_{r\parallel}$ and $v_{t\parallel}$ describe the speeds of disturbance oscillating parallel to propagation axes along the radial and tangential directions, respectively. Meanwhile, $v_{r\perp}$, $v_{t\perp r}$, and $v_{t\perp t}$ represent the speeds of transverse waves. Specifically, $v_{r\perp}$ is the transverse wave speed propagating along the radial direction, with disturbances perpendicular to the propagation direction (radial). Similarly, $v_{t\perp r}$ is the transverse wave speed in the tangential direction, with disturbances perpendicular to the propagation direction

(tangential), influenced by both p_r and p_t . In contrast, $v_{t\perp t}$ is the transverse wave speed within the tangential plane, where both the wave propagation and the disturbance lie, and it is determined only by p_t . Therefore, we must carefully select the fluid sound speed such that all the wave speeds do not exceed the speed of light, as required by the causality limit in relativistic contexts.

2. Parameter Space Depiction of Wave Speed

Let us first examine the behavior of wave speeds. Figure 9 illustrates how the wave speeds vary as one moves outward from the core of the star. At the stellar center, where the material is unsheared, we observe only two distinct wave speeds: longitudinal and transverse waves. As the radius increases, all wave speeds show a general upward trend, reaching their maximum values at the core surface, consistent with our previous discussion. This growth in wave speed results from the combined effects of the unsheared and sheared properties of the material.

The wave speed at the core surface is required not to exceed the speed of light. In Fig. 10, we constructed a parameter space depiction of the valid region for fluid sound speed by constraining all the wave speeds in Eq. (B4). Models with a large energy density gap can accommodate higher fluid sound speeds, allowing for greater \tilde{v}^2 without exceeding the causality constraint. Conversely, for models with a smaller energy density gap, the wave speed is more significantly influenced by the shear component, indicating that the transverse wave component becomes dominant in these scenarios (we discuss this in Sec. III A). We also observe that the valid region is dependent on the central pressure. For cases with higher p_c , the permissible range for wave speeds becomes narrower. We identify a value of 0.8 for \tilde{v}^2 as a practical upper limit for all the stable HSs.

Additionally, we provide in Fig. 10 the excluded parameter space computed from a linear Hookean approx-

FIG. 9. The principal speeds in Eq. (B4) for the maximum mass star of the HS-A model with $\kappa = 7 \times 10^{26} \text{ cm}^{1/2} \text{ g}^{1/2} \text{ s}^{-2}$.

imation in Eq. (B3). Notice that the approximation is only valid when the energy density gap is large. In other words, the nonlinearity in the quasi-Hookean relation becomes more important for the low-density gap, which is consistent with the results in Fig. 6. As shown in the figure, the green curve represents a smaller density gap compared to the blue curve, leading to a larger core and a larger shear contribution.

Appendix C: Junction Condition

There are two possible choices for the junction conditions between the core and envelope of an HS at the transition pressure p_{trans} . From a physical standpoint, \tilde{p}_+ represents the pressure in the isotropic layer, while \tilde{p}_- corresponds to the unsheared pressure in the anisotropic quark core. Simply put, p_{trans} should be understood as

FIG. 10. The upper bound of \tilde{v}^2 for HS models against energy density gaps, with fixed parameters $\kappa = 7 \times 10^{26} \text{ cm}^{1/2} \text{ g}^{1/2} \text{ s}^{-2}$, $p_{\text{trans}} = 2 \times 10^{33} \text{ dyn cm}^{-2}$. The gray and blue shaded regions correspond to different central pressures, p_c , with $1.2 \times 10^{35} \text{ dyn cm}^{-2}$ and $8.0 \times 10^{34} \text{ dyn cm}^{-2}$, respectively. The red-shaded region represents the linear Hookean approximation from Eq. (B3).

real pressure rather than unsheared pressure.

With this distinction in mind, we can now explore the reasoning behind the junction condition we chose. In the approach that we use (BC1), the boundary condition at the core is $\tilde{p}_+ = p_{\text{trans}}$, which means that the initial condition at the fluid envelope starts from p_{trans} . This method ensures that the star maintains its hybrid structure with a distinct quark core and hadronic envelope. On the other hand, if the boundary condition at the core is defined as $\tilde{p}_- = p_{\text{trans}}$ (BC2) and starts the integration of the envelope from \tilde{p}_+ , it is possible that \tilde{p}_+ is negative, which means that the star behaves as a quark star beyond the transition pressure. Obviously, this scenario is not the one we want in this study.

Figure 11 compares the M – R relations for the HS-A model under these two different boundary conditions at the transition pressure $p_{\text{trans}} = 2 \times 10^{33} \text{ dyn/cm}^2$. The HS model with BC2 deviates significantly from both the HS model with BC1 and the isotropic case. Most configurations resemble quark stars rather than HSs. This inconsistency with our research goal—focused on HSs with an elastic quark core and an NM envelope—makes BC2 not an ideal choice for boundary conditions.

Appendix D: Revisiting the Elastic Effects on Maximum Mass in HSs

In this appendix, we revisit the analysis performed by Karlovini and Samuelsson [13] to justify the results presented in Sec. III. We resolve the structural equations for

an elastic HS using the EOS defined as follows (see also

FIG. 11. M – R relation for HS-A with different junction conditions at the phase transition. The dashed line is identified with the one in Fig. 1. The gray dots represent the results of isotropic fluid HS.

Eq. (209) in [13]):

$$\tilde{\rho} = \frac{p_1}{\tilde{\Gamma} - 1} \left[\frac{\tilde{p}}{p_1} + \left(\frac{\tilde{p}}{p_1} \right)^{1/\tilde{\Gamma}} \right], \quad (\text{D1})$$

where $\tilde{\Gamma} = \tilde{\beta}/\tilde{p}$. Here, $\tilde{\Gamma}$ is set to $5/3$, and the reference pressure p_1 is given as $1.5 \times 10^{37} \text{ dyn cm}^{-2}$. The shear modulus is assumed to be proportional to the unsheared pressure $\tilde{\mu} = k \tilde{p}$, where k is a free parameter.

Karlovini and Samuelsson [13] reported that the maximum mass of an HS decreases with an increasing k . However, in Fig. 12, we observe the opposite trend compared with their conclusions, where the maximum mass increases as k increases, and the maximum mass of our results is higher than theirs. Our increasing trend is consistent with previous studies of anisotropic stars with $p_t > p_r$ (see, e.g., [44]).

To further verify our results, we compared the solutions derived from the structural equations with those obtained directly from the anisotropic TOV equations (Eqs. (11)–(12)). Starting with the z –profile obtained from the structural equations, which relates to the anisotropy σ via Eq. (17), we treated this profile as an “effective EOS” and solved the anisotropic TOV equations with the same boundary conditions as we mentioned in Sec. II C. These two sets of equations yield equivalent results. As shown in Fig. 13, the fractional difference in mass between the two sets of differential equations remains around 10^{-6} for various shear moduli. This minimal difference falls within an acceptable range, providing strong evidence for the reliability of our results. Furthermore, the consistency of this calculation has been verified using two independent numerical codes.

FIG. 12. M - R relation for HSs. The curves correspond to our results with different values of k , while the dots represent the results from [13].

FIG. 13. Fractional difference in mass between the solutions derived from Eqs. (14)–(16) and the anisotropic TOV equations (Eqs. (11)–(12)), across different values of the shear modulus parameter k .
