(Dated: December 24, 2024)

Fault-tolerant quantum computing is a promising technology to solve linear partial differential equations that are classically demanding to integrate. It is still challenging to solve non-linear equations in fluid dynamics, such as the Burgers equation, using quantum computers. We propose a novel quantum algorithm to solve the Burgers equation. With the Cole–Hopf transformation that maps the fluid velocity field u to a new field  $\psi$ , we apply a sequence of quantum gates to solve the resulting linear equation and obtain the quantum state  $|\psi\rangle$  that encodes the solution  $\psi$ . We also propose an efficient way to extract stochastic properties of  $u$ , namely the multi-point functions of  $u$ , from the quantum state of  $|\psi\rangle$ . Our algorithm offers an exponential advantage over the classical finite difference method in terms of the number of spatial grids when a perturbativity condition in the information-extracting step is met.

### I. INTRODUCTION

With the recent rapid development of hardware platforms, quantum computing attracts great interest and hope in physical science  $[1-8]$  $[1-8]$ , including cosmology and astrophysics  $[9-16]$  $[9-16]$ . Although we are still in the era of noisy intermediate-scale quantum technologies (NISQ) [\[17\]](#page-9-3), there have been a variety of studies aimed at faulttolerant quantum computing  $(FTQC)$  [\[18–](#page-9-4)[21\]](#page-9-5), which enables us to tackle classically intractable problems. Fluid dynamics continues to provide such challenging problems. For instance, [\[14–](#page-9-6)[16,](#page-9-2) [22\]](#page-9-7) proposed quantum algorithms to integrate the collisionless Boltzmann equation (CBE) [\[23\]](#page-9-8), which describes the evolution of a dilute system such as rarefied gas, and cosmic neutrinos and dark matter in the structure formation of the universe.

There remains an "apparent" limitation that quantum computing is applicable to only linear problems in a direct manner because of the linearity of quantum operations. Although quantum algorithms to solve a wide class of linear problems have been proposed [\[24–](#page-9-9)[29\]](#page-9-10), solving nonlinear problems has been a challenging task for FTQC algorithms.

Nevertheless, applying quantum computing to nonlinear problems such as the Navier–Stokes equation (NSE) is important and timely. The NSE is a nonlinear

partial differential equation that governs fluid dynamics [\[30\]](#page-9-11), and there are a broad range of potential applications in astrophysics and cosmology , e.g. the primordial gravitational wave [\[31–](#page-9-12)[33\]](#page-9-13) and the primordial magnetic field [\[34–](#page-9-14)[38\]](#page-9-15) coupled with a photon-baryon plasma in the early universe, as listed in Ref. [\[39\]](#page-9-16). Although no general framework is known to efficiently solve the NSE, a variety of attempts have been proposed [\[40–](#page-9-17)[45\]](#page-10-0).

Several approaches have been proposed to deal with non-linear problems with FTQC algorithms. Many of them are based on linearization of the non-linear equations by introducing a large number of auxiliary variables [\[46–](#page-10-1)[48\]](#page-10-2). Practically, we need to truncate auxiliary variables at a finite number, and this is guaranteed to work only for problems and systems with moderate nonlinearity.

An intriguing example is the one-dimensional Burgers equation  $[49, 50]$  $[49, 50]$  $[49, 50]$ . It is a non-linear equation that describes the time evolution of fluid velocity  $u$ , and can be viewed as the simplest model of non-linear fluid dynamics and hence as an important first step to solve the full NSE [\[51,](#page-10-5) [52\]](#page-10-6). A crucial point is that the one-dimensional Burgers equation is transformed to a linear heat equation by the Cole–Hopf transformation  $[53, 54]$  $[53, 54]$  $[53, 54]$ , which maps u to a new field  $\psi$ . However, this does not mean that Burgers turbulence is completely understood. Turbulence velocities are described by the Burgers equation, and its stochastic properties have been extensively investigated [\[55–](#page-10-9)[60\]](#page-10-10).

In the present study, we propose a quantum algorithm to measure the statistical properties of the onedimensional Burgers turbulence. We apply the quantum differential equation solver [\[61\]](#page-10-11) to the equation obtained

by the Cole–Hopf transformation on the Burgers equation to get the quantum state  $|\psi\rangle$  that encodes the solution  $\psi$  in the amplitudes. Furthermore, from  $|\psi\rangle$ , we extract the statistical properties of the solution, specifically, the multi-point functions of  $u$ , via estimating expectation values of some operators. This is a well-defined and wellsuited task for quantum computing. If one would like to understand the full real-space configuration, measurement with a given accuracy would cost an enormous time complexity. In contrast, we aim at deriving only a limited number of values as classical data from a quantum state, taking full advantage of a quantum speedup. In this information extraction step, due to the nonlinearity of the Cole–Hopf transformation, we need to apply a certain approximation that a perturbative nature holds with respect to  $\psi$ , which is non-trivial for fluid with a large Reynolds number. Nevertheless, when the perturbative condition holds, our algorithm offers an exponential advantage over the classical finite difference method in terms of the number of spatial grids. To validate our approach, we perform simple test calculations and show that the solution by our method is sufficiently accurate compared to that without the approximation.

The paper is organized as follows. In Sec. [II,](#page-1-0) we introduce the Burgers equation and multi-point functions of the velocity field. In Sec. [III,](#page-1-1) we present our algorithm to solve the Burgers equation and extract the multi-point functions from the solution-encoding quantum state. In Sec. [IV,](#page-6-0) we discuss the complexity analysis for our algorithm and possible generalizations, along with presenting the results of numerical demonstrations. Sec. [V](#page-8-1) concludes this paper.

### <span id="page-1-0"></span>II. BURGERS TURBULENCE

#### A. Burgers equation and Cole–Hopf transformation

We consider a velocity field  $u(t, x)$  in one-dimensional system, which is governed by the Burgers equation

$$
\partial_t u + u \partial_x u = \nu \partial_x^2 u,\tag{1}
$$

where  $\nu > 0$  is a viscosity coefficient that dissipates kinetic energy into heat. The advection term introduces a nonlinearity, of which significance may be quantified as the Reynolds number,

$$
\text{Re} := \frac{ul}{\nu},\tag{2}
$$

where  $l$  is the typical length scale of the system, and  $Re \gg 1$  implies a highly nonlinear state.

However, irrespectively of how large the Reynolds number is, Hopf [\[53\]](#page-10-7) and Cole [\[54\]](#page-10-8) found that, by introducing a new field  $\psi$ , s.t.

$$
\psi = \exp\left(-\frac{1}{2\nu} \int^x dy \, u(y)\right),\tag{3}
$$

or equivalently,

<span id="page-1-4"></span>
$$
u = -2\nu \frac{\partial_x \psi}{\psi},\tag{4}
$$

Eq.  $(1)$  is reduced to a linear heat equation

<span id="page-1-3"></span>
$$
\partial_t \psi = \nu \partial_x^2 \psi. \tag{5}
$$

The heat equation can be formally integrated, although its numerical evaluation is not necessarily easy. Our aim is to bypass the nonlinearity of the original problem with the Cole–Hopf transformation and take advantage of the linear nature of quantum computing. Note that solving the heat equation with a quantum speedup is an area of study  $[62]$ , but we do not extensively investigate this point in this work.

#### B. Statistical quantities of Burgers turbulence

We suppose that we are interested in statistical quantities, namely the multi-point functions, of the velocity field. We define the multi-point functions  $P^{(n)}$  and the higher-order moments  $I^{(n)}$  for  $n \geq 2$  of the velocity field

$$
P^{(n)}\left(\{x_i - x_0\}_{i=1,\dots,n-1}, t\right) := \prod_{i=0}^{n-1} u(x_i, t), \qquad (6)
$$

$$
I^{(n)}(t) := P^{(n)}\left(\{0\}_{i=0,\cdots n-1}, t\right),\qquad(7)
$$

where the bar takes a volume average, where  $\overline{X(\{x_i\}_i)} \coloneqq$  $(1/L)\int_0^L dx' X(\lbrace x'+x_i \rbrace_i)$  for a general function X with the periodic boundary condition, of the inside. We may further average over ensembles, when we have a bunch of random initial conditions, to explore the universal properties of turbulence with those initial conditions.

In the following sections, we will propose an algorithm to measure these quantities up to a common normalization factor among all the quantities.

#### <span id="page-1-1"></span>III. QUANTUM ALGORITHM

<span id="page-1-2"></span>In this section, we will explain that the Burgers equation can be solved efficiently, by using a quantum computer.

The algorithm to compute the multi-point functions for one realization of the velocity field proceeds in the following three steps:

- Classical to quantum: loading the initial condition into the quantum state  $(Sec. III A)$  $(Sec. III A)$
- Quantum operation: integration of the heat equation (Sec. [III B\)](#page-2-1)
- Quantum to classical: extracting the wanted information (Sec. [III C\)](#page-2-2)

On top of this, in Sec. [III D,](#page-5-0) we explain how to efficiently take an ensemble average of the multi-point functions.

# <span id="page-2-0"></span>A. Implementing the initial condition

We discretize the spatial coordinate  $0 \le x \le L$  into  $N_x =$  $2^{n_x}$  grids and impose, for now, the periodic boundary condition. Generalization to non-periodic conditions will be discussed in Sec. [IV.](#page-6-0) We assume that we have an oracle  $O_{\psi'_0}$  to generate a quantum state encoding the initial value of  $\partial_x \psi$ :

$$
O_{\psi_0'} |\mathbf{0}\rangle = |\partial_x \psi(0)\rangle. \tag{8}
$$

Here, we define

$$
|\partial_x \psi(t)\rangle := \sum_{j=0}^{N_x - 1} \frac{\partial_x \psi_j(t)}{\mathcal{N}(t)} |j\rangle \tag{9}
$$

where  $\partial_x \psi_i(t) \coloneqq \partial_x \psi(j\Delta x, t)$ , and  $\Delta x \coloneqq L/N_x$ . A normalization factor  $\mathcal N$  is introduced so that  $\langle \partial_x \psi(t) | \partial_x \psi(t) \rangle = 1.$ 

The methods to generate a quantum state encoding a known function like Eq. [\(9\)](#page-2-3) have been investigated in the literature. For example, if  $\partial_x \psi(x,0)$  is analytically calculated and satisfies some conditions, the Grover-Rudolph method [\[63\]](#page-10-13) and other methods [\[64–](#page-10-14)[68\]](#page-10-15) can be used. If  $\partial_x \psi_i(0)$  is given pointwise and the values are stored in the quantum random access memory [\[69\]](#page-10-16), we can generate  $|\partial_x\psi(0)\rangle$  by the method in Ref. [\[70\]](#page-10-17).

#### <span id="page-2-1"></span>B. Integration of the heat equation

Let us discretize the heat equation [\(5\)](#page-1-3). In terms of  $\partial_x \psi$ , Eq.  $(5)$  is

$$
\partial_t \partial_x \psi = \nu \partial_x^2 \partial_x \psi. \tag{10}
$$

By normalizing the temporal coordinate properly and discretizing the spatial coordinate, it becomes

$$
\frac{d\partial_x \psi_j}{d\tau} = \partial_x \psi_{j-1} - 2\partial_x \psi_j + \partial_x \psi_{j+1}, \quad j \in \mathbb{Z}_{N_x}, \quad (11)
$$

where we introduced a normalized temporal coordinate  $\tau := \nu t / \Delta x^2$ . Equation [\(11\)](#page-2-4) can also be written as

$$
\frac{d\partial_x \psi}{d\tau} = A \partial_x \psi, \quad A := \begin{pmatrix} -2 & 1 & 0 & \cdots & 1 \\ 1 & -2 & 1 & \cdots & 0 \\ 0 & 1 & -2 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 1 & 0 & \cdots & 1 & -2 \end{pmatrix}, \quad (12)
$$

which is integrated formally as

$$
\partial_x \psi(\tau) = e^{A\tau} \partial_x \psi(0). \tag{13}
$$

Obtaining  $|\partial_x \psi(\tau) \rangle$  as a quantum state is possible as shown in Corollary 16 of Ref. [\[61\]](#page-10-11). By noting  $||A|| \leq$ 

 $\sqrt{\|A\|_1 \|A\|_{\infty}} = 4^1$  $\sqrt{\|A\|_1 \|A\|_{\infty}} = 4^1$  $\sqrt{\|A\|_1 \|A\|_{\infty}} = 4^1$ , an oracle  $O_{\psi_{\tau}'}$  that act on the initial state  $|\partial_x\psi(0)\rangle$  to generate  $|\partial_x\psi(\tau)\rangle$  with an error tolerance  $\epsilon_1 > 0$  costs

<span id="page-2-7"></span><span id="page-2-6"></span>
$$
\tilde{\mathcal{O}}\left(\frac{||\partial_x \psi_0||}{||\partial_x \psi(\tau)||}\tau \times \text{polylog}\left(\frac{1}{\epsilon_1}\right)\right) \text{ queries to } U_A, (14)
$$
  
and 
$$
\mathcal{O}\left(\frac{||\partial_x \psi_0||}{||\partial_x \psi(\tau)||}\right) \text{ queries to } O_{\psi'_0}, (15)
$$

<span id="page-2-3"></span>where  $U_A$  is a block-encoding of A. If the block-encoding of A has an error  $\epsilon_2$ , the factor  $e^{A\tau}$  in Eq. [\(13\)](#page-2-5) has a relative error  $\epsilon_2 \tau$ , resulting in a total error  $\epsilon_1 + \epsilon_2 \tau$  for the state  $|\partial_x \psi(\tau) \rangle$ . According to Ref. [\[71\]](#page-10-18) (Lemma 48 in the full-version), with A's sparsity and max norm being 3 and 2, respectively, we can implement a  $(6, n_x + 3, \epsilon_2)$ block-encoding<sup>[2](#page-0-5)</sup> of  $A$ , using

<span id="page-2-9"></span><span id="page-2-8"></span>
$$
\mathcal{O}\left(n_x + \log^{\frac{5}{2}}\left(\frac{18}{\epsilon_2}\right)\right) \text{ fundamental gates} \qquad (16)
$$

and  $\mathcal{O}(\log^{5/2}(18/\epsilon_2))$  ancilla qubits, along with

# $\mathcal{O}(1)$  calls to the sparse-access oracles for A. (17)

We will discuss query complexity of our algorithm in terms of the numbers of uses of the sparse-access oracles, which access elements of a sparse matrix, and fundamental gates, i.e., a universal set of one- and two-qubit gates, not included therein.

At this point, we have an oracle  $O_{\psi_{\tau}}O_{\psi_{0}'}$  to generate the "solution" state  $|\partial_x \psi(\tau) \rangle$ , which has values of  $\partial_x \psi_i(\tau)$  in the amplitude of  $|j\rangle$ . Nonlinearity in terms of  $u$  and high spatial resolution is achieved up to limitations originating from the finite discretization scheme.

However, extracting arbitrary information from a quantum state is a non-trivial task, and we address this issue in the next section.

#### <span id="page-2-2"></span>C. Retrieving the desired information

<span id="page-2-4"></span>In this step, we introduce approximations to extract statistical information on the velocity field  $u$ . We begin by discussing the two- and three-point functions  $P^{(2)}$  and  $P^{(3)}$ , and then generalize them to higher-order multipoint functions.

### 1. Two-point function

We apply a perturbative description to linearize the relation between  $\psi$  and  $u$ . We approximate the velocity field

<span id="page-2-5"></span><sup>1</sup> For  $M = (m_{ij}) \in \mathbb{C}^{m \times n}$ , ||M|| denotes its spectral norm,  $||M||_1 = \max_j \sum_{i=1}^m |m_{ij}|$ , and  $||M||_{\infty} = \max_i \sum_{j=1}^n |m_{ij}|$ .

 $^2$  For the definition of  $(\alpha, a, \epsilon)$  block-encoding, where  $\alpha, \epsilon > 0$  and  $a \in \mathbb{N}$ , see Ref. [\[71\]](#page-10-18).

 $\boldsymbol{u}$  as

$$
u_j \simeq -\frac{\nu \partial_x \psi_j}{\bar{\psi}},\tag{18}
$$

where we replace  $\psi$  in the denominator with the spatial average  $\bar{\psi} := \frac{1}{L} \int_0^L \psi(x, t) dx$ . Hereafter, we will consider the statistics on the right-hand side of Eq. [\(18\)](#page-3-0), but identifying both sides is not always trivial. See the discussion in Sec. [IV.](#page-6-0) With this approximation, we have

$$
|\mathbf{u}\rangle := \sum_{j} \frac{u_j}{||\mathbf{u}||} |j\rangle
$$
  
 
$$
\simeq -|\partial_x \psi(t)\rangle.
$$
 (19)

Then, the two-point function of the velocity field  $P^{(2)}(r = \rho \Delta x), \rho \in \mathbb{Z}_{N_x}$  can be approximated as

$$
P^{(2)}(r) = \overline{u(x)u(x+r)}
$$
  
=  $N_x^{-1} \sum_{k=0}^{N_x - 1} u_k u_{k+\rho}$   
=  $N_x^{-1} ||\mathbf{u}||^2 \sum_{j,k=0}^{N_x - 1} C_{jk}^{(2)}(\rho) \frac{u_j}{||\mathbf{u}||} \frac{u_k}{||\mathbf{u}||}.$  (20)

Here,  $C_{jk}^{(2)}(\rho)$  is given by

$$
C_{jk}^{(2)}(\rho) \coloneqq \sum_{\sigma,\sigma'} \delta_{j-\sigma,k-\sigma'} c_{\sigma\sigma'}^{(2)}(\rho),\tag{21}
$$

where

$$
c_{\sigma\sigma'}^{(2)}(\rho) := \begin{cases} +\frac{1}{2} & (\sigma, \sigma') = (0, \rho), \\ 0 & (\sigma, \sigma') = (\rho, 0), \\ 0 & \text{otherwise} \end{cases}
$$
 (22)

for  $\rho \neq 0$ , and

$$
c_{\sigma\sigma'}^{(2)}(0) \coloneqq \begin{cases} 1 & \sigma = \sigma' = 0, \\ 0 & \text{otherwise} \end{cases} \tag{23}
$$

for  $\rho = 0$ . From Eq. [\(20\)](#page-3-1), we obtain an expression for the two-point function  $P^{(2)}(r,\tau)$  normalized by the second moment  $I^{(2)}(\tau) = P^{(2)}(0,\tau),$ 

$$
\frac{P^{(2)}(r,\tau)}{I^{(2)}(\tau)} = \frac{\langle \boldsymbol{u}(\tau)|C^{(2)}(\rho)|\boldsymbol{u}(\tau)\rangle}{\langle \boldsymbol{u}(\tau)|C^{(2)}(0)|\boldsymbol{u}(\tau)\rangle}.
$$
(24)

Both the numerator and the denominator are  $\mathcal{O}(1)$  quantities, as understood from the expression in Eq. [\(20\)](#page-3-1), where  $N_x^{-1} ||u||^2 = \mathcal{O}(1)$ .

The values of the numerator and the denominator in the right-hand side can be measured by applying the overlap estimation algorithm [\[72\]](#page-10-19). For that purpose, we decompose  $C^{(2)}(\rho)$  as

$$
C^{(2)}(\rho) = \frac{1}{2} \left( P_{N_x}^{\rho} + P_{N_x}^{-\rho} \right), \tag{25}
$$

<span id="page-3-0"></span>where  $P_{N_x}$  is the cyclic increment

$$
P_{N_x} := \sum_{j=0}^{N_x - 2} |j+1\rangle \langle j| + |0\rangle \langle N_x - 1|, \qquad (26)
$$

which is impremented with  $\mathcal{O}(n_x)$  fundamental gates and ancilla qubits [73].  $\sum_{a=0}^{n_x} \rho_a 2^a$ , because we can decompose  $P_{N_x}^{\rho}$  as  $P_{N_x}^{\rho}$ Therefore, for  $\rho =$  $\overline{\prod}_{a=0}^{n_x} \delta_{\rho_a,1} P_{2^{n_x-a}} \otimes 1_{2^a}$ , we can construct  $P_{N_x}^{\tilde{\rho}}$  with

<span id="page-3-7"></span>
$$
\mathcal{O}(n_x^2)~fundamental~gates \qquad (27)
$$

<span id="page-3-3"></span>and  $\mathcal{O}(n_x)$  ancilla qubits, which is reused in each  $P_{2^nx-a}$ .

Since  $P_{N_x}^{\rho}$  is unitary, we can estimate  $\bra{\bm{u}(\tau)} P_{N_x}^{\rho} \ket{\bm{u}(\tau)}$ by the overlap estimation algorithm in [\[72\]](#page-10-19), making

$$
\mathcal{O}\left(\frac{1}{\epsilon_3}\right) \text{ queries to } P_{N_x}^{\pm \rho}, \ P_{N_x}^{\pm \rho \pm 2}, \text{and } O_{u_\tau}, \qquad (28)
$$

<span id="page-3-1"></span>where  $O_{u_{\tau}} \coloneqq -O_{\psi_{\tau}'} O_{\psi_{0}'}$ , to achieve an error tolerance  $\epsilon_3 > 0$ . After measuring the numerator and the denominator separately, one can obtain the value of Eq. [\(24\)](#page-3-2) for given r and  $\tau$  with the precision  $\epsilon_1 + \tau \epsilon_2 + \epsilon_3$ .

### <span id="page-3-4"></span>2. Three-point function

Next, we discuss the three-point functions of the velocity field. To reduce the computational complexity of reading out classical information, we introduce sub-grids,  $x_{cgh} := 2^{n_x - m} k \Delta x$ , where an integer  $m \ge 1$  is taken independent of  $n_x$ , and coarse-grain the high-resolution  $|u\rangle$ onto the sub-grids. This is motivated when the smallscale modes are nonsignificant because increasing  $n_x$  beyond the smallest among the relevant scales of turbulence would not provide better information. We can integrate out the small-scale modes within each sub-grid by acting Hadamard gates on the subspace corresponding to the last  $n_x - m$  digits of each  $|j\rangle$ :

<span id="page-3-5"></span>
$$
|\mathbf{u}\rangle_{\text{cg}} := \mathbf{1}_{2^m} \otimes H^{\otimes n_x - m} |\mathbf{u}\rangle
$$
  
= 
$$
\sum_{k=0}^{2^m - 1} u_{\text{cg}} k |k\rangle |0\rangle_{\text{ss}} + |\perp\rangle, \tag{29}
$$

<span id="page-3-2"></span>where  $H$  is the Hadamard gate,

$$
u_{\text{cg }k} := 2^{-\frac{n_x - m}{2}} \sum_{j=2^{n_x - m}k}^{2^{n_x - m}(k+1) - 1} \frac{u_j}{||u||},\tag{30}
$$

 $|0\rangle_{\text{ss}} := |0\rangle^{\otimes n_x-m}$ ,  $1_{2^m}$  is the indentity opeartor on the first m qubits, and  $| \perp \rangle$  is a garbage state such that  $(1_{2^m} \otimes |0\rangle_{\rm ss} \langle 0|_{\rm ss}) |\perp\rangle = 0.$  Hereafter, we define  $O_{u_{cg}} \coloneqq$  $(1_{2^m} \otimes H^{\otimes n_x - m}) O_{u_\tau}$  so that  $O_{u_{cg}}(0) = |u\rangle_{cg}$ .

Then, a three-point function of the velocity field  $P^{(3)}(r_1 = 2^{n_x - m} \rho_1 \Delta x, r_2 = n_x - m \rho_2 \Delta x), \ \rho_1, \rho_2 \in \mathbb{Z}_{2^m}$ can be approximated as

<span id="page-3-6"></span>
$$
P^{(3)}\left(r_1,r_2\right)
$$

$$
\simeq 2^{-n_x} \sum_{j=0}^{2^{n_x}-1} u_j u_{j+2^{n_x-m}\rho_1} u_{j+2^{n_x-m}\rho_2}
$$
  

$$
\simeq 2^{-\frac{3}{2}n_x+\frac{1}{2}m} ||\mathbf{u}||^3 \sum_{j,k,l=0}^{2^m-1} C_{jkl}^{(3)}(\rho_1, \rho_2) u_{cgj} u_{cgk} u_{cgl}. (31)
$$

Here, in the second equality, we replace  $u_j$ ,  $j \in \mathbb{R}$  $[2^{n_x-m}k, 2^{n_x-m}(k+1)-1]$  with

$$
2^{-(n_x-m)}\sum_{j'=2^{n_x-m}k}^{2^{n_x-m}(k+1)-1}u_{j'}=2^{-\frac{n_x-m}{2}}||\mathbf{u}||u_{\text{cg }k},\quad(32)
$$

assuming that u is coherent over the length scale  $2^{-m}L$ , *i.e.*, smaller-scale modes within the scale  $2^{-m}L$  are subdominant. We define

$$
C_{jkl}^{(3)}(\rho_1, \rho_2) \coloneqq \sum_{\sigma, \sigma', \sigma''} \delta_{j-\sigma, k-\sigma'} \delta_{j-\sigma, l-\sigma''} c_{\sigma \sigma' \sigma''}^{(3)}(\rho_1, \rho_2) \tag{33}
$$

and

$$
c_{\sigma\sigma'\sigma''}^{(3)}(\rho_1, \rho_2) \coloneqq \mathcal{S}\left[\begin{cases} 1 & (\sigma, \sigma', \sigma'') = (0, \rho_1, \rho_2) \\ 0 & \text{otherwise} \end{cases}\right], (34)
$$

where  $S$  is symmetrization with respect to the indices. Note that the prefactor in front of the summation in Eq. [\(31\)](#page-4-0) scales as  $\mathcal{O}(2^{m/2})$ , independently of  $n_x$ .

From Eq. [\(31\)](#page-4-0), we obtain an expression for the threepoint function  $P^{(3)}(r_1, r_2, \tau)$  normalized by the third moment  $I^{(3)}(\tau) = P^{(3)}(0,0,\tau),$ 

$$
\frac{P^{(3)}(r_1, r_2, \tau)}{I^{(3)}(\tau)} = \frac{\langle U^{(3)}(\tau) | \tilde{C}^{(3)}(\rho_1, \rho_2) | U^{(3)}(\tau) \rangle}{\langle U^{(3)}(\tau) | \tilde{C}^{(3)}(0, 0) | U^{(3)}(\tau) \rangle}, (35)
$$

where we define

$$
|U^{(3)}\rangle := \frac{|\boldsymbol{u}\rangle_{\rm cg}^{\otimes 2}\otimes|0\rangle + |\boldsymbol{u}\rangle_{\rm cg}\otimes|0\rangle\otimes|1\rangle}{\sqrt{2}}\tag{36}
$$

$$
= \sum_{j,k} \frac{u_{cgj} u_{cgk}}{\sqrt{2}} |j,k,0\rangle + \sum_{l} \frac{u_{cgl}}{\sqrt{2}} |l,0,1\rangle + |\perp\rangle ,
$$
\n(37)

and

$$
\tilde{C}^{(3)} := \sum_{j,k,l=1}^{N_x} C_{jkl}^{(3)} \frac{|j,k,0\rangle\langle l,0,1| + |l,0,1\rangle\langle j,k,0|}{2}
$$
  
 
$$
\otimes |0\rangle_{\text{ss}}\langle 0|_{\text{ss}}, \quad (38)
$$

where  $| \perp \rangle$  is the garbage state originating from the one that  $|u\rangle_{cg}$  has, and the projection  $|0\rangle_{ss}\langle 0|_{ss}$  eliminates the garbage state. Note that, since the prefactor in the last line in Eq.  $(31)$  scales as  $2^{m/2}$ , the numerator and the denominator in the right-hand side of Eq. [\(35\)](#page-4-1) are  $\mathcal{O}(2^{-m/2})$ .

The state  $|U^{(3)}\rangle = O_{U^{(3)}}|0\rangle$ , where  $O_{U^{(3)}} = O_{u_{cg}}$  $[CO_{u_{cg}}(1_{N_x} \otimes H)],$  and H is the Hadamard gate, can be

constructed if we have  $CO_{u_{cg}} := 1_{N_x} \otimes |0\rangle\langle 0| + O_{u_{cg}} \otimes$  $|1\rangle\langle 1|$ , namely a controlled- $\overline{O}_{u_{cg}}$  operation. In the complexity estimate, we assume that  $CO_{u_{cg}}$  requires the same query complexity as  $O_{u_{\rm cc}}$  does.

<span id="page-4-0"></span>The operator  $\tilde{C}^{(3)}$  is a matrix of  $\mathcal{O}(1)$  sparsity and maximum norm, and it has an  $(\mathcal{O}(1), \mathcal{O}(n_x), \epsilon_4)$  blockencoding  $\mathcal{C}^{(3)}$  with  $\mathcal{O}(n_x)$  ancilla qubits. To construct this, we make  $\mathcal{O}(1)$  queries to the sparse-access oracles for  $\tilde{C}^{(3)}$  and use

$$
\mathcal{O}\left(n_x + \log^{\frac{5}{2}}\left(\frac{1}{\epsilon_4}\right)\right) \text{ fundamental gates} \tag{39}
$$

and  $\mathcal{O}(\log^{5/2}(1/\epsilon_4))$  ancilla qubits [\[71\]](#page-10-18).

Since  $\mathcal{C}^{(3)}$  is unitary, the numerator and the denominator in the right-hand side of Eq. [\(35\)](#page-4-1) can be measured with the error tolerance  $2^{-m/2} \epsilon_3$  by the overlap estimation algorithm [\[72\]](#page-10-19), which makes

<span id="page-4-2"></span>
$$
\mathcal{O}\left(\frac{2^{\frac{m}{2}}}{\epsilon_3}\right) \text{ queries to } \mathcal{C}^{(3)} \text{ and } O_{U^{(3)}}.
$$
 (40)

Then, after measuring the numerator and the denominator separately, one may obtain the value of Eq. [\(35\)](#page-4-1) for given  $r_1$ ,  $r_2$ , and t, with an error tolerance  $\epsilon_3$ . Note that, if one skips the coarse-graining procedure by taking  $m = n_x$ , we need  $2^{-n_x/2} \epsilon_3$  accuracy in the overlap estimation algorithm to achieve an error tolerance  $\epsilon_3$  in evaluating Eq.  $(35)$ , implying an exponentially larger query complexity in Eq. [\(40\)](#page-4-2).

#### 3. Higher-order multi-point function

<span id="page-4-1"></span>We then generalize the procedure to the higher-order multi-point functions. For a general integer  $n$ , we may approximate

$$
P^{(n)}(\mathbf{r}) = 2^{-\frac{n}{2}n_x + \frac{n-2}{2}m} ||\mathbf{u}||^n \sum_{j} C_j^{(n)}(\boldsymbol{\rho}) \prod_{i=1}^n u_{cg_j}, \qquad (41)
$$

where  $\mathbf{r} = (r_1, \dots, r_{n-1}), r_0 = 0, \, \mathbf{\rho} = 2^{-n_x + m} \mathbf{r} / \Delta x \in$  $\mathbb{Z}^{n-1}$ , and  $\mathbf{j} = (j_1, \dots j_n)$ , respectively. The matrix  $C^{(n)}$ is defined such that

$$
C_{\boldsymbol{j}}^{(n)}(\boldsymbol{\rho}) \coloneqq \sum_{\boldsymbol{\sigma}} \delta_{\boldsymbol{j} - \boldsymbol{\sigma}} c_{\boldsymbol{\sigma}}^{(n)}(\boldsymbol{\rho}), \qquad (42)
$$

$$
c_{\boldsymbol{\sigma}}^{(n)}(\boldsymbol{\rho}) \coloneqq \mathcal{S} \left[ \begin{Bmatrix} 1 & \boldsymbol{\sigma} = \boldsymbol{\rho}, \\ 0 & \text{otherwise} \end{Bmatrix}, \qquad (43)
$$

where S is symmterization with respect to the indices  $\sigma_i$ . If  $n = 2n'$  is an even number, we define

<span id="page-4-3"></span>
$$
|U^{(2n')} \rangle := O_{U^{(2n')}}|0\rangle = |\boldsymbol{u}\rangle_{\text{cg}}^{\otimes n'},\tag{44}
$$

where  $O_{U^{(2n')}} := O_{u_{cg}}^{\otimes n'}$  is constructed by the following quantum circuit,

where cg denotes the coarse-graining procedure. We also define

$$
\tilde{C}^{(2n')} := \sum_{\mathbf{j}} C_{\mathbf{j}}^{(2n')} \left( \frac{|j_1, \cdots, j_{n'}\rangle \langle j_{n'+1}, \cdots, j_{2n'}|}{2} + \frac{|j_{n'+1}, \cdots, j_{2n'}\rangle \langle j_1, \cdots, j_n'|}{2} \right). \tag{45}
$$

This is n!-sparse and has an  $(\mathcal{O}(n!), \mathcal{O}(nn_x), \epsilon_4)$  blockencoding  $\mathcal{C}^{(n)}$ , which is constructed with

$$
\mathcal{O}(1) \text{ queries to the sparse-access oracles for } \tilde{C}^{(n)} \text{ (46)}
$$

and

$$
\mathcal{O}\left(nn_x + \log^{\frac{5}{2}}\left(\frac{n!}{\epsilon_4}\right)\right) \text{ fundamental gates.} \tag{47}
$$

If  $n = 2n' + 1$  is an odd number, we define

$$
\left|U^{(2n'+1)}\right\rangle := O_{U^{(2n'+1)}}|0\rangle
$$
  
= 
$$
\frac{|\mathbf{u}\rangle_{cg}^{\otimes n'+1}\otimes|0\rangle + |\mathbf{u}\rangle_{cg}^{\otimes n'}\otimes|0\rangle\otimes|1\rangle}{\sqrt{2}}, \quad (48)
$$

where  $O_{U^{(2n'+1)}} \coloneqq O_{u_{cg}}^{\otimes n'} \otimes [CO_{u_{cg}}(1_{N_x} \otimes H)]$  is constructed by the following quantum circuit,

and

$$
\tilde{C}^{(2m+1)}
$$

$$
\begin{split} \coloneqq & \sum_{\mathbf{j}} C_{\mathbf{j}}^{(2n'+1)} \bigg( \frac{|j_1, \cdots, j_{n'+1}, 0\rangle \langle j_{n'+2}, \cdots, j_{2n'+1}, 0, 1|}{2} \\ &+ \frac{|j_{n'+2}, \cdots, j_{2n'+1}, 0, 1\rangle \langle j_1, \cdots, j_{n'+1}, 0|}{2} \bigg), \end{split} \tag{49}
$$

which also has an  $(\mathcal{O}(n!), \mathcal{O}(nn_x), \epsilon_4)$  block-encoding with the same cost as Eqs.  $(46)$  and  $(47)$ .

<span id="page-5-1"></span>Similarly to the case of  $P^{(3)}$ , we can obtain

$$
\frac{P^{(n)}(\mathbf{r},\tau)}{I^{(n)}(\tau)} = \frac{\langle U^{(n)}(\tau) | \tilde{C}^{(n)}(\boldsymbol{\rho}) | U^{(n)}(\tau) \rangle}{\langle U^{(n)}(\tau) | \tilde{C}^{(n)}(\mathbf{0}) | U^{(n)}(\tau) \rangle} \tag{50}
$$

<span id="page-5-2"></span>by applying the overlap estimation algorithm [\[72\]](#page-10-19). To achieve error tolerance  $\epsilon_3$ , we have to make

$$
\mathcal{O}\left(\frac{2^{\frac{n-2}{2}m}}{\epsilon_3}\right) \text{ queries to } \mathcal{C}^{(n)} \text{ and } O_{U^{(n)}}.\tag{51}
$$

# <span id="page-5-4"></span><span id="page-5-0"></span>D. Taking ensemble averages

So far, we have discussed computing spatial correlations of the velocity field for a single realization of Burgers turbulence. As discussed in Sec. D.2 of Ref. [\[15\]](#page-9-18), we can extend it to taking ensemble averages of multiple realizations.

<span id="page-5-3"></span>To this end, we assume that we have  $N_{en} = 2^{n_{en}}$  initial conditions and have an oracle

$$
O_{\rm IC} := \left(\sum_{\alpha=1}^{N_{\rm en}} O_{\psi_0^{\prime(\alpha)}} \otimes |\alpha\rangle \langle \alpha| \right) \left(1_{N_x} \otimes H^{\otimes n_{\rm en}}\right) \quad (52)
$$

so that a superposition of  $N_{\rm en}$  initial conditions are generated as

$$
O_{\rm IC}|0\rangle = 2^{-\frac{n_{\rm en}}{2}} \sum_{\alpha=1}^{N_{\rm en}} \left| \partial_x \psi^{(\alpha)}(0) \right\rangle |\alpha\rangle , \qquad (53)
$$

where we introduce additional  $n_{\text{en}}$  qubits to label the ensembles.

We then integrate the heat equation as explained in Sec. [III B.](#page-2-1) We apply  $O_{\psi_{\tau}'} \otimes 1_{N_{\text{en}}}$  to the state [\(53\)](#page-6-1) with error tolerance  $\epsilon_1$  for the integration algorithm and  $\epsilon_2$  for the block-encoding of A. With the approximation [\(19\)](#page-3-3), this yields

$$
2^{-\frac{n_{\text{en}}}{2}}\sum_{\alpha=1}^{N_{\text{en}}}|\boldsymbol{u}^{(\alpha)}\rangle|\alpha\rangle\,,\tag{54}
$$

where  $|\boldsymbol{u}^{(\alpha)}\rangle := \sum_j$  $u_j^{(\alpha)}$  $\frac{d}{\|u^{(\alpha)}\|}|j\rangle$  encodes the solution  $u^{(\alpha)}$ 

with the  $\alpha$ -th initial condition. By applying the coarsegraining operation described in Sec. III  $C_2$ , we obtain

$$
2^{-\frac{n_{\text{en}}}{2}}\sum_{\alpha=1}^{N_{\text{en}}}|\boldsymbol{u}^{(\alpha)}\rangle_{\text{cg}}|\alpha\rangle\,,\tag{55}
$$

where  $|u^{(\alpha)}\rangle_{cg}$  is given as Eq. [\(29\)](#page-3-5) with  $u = u^{(\alpha)}$ .

Then, using the above operation, we can generate

$$
|U^{(n)}\rangle_{\text{en}} \coloneqq 2^{-\frac{n_{\text{en}}}{2}} \sum_{\alpha=1}^{N_{\text{en}}} |U^{(n,\alpha)}\rangle |\alpha\rangle,\tag{56}
$$

where  $U^{(n,\alpha)}$  is given as Eq. [\(44\)](#page-4-3) or [\(48\)](#page-5-3) with  $u = u^{(\alpha)}$ . Defining the ensemble average of the  $n$ -point function as

$$
\left\langle P^{(n)}(\boldsymbol{r})\right\rangle := 2^{-n_{\text{en}}}\sum_{\alpha=1}^{N_{\text{en}}} P^{(n,\alpha)}(\boldsymbol{r}),\tag{57}
$$

where  $P^{(n,\alpha)}(r)$  is the *n*-point function for  $u^{(\alpha)}$ , and  $\langle I^{(n)} \rangle \coloneqq \langle P^{(n)}(0) \rangle$ , we see that

$$
\frac{\langle P^{(n)}(\mathbf{r}) \rangle}{\langle I^{(n)} \rangle} = \frac{\langle U^{(n)}|_{\text{en}} \tilde{C}^{(n)}(\mathbf{\rho}) \otimes 1_{N_{\text{en}}} |U^{(n)}\rangle_{\text{en}}}{\langle U^{(n)}|_{\text{en}} \tilde{C}^{(n)}(\mathbf{0}) \otimes 1_{N_{\text{en}}} |U^{(n)}\rangle_{\text{en}}}, \quad (58)
$$

and thus we can calculate this in a parallel way to the procedure in Sec. [III C.](#page-2-2) Namely, we perform the overlap estimation with an error tolerance  $\epsilon_3$ , by replacing  $C^{(2)}$ and  $\mathcal{C}^{(n)}$  with  $C^{(2)} \otimes 1$  and  $\mathcal{C}^{(n)} \otimes 1$ , respectively.

#### <span id="page-6-0"></span>IV. DISCUSSION

# A. Total complexity

We first estimate the complexity of the algorithm, apart from the discretization error, which is common in both quantum and classical algorithms and may be reduced <span id="page-6-1"></span>by implementing higher-order stencils. Our algorithm accepts errors of  $\mathcal{O}(\epsilon_1 + \tau \epsilon_2 + \epsilon_3 + \epsilon_4)$  for  $P^{(n)}/I^{(n)}$ . By taking  $\tau \epsilon_2 \sim \epsilon$  and  $\epsilon_1 \sim \epsilon_3 \sim \epsilon_4 \sim \epsilon$  to be of the order of the desired error tolerance  $\epsilon$ , we require query complexities at each step of the operation as summarized in TABLE [I.](#page-7-0) In total, to measure  $P^{(n)}/I^{(n)}$  for a general n, we make

$$
\mathcal{O}\left(2^{\frac{n-2}{2}m}n\frac{||\partial_x\psi_0||}{||\partial_x\psi(\tau)||}\frac{\tau}{\epsilon}\text{polylog}\left(\frac{1}{\epsilon}\right)\left(n_x + \log^{\frac{5}{2}}\left(\frac{\tau}{\epsilon}\right)\right)\right)
$$

$$
=\tilde{\mathcal{O}}\left(2^{\frac{n-2}{2}m}n\frac{||\partial_x\psi_0||}{||\partial_x\psi(\tau)||}\frac{n_x\tau}{\epsilon}\right) \tag{59}
$$

uses of sparse-access queries and other fundamental gates and use

$$
\mathcal{O}\left(n_x + \log^{\frac{5}{2}}\left(\frac{\tau}{\epsilon}\right)\right) \tag{60}
$$

ancilla qubits, where  $n_x = \log N_x$  and  $\tau = \nu t / \Delta x^2$ . In particular, for  $n = 2$ , we can use Eq. [\(25\)](#page-3-6) to construct  $\mathcal{C}^{(n=2)}$  with  $\mathcal{O}(n_x^2)$  fundamental gates instead of applying the sparse-oracle-based block-encoding technique, and the number of uses of other oracles and fundamental gates is also reduced. Note that, if  $\partial \psi_0$  has large long-wavelength modes, which dissipate slowly, then the growth of the factor  $||\partial_x \psi_0||/||\partial_x \psi(\tau)||$  is slow as well.

This can be significantly less than a naive estimate of the classical complexity. Since  $\psi(x, t)$  is the convolution of  $\psi(0, t)$  and the heat kernel, it takes  $\mathcal{O}(N_x)$  computations to obtain  $u(x, t)$  for a given  $(x, t)$ . To compute  $P^{(n)}$ , we identify the ensemble average with the spatial average and compute  $u(x, t)$  at all sites  $x_i$  for a given t, which costs  $\mathcal{O}(N_x^2)$  computations in total. Therefore, when one increases  $N_x$  to achieve high-resolution simulation, our quantum algorithm is exponentially faster.

### B. Validity of the assumptions and generalization

Next, let us clarify what assumptions are made for our algorithm to work and discuss possible generalizations to go beyond the direct application of the algorithm.

### 1. Periodic boundary condition

In Sec. [III A,](#page-2-0) we imposed the periodic boundary condition on  $\psi$ . We can straightforwardly generalize the algorithm to another boundary condition, say the Dirichlet boundary condition, by just modifying the matrix A and  $C^{(n)}$ . The complexity estimate of our algorithm does not change with this modification.

# 2. Approximation in Eq. [\(18\)](#page-3-0)

An issue is the applicability of Eq.  $(18)$ . The approximation is not always valid for a large Reynolds number. If

purpose	$\boldsymbol{n}$	oracle	number of uses	
initial value encoding	-	$O_{\psi'_0}$	$2^{\frac{n-2}{2}m}n$ $  \partial_x\boldsymbol{\psi}_0  $ O $  \partial_x \boldsymbol \psi(\tau)  $	$= n \times Eq. (15) \times Eq. (51)$
time integration	$\overline{\phantom{0}}$	sparse-access oracles for A	$2^{\frac{n-2}{2}m}n\tau$ $  \partial_x \psi_0  $ $\left(\frac{1}{\epsilon}\right)$ O -polylog	$= n \times Eq. (14) \times Eq. (17) \times Eq. (51)$
	$\overline{\phantom{a}}$	other fundamental gates	$\frac{  \partial_x \psi_0  }{  \partial_x \psi(\tau)  } \frac{2^{\frac{n-2}{2}m} n \tau}{\epsilon} \left(n_x + \log^{\frac{5}{2}}\left(\frac{\tau}{\epsilon}\right)\right) \text{polylog}\left(\frac{1}{\epsilon}\right) = n \times \text{Eq. (14)×Eq. (16)×Eq. (51)}$ $\mathcal{O}$	
block-encoding $ n \geq 3 $ oracles for $\tilde{C}^{(n)}$ of $\tilde{C}^{(n)}$		sparse-access	$\frac{n-2}{2}m$ $\epsilon$	$=$ Eq. (46) $\times$ Eq. (51)
		other fundamental gates	$-\left(nn_x+\log^{\frac{5}{2}}\left(\frac{n!}{\epsilon}\right)\right)$	$=$ Eq. $(47) \times$ Eq. $(51)$
	$\overline{2}$	fundamental gates	$\frac{n_x^2}{2}$ O	$=$ Eq. $(27) \times$ Eq. $(51)$

<span id="page-7-0"></span>TABLE I. The number of uses of various oracles in the proposed method to calculate the n-point function. Subdominant contributions and additional ones for controlled operations are neglected.

we decompose  $\psi$  into homogeneous and fluctuation parts as  $\psi(x) = \psi + \delta \psi(x)$ , a naive estimate  $\delta \psi / \psi \sim$  Re implies that the equation is not a good approximation when the Reynolds number is large.

To classically demonstrate the difference between using the approximation Eq. [\(18\)](#page-3-0) and the exact relation Eq. [\(4\)](#page-1-4), we take a random initial condition,

$$
\psi(x,0) = e^{\xi_0 + \sum_{j=1}^{j_{\text{max}}}{(\xi_j \cos \frac{2\pi jx}{L} + \xi_{j_{\text{max}}+j} \sin \frac{2\pi jx}{L})},
$$
(61)

where  $\xi_j$ ,  $j = 1, \dots, 2j_{\text{max}}$  are random variables generated by a normal distribution with the expectation value 0 and the standard deviation  $\sigma_{\xi}$ . Here we take  $\sigma_{\xi} = 0.3$ ,  $j_{\text{max}} = 5$ , and  $n_x = 7$ , and obtain an initial condition of  $\psi$  as shown in the red-solid line in Fig. [1.](#page-7-1) The greensolid and beige-solid lines represent the evolution of  $\psi$ , and the blue-dashed line represents  $\bar{\psi}$ . We see that a long-wavelength mode survives and  $\psi$  typically deviates from  $\bar{\psi}$  by more than ~ 10% until  $\tau = 0.02$ . As a test of the validity of the approximation, we plot in Fig. [2](#page-8-2) the flatness  $\beta$  defined as

$$
\beta := \frac{I^{(4)}}{\left(I^{(2)}\right)^2} - 3. \tag{62}
$$

This generally approaches  $\beta = -3/2$  in a perturbative regime (see Appendix  $A$ ), and we thus expect that calculating  $\beta$  would be useful as a test also in quantum computing on future real hardware. In Fig. [2,](#page-8-2) both the exact value (solid line) and the approximation (dashed line) converge to the asymptotic value in the perturbative regime,  $\beta = -3/2$ , at  $\tau \sim 0.02$ . We see that our approximation works in the late dissipative regime, even though  $\delta\psi$  is set large at the beginning.

<span id="page-7-2"></span><span id="page-7-1"></span>FIG. 1. An example of the evolution of  $\psi$  with a random initial condition given in Eq. [\(61\)](#page-7-2) (Red-solid line at  $\tau = 0$ , green-solid at  $\tau = 0.01$ , and beige-solid at  $\tau = 0.02$ ). We also show the spatial average  $\bar{\psi}$  with the blue-dashed line.

# 3. Homogeneous background

<span id="page-7-3"></span>We assumed the existence of a homogeneous background  $\psi$ . Therefore, for example, a Brownian motion, which is often taken in the literature as the initial condition [\[74–](#page-10-21) [77\]](#page-10-22), is beyond the direct applicability of our algorithm because it does not have a homogeneous baseline  $\psi$ .

To generalize the assumption, suppose that we can find a linear baseline for the initial condition of interest, namely,  $\psi_j(0) = \bar{\psi}_j(0) + \delta \psi_j(0)$ , where  $\bar{\psi}_j(0) = aj + b$ and  $\delta\psi_i(0)$  is statistically homogeneous. Then, the baseline does not evolve in time, and a similar discussion in the previous sections holds. We may modify definitions

<span id="page-8-2"></span>FIG. 2. Comparison between the values of flatness  $\beta$  obtained by the approximation Eq. [\(18\)](#page-3-0) (green-dashed) and the exact relation Eq. [\(4\)](#page-1-4) (red-solid).

of 
$$
C_j^{(n)}
$$
 and replace  $C_j^{(n)}/(\bar{\psi})^n$  with  
\n
$$
\frac{1}{(\bar{\psi})^n} C_j^{(n)} \to \sum_{\sigma} \delta_{j-\sigma} \frac{c_{\sigma}^{(n)}}{(a(j_1 - \sigma_1) + b)^2}.
$$
\n(63)

However, we note that how large the computational cost becomes depends on  $\min\{ax + b\}$  because it affects the cost of block-encoding and the error tolerance in the measurement. We will leave such an extension for future work.

#### <span id="page-8-1"></span>V. CONCLUSION

We developed an FTQC algorithm to measure the statistical properties of Burgers turbulence. By applying the Cole–Hopf transformation, we are able to effectively linearize the non-linear equation in terms of a redefined field. From the solution as a quantum state, we can extract classical information about the multi-point functions of the original velocity field. Although there is a limitation in the information extraction step for turbulence with a high Reynolds number, our algorithm offers exponential advantages over classical methods in terms of the number of spatial grids  $N_x$  (from  $\mathcal{O}(N_x^2)$  to  $\mathcal{O}(\text{polylog}N_x)$ . This work serves as a proof of concept for solving non-linear systems using quantum computing.

# <span id="page-8-3"></span>Appendix A: Perturbative flatness for a plane wave initial condition

For the plane-wave initial condition,

$$
\psi(x,0) = 1 + \delta_m \sin\left(\frac{2\pi mx}{L}\right), \quad m \in \mathbb{Z}_+, \qquad (A1)
$$

one can analytically integrate Eq. [\(5\)](#page-1-3) to obtain

$$
\psi(x,t) = 1 + \delta_m \sin\left(\frac{2\pi mx}{L}\right) \exp\left(-\frac{4\pi^2 m^2 \tau}{N_x^2}\right). \tag{A2}
$$

In the large  $\tau$  limit, it is clear that  $||\psi_0||/||\psi(\tau)|| = 1$ .

We can also easily compute  $\beta$ . The velocity field, u, is computed by the relation [\(4\)](#page-1-4), and by expanding  $\langle u^2 \rangle$ and  $\langle u^4 \rangle$  by powers of  $\delta_m$ , one obtains

$$
\langle u^2 \rangle = \left(\frac{4\pi m\nu \delta_m}{L}\right)^2 \frac{1}{2} \exp\left(-\frac{8\pi^2 m^2 \tau}{N_x^2}\right)
$$

$$
\cdot \left(1 + \frac{3\delta_m^2}{4} \exp\left(-\frac{8\pi^2 m^2 \tau}{N_x^2}\right) + \cdots\right), \quad \text{(A3)}
$$

$$
\langle u^4 \rangle = \left(\frac{4\pi m \nu \delta_m}{L}\right)^4 \frac{3}{8} \exp\left(-\frac{16\pi^2 m^2 \tau}{N_x^2}\right)
$$

$$
\cdot \left(1 + \frac{5\delta_m^2}{3} \exp\left(-\frac{8\pi^2 m^2 \tau}{N_x^2}\right) + \cdots\right). \quad \text{(A4)}
$$

By substituting it into Eq.  $(62)$ , one obtains

$$
\beta = -\frac{3}{2} \left( 1 - \frac{\delta_m^2}{6} \exp\left(-\frac{8\pi^2 m^2 \tau}{N_x^2}\right) + \cdots \right). \tag{A5}
$$
