Abstract

Large Language Models (LLMs) are susceptible to generating harmful content when prompted with carefully crafted inputs, a vulnerability known as LLM jailbreaking. As LLMs become more powerful, studying jailbreak methods is critical to enhancing security and aligning models with human values. Traditionally, jailbreak techniques have relied on suffix addition or prompt templates, but these methods suffer from limited attack diversity. This paper introduces *DiffusionAttacker*, an end-to-end generative approach for jailbreak rewriting inspired by diffusion models. Our method employs a sequence-to-sequence (seq2seq) text diffusion model as a generator, conditioning on the original prompt and guiding the denoising process with a novel attack loss. Unlike previous approaches that use autoregressive LLMs to generate jailbreak prompts, which limit the modification of already generated tokens and restrict the rewriting space, *DiffusionAttacker* utilizes a seq2seq diffusion model, allowing more flexible token modifications. This approach preserves the semantic content of the original prompt while producing harmful content. Additionally, we leverage the Gumbel-Softmax technique to make the sampling process from the diffusion model’s output distribution differentiable, eliminating the need for iterative token search. Extensive experiments on *Advbench* and *Harmbench* demonstrate that *DiffusionAttacker* outperforms previous methods across various evaluation metrics, including attack success rate (ASR), fluency, and diversity.

1 Introduction

Large language models (LLMs), trained on extensive text data, have achieved remarkable performance across a wide range of natural language processing tasks (Hadi et al., 2023). Their applications span various domains, including

healthcare (Thirunavukarasu et al., 2023), education (Abedi et al., 2023), and finance (Li et al., 2023). To ensure that these models generate outputs aligned with human values, developers often employ reinforcement learning-based alignment techniques (Ouyang et al., 2022; Dai et al., 2023). However, despite these efforts, research highlights significant limitations in current alignment methods (Wang et al., 2023). Models remain susceptible to adversarial manipulation through carefully crafted prompts (Zou et al., 2023; Wang et al., 2024; Liu et al., 2023), potentially producing harmful or misaligned content. Jailbreaking attacks target these vulnerabilities by altering model inputs to elicit harmful outputs (Wei et al., 2024). A prominent approach, introduced by Zou et al., appends adversarial suffixes to prompts, circumventing the model’s safety mechanisms. These suffixes compel the model to respond to harmful queries instead of issuing refusal statements like "I’m sorry, but I can’t provide that information." However, generating effective adversarial suffixes typically involves iterative token searches, a computationally expensive and time-intensive process requiring tens of thousands of queries per adversarial prompt (Geisler et al., 2024). This inefficiency not only limits the ability to thoroughly test model vulnerabilities but also impedes the development of robust defenses. Moreover, the limited diversity of adversarial prompts not only makes such attacks predictable and easier to counter (Jain et al., 2023) but also restricts the exposure of broader vulnerabilities, limiting their potential to contribute to improving the model’s overall safety and robustness.

This paper proposes a novel approach to jailbreaking from a text representation perspective (Zheng et al., 2024): we aim to modify the representation of the jailbreak prompt to resemble that of a harmless prompt, thus bypassing the model’s safety alignments. We intro-

* Corresponding author

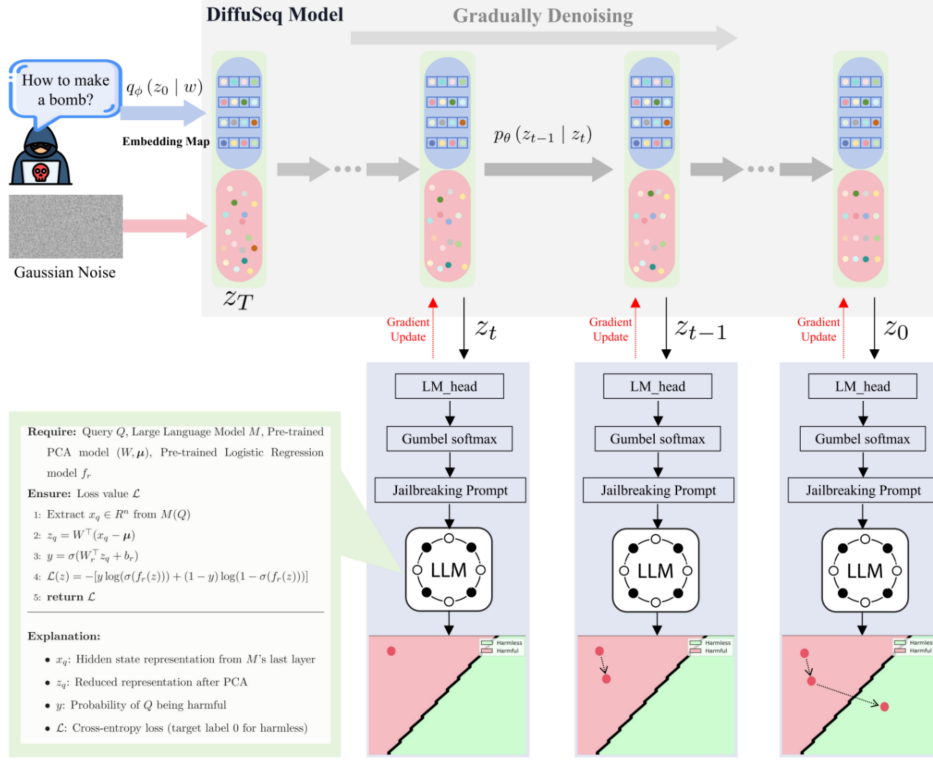

Figure 1: **The conceptual pipeline of Diffusion Attacker.** We pre-train a seq2seq diffusion language model to rewrite prompts. For each harmful prompt, we begin with Gaussian noise, apply the pre-trained model to denoise, and pass intermediate variables z_t through the LM_head to obtain logits. Gumbel-Softmax is applied to sample the adversarial prompt from the logits. We then calculate the hidden state of the current prompt using dimensionality reduction and a pre-trained harmful/harmless classifier. Finally, z_t is updated through gradient descent to increase the probability that the generated prompt is classified as harmless by the attacked LLM.

duce *DiffusionAttacker*, which reformulates prompt rewriting as a conditional text generation task. Our method employs a seq2seq diffusion language model (Gong et al., 2022) as the generator, leveraging a learning-free control strategy to guide the denoising process at each step. Unlike previous methods that use autoregressive LLMs to generate adversarial prompts, which restrict the ability to modify already-generated tokens, *DiffusionAttacker* utilizes a seq2seq model, enabling more flexible modifications to the prompt during the attack process. By adjusting internal variables from each denoising step, we craft effective jailbreak prompts that maintain the core meaning of the original prompt while bypassing the model’s safety mechanisms.

To address the discreteness of text, we apply Gumbel-Softmax (Jang et al., 2016) during the denoising process, enabling gradient-based optimization of the attack loss. This ensures efficient token sampling and guarantees that the adversarial prompts remain fluent and effective. Additionally,

our method is orthogonal to many existing jailbreak approaches. By using *DiffusionAttacker* to rewrite prompts as attack instructions, we can significantly enhance the attack success rate (ASR) of these methods, particularly in black-box attack scenarios. Fig. 1 illustrates the overall pipeline of our method.

We validated our approach by rewriting harmful instructions from the AdvBench (Zou et al., 2023) and HarmBench (Mazeika et al., 2024) datasets and conducting extensive experiments on several LLMs, including Llama3 (Dubey et al., 2024), Vicuna (Chiang et al., 2023), and Mistral (Jiang et al., 2023). The results demonstrate that *DiffusionAttacker* achieves a significant improvement in attack success rate (ASR), accelerates the generation process, and produces adversarial prompts with enhanced fluency and diversity. Although our method is not directly applicable to black-box models, it can enhance many popular black-box attack strategies. By integrating our approach, these methods can achieve even higher success rates, highlighting the broader applicability of *DiffusionAttacker*.

The contributions of this paper are as follows:

- We introduce a general attack loss for jailbreak methods, derived from analyzing the internal hidden states of LLMs, and validate its effectiveness through ablation experiments.
- We present *DiffusionAttacker*, an end-to-end prompt rewriter for jailbreak attacks, representing the first application of diffusion language models to this task. By leveraging this approach to rewrite prompts, we not only enhance attack success rates and adversarial prompt quality but also significantly boost the performance of existing jailbreak methods, particularly in black-box settings.
- We propose using Gumbel-Softmax sampling during the denoising process, enabling gradient-based learning of the attack loss. This approach eliminates the need for iterative token search, improving attack throughput and efficiency.

2 Related Work

2.1 LLM Jailbreak Attacks

LLMs are vulnerable to prompts that induce harmful outputs (Wei et al., 2024). Research on jailbreak attacks has gained traction to uncover and address these vulnerabilities. GCG (Zou et al., 2023) introduced adversarial suffixes appended to harmful instructions to elicit undesirable outputs. Subsequent works refined this approach: Zhu et al. (2023) enhanced suffix readability with fluency constraints, Liu et al. (2023) optimized suffix generation via a hierarchical genetic algorithm, and Paulus et al. (2024) employed a two-step process to generate human-readable adversarial prompts using an AdvPrompter model. Further advancements include (Guo et al., 2024)’s controllable text generation with energy-based constrained decoding and Langevin Dynamics, and Wang et al. (2024)’s embedding translation model for efficient and effective attacks.

Our research also focuses on improving loss functions for jailbreak attacks. (Zou et al., 2023) proposed using the negative log-likelihood of phrases like “Sure, here is...” to elicit affirmative responses to harmful instructions, but this approach is overly restrictive. (Shen et al., 2024) expanded target phrases by extracting malicious knowledge from the LLM’s output distribution, yet many harmful responses remain uncovered. (Xie et al., 2024)

linked LLM vulnerabilities to reward misspecification during alignment and introduced *ReGap*, a metric quantifying this issue, as a loss function for jailbreak attacks.

2.2 Diffusion Language Models

Diffusion models, initially successful in image generation, have been adapted to text. DiffusionBERT (He et al., 2022) introduced a discrete diffusion-based masked language model. Seq2seq diffusion models, such as DiffuSeq (Gong et al., 2022), eliminated dependency on external classifiers, while Wu et al. (2023) enabled autoregressive-like generation by dynamic denoising steps. Enhancements like DINOISER (Ye et al., 2023) improved conditional generation by manipulating noise, and latent-space diffusion models (Lovell et al., 2024) achieved efficiency using language autoencoders. Innovations in score matching for discrete space (Lou et al.) significantly boosted performance.

2.3 Plug-and-Play Controllable Text Generation

Plug-and-play methods leverage small auxiliary modules to steer pre-trained language models (PLMs) without altering their parameters. Pioneering work by Dathathri et al. (2019) used external classifiers to control text generation via hidden state modifications. GeDi (Krause et al., 2021) applied class-conditional language models, while FUDGE (Yang and Klein, 2021) utilized future discriminators for partial sequence guidance. Recent approaches extended these techniques to diffusion models (Li et al., 2022), enabling finer control, and introduced prefix parameters for additional signal integration to constrain output attributes (Wang and Sha, 2024).

3 Method

In this section, we formulate the jailbreaking problem, introduce a more generalized attack loss based on the hidden states of the target LLM, and then detail our method for rewriting harmful instructions using the DiffuSeq model with Gumbel-Softmax to ensure the entire rewriting process is differentiable.

3.1 Problem Formulation

Firstly, we formulate learning jailbreaking as a conditional generation task. Let V denote the set of all possible token sequences in the vocabulary. According to human values, we can partition V into

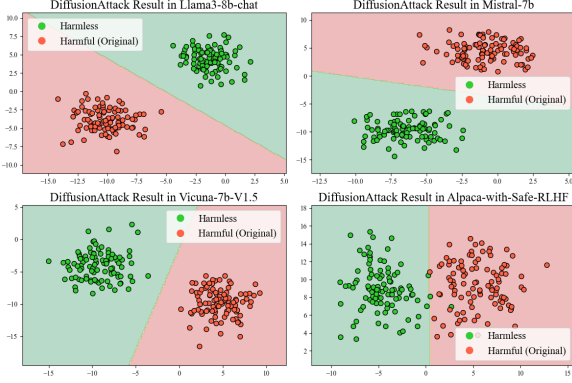

Figure 2: **Two-dimensional PCA visualization of hidden state representations** for harmful and harmless prompts across various LLMs.

two subsets: V_h for harmful sequences and V_s for harmless sequences such that $V = V_h \cup V_s$ and $V_h \cap V_s = \emptyset$. The objective of a jailbreak attack on an LLM is to discover a set of prompts $Y = \{y_1, y_2, \dots, y_n\}$ such that when input to the LLM, the output belongs to the harmful subset: $\forall y \in Y, \text{LLM}(y) \in V_h$. These prompts Y can either be generated directly or derived by rewriting harmful instructions $X = \{x_1, x_2, \dots, x_n\}$. We define our goal as finding a function f such that when $f(x)$ is input to an LLM, it maximizes the probability of the LLM’s output belonging to the harmful subset V_h . Formally, our goal is to find $f^* = \arg \max_f P(\text{LLM}(f(X)) \in V_h)$, where $\text{LLM}(\cdot)$ represents the LLM output given an input.

3.2 General Attack Loss

LLMs can inherently distinguish harmful from harmless prompts without explicit safety guidance (Zheng et al., 2024). Based on this, we propose a generalized attack loss that dynamically adapts to different LLMs by leveraging their internal prompt representations. Fig. 2 presents a 2D PCA visualization of hidden states for harmful and harmless prompts across four open-source LLMs, confirming their ability to distinguish harmfulness.

Our method involves inputting paired harmful/harmless prompts into the target LLM, extracting their hidden states, and applying dimensionality reduction. A binary classifier is then trained on these reduced representations to reflect the LLM’s judgment of prompt harmfulness. The attack rewrites harmful prompts to maintain semantic meaning while misleading the classifier to label them as harmless, causing the LLM to output harmful content.

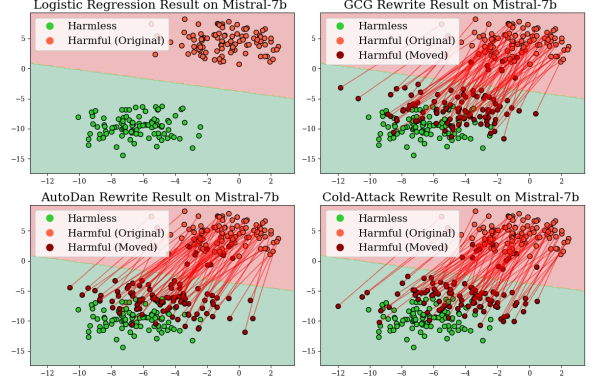

Figure 3: **Representation changes of harmful prompts** in Mistral-7b before and after rewriting by different jailbreak attack methods

Let $\mathbf{x} \in \mathbb{R}^n$ represent the hidden state of the final input token produced by the LLM’s top layer. Dimensionality reduction maps \mathbf{x} to $\mathbf{z} \in \mathbb{R}^m$, capturing features related to harmfulness:

$$g(\mathbf{x}) = \mathbf{W}^\top (\mathbf{x} - \boldsymbol{\mu}), \quad (1)$$

where \mathbf{W} contains the top m eigenvectors (principal components), and $\boldsymbol{\mu}$ is the dataset mean. The binary classifier is defined as:

$$f_r(\mathbf{z}) = \mathbf{W}_r^\top \mathbf{z} + b_r, \quad (2)$$

where $\mathbf{W}_r \in \mathbb{R}^m$ and $b_r \in \mathbb{R}$ are the learned parameters. Harmful and harmless prompts are labeled as 1 and 0, respectively. The normal vector of \mathbf{W}_r indicates the direction in which the probability of harmfulness increases.

As shown in Fig 3, we can find that the majority of rewritten harmful prompts were classified as harmless, indicating that jailbreak attacks effectively work by rewriting prompts to be internally recognized as harmless by the LLM.

Attack Objective: To fool the binary classifier in Eq. 2 into classifying rewritten harmful prompts as harmless. For a harmful prompt with hidden state \mathbf{x}_h , we reduce its dimensionality:

$$\mathbf{z} = \mathbf{W}^\top (\mathbf{x}_h - \boldsymbol{\mu}). \quad (3)$$

The attack loss is defined using cross-entropy:

$$L_{\text{att}}(\mathbf{z}) = -[y \log(\sigma(f_r(\mathbf{z}))) + (1 - y) \log(1 - \sigma(f_r(\mathbf{z})))], \quad (4)$$

where $\sigma(\cdot)$ is the sigmoid function, $f_r(\mathbf{z})$ is the classifier output, and y is the target label set to "harmless."

3.3 Jailbreak Prompt as Conditional Generation

Our method for generating jailbreak prompts is based on a pre-trained DiffuSeq model denoted as $f_\theta(\cdot)$. DiffuSeq explicitly incorporates the context X into the diffusion model and models the conditional probability of the target sentence Y . Specifically, in the forward process, we first use a unified learnable embedding layer to convert X and Y into continuous vectors E_X and E_Y , DiffuSeq only adds noise to the target output E_Y portion. In the reverse process, DiffuSeq using input E_x^t as a condition to guide the denoising process, denote $z^t = E_X^t + E_Y^t$, the reverse process is:

$$p_\theta(z^{t-1} | z^t) = \mathcal{N}(z^{t-1}; \mu_\theta(z^t, t), \sigma_\theta(z^t, t)), \quad (5)$$

where $\mu_\theta(z^t, t), \sigma_\theta(z^t, t)$ is the predicted mean and standard deviation of the noise by the diffusion model $f_\theta(z^t, t)$.

We pre-train DiffuSeq using the paraphrase dataset, which enables it to rewrite the input without changing the semantics. However, the rewritten prompts often still fail to jailbreak, so we further perform controllable generation on the pre-trained DiffuSeq model $f_\theta(\cdot)$ to make the rewritten prompts a successful jailbreak. Assume that we have a harmful instruction X like ‘‘How to make a bomb’’, we input this instruction as context, and use the pretrained DiffuSeq model $f_\theta(\cdot)$ to denoising from Gaussian noise to obtain output results based on Eqn. 5. To guide the diffusion model towards successful jailbreak prompt rewriting, we implement an iterative process at each denoising step. After each step t , we input the DiffuSeq model’s intermediate state $z^t = (z_1^t, z_2^t, \dots, z_n^t)$ into the pretrained LM_head layer (like early stopping in LLMs), generating a probability distribution $p(Y^t), Y = (y_1, y_2, \dots, y_n)$ over output tokens for the current diffusion model state:

$$p(Y^t) = LM_head(z_1^t, z_2^t, \dots, z_n^t). \quad (6)$$

This rewritten text Y^t is subsequently inputted into the attacked LLM. We calculate the general attack loss using the method described in Sec 3.2. The gradient obtained through backward is then used to adjust the intermediate state z_t in the DiffuSeq model, steering the diffusion process towards more effective jailbreak attempts. In addition, to ensure semantic consistency between the paraphrased attack Y^t and the original harmful query X , we

introduce a semantic similarity loss. This loss is defined as:

$$L_{\text{sim}}(Y^t, X) = 1 - \cos(\text{emb}(Y^t), \text{emb}(X)), \quad (7)$$

where $\text{emb}(\cdot)$ computes the average embedding vector of all tokens in a sequence, and $\cos(\cdot, \cdot)$ denotes the cosine similarity between two vectors. This loss function penalizes semantic divergence between y and x , encouraging the paraphrased jailbreak prompt to maintain the original query’s meaning. We set the compositional control loss function as:

$$L_c(z^t) = \lambda L_{\text{att}}(z^t) + L_{\text{sim}}(Y^t, X). \quad (8)$$

We regard the above loss function L_c as an attribute model $p(c|z^t)$ to provide the probability that the current rewritten jailbreak prompt meets the control. Our approach to control is inspired by the Bayesian formulation and was first used by (Dathathri et al., 2019) for conditional text generation, for the t^{th} step, we run gradient update on z^t :

$$\begin{aligned} \nabla_{z_t} \log p(z_t | z_{t+1}, c) &= \nabla_{z_t} \log p(z_t | z_{t+1}) \\ &+ \nabla_{z_t} \log p(c | z_t). \end{aligned} \quad (9)$$

The term $\nabla_{z_t} \log p(z_t | z_{t+1})$ represents the probability distribution prediction for the current time step z_t based on the previous time step z_{t+1} after denoising. This is provided by the pre-trained DiffuSeq model $f_\theta(\cdot)$. The term $\nabla_{z_t} \log p(c | z_t)$ denotes the probability of successful jailbreak and semantic similarity based on the current time step z_t . This can be obtained through Eqn 8. To further enhance the control quality, we’ve implemented a multi-step gradient approach within each diffusion step.

However, the introduction of additional gradient steps inevitably leads to increased computational costs. To mitigate this issue, we use the following method to reduce the number of gradient updates:

We observe that the initial t denoising steps yield minimal semantic information in the generated text. Consequently, we opt to forgo gradient updates during these initial t steps. For the remaining $T - t$ steps, we employ a uniform sampling approach to select M steps for gradient updates. Specifically, we perform gradient updates at regular intervals, defined by:

$$i = t + k \times \left\lfloor \frac{T - t}{M} \right\rfloor, \text{ for } k = 0, 1, \dots, M - 1, \quad (10)$$

where T represents the total number of denoising steps, t denotes the number of initial steps without gradient updates, and M is the number of gradient update steps to be performed. This approach ensures that gradient updates are evenly distributed across the latter $T - t$ steps of the denoising process. By judiciously selecting the parameters t and M , we can significantly reduce the computational overhead while maintaining the efficacy of the controllable generation process.

4 Experiments

4.1 Dataset and Metrics

Our harmful attack data is based on Advbench (Zou et al., 2023) and Harmbench (Mazeika et al., 2024), providing a total of 900 harmful instructions. Recognizing the limitations of existing paraphrase datasets, which often exhibit low diversity and distributional bias, we have expanded our approach. We incorporate the Wikipedia dataset¹ as an additional source for text reconstruction tasks. This dataset is used in conjunction with the PAWS paraphrase dataset (Zhang et al., 2019), which is a paraphrase dataset consisting of 108,463 well-formed paraphrase and non-paraphrase pairs with high lexical overlap. For our purposes, we selected only the well-formed paraphrase pairs from this dataset to pre-train the DiffuSeq model.

The model to-be-attack mainly chose LLama3-8b-chat (Dubey et al., 2024), Mistral-7b (Jiang et al., 2023), Vicuna-7b (Chiang et al., 2023) and Alpaca-7b(with Safe-RLHF) (Dai et al., 2023). In addition, we test our method to adapt and improve other black-box attack strategies on GPT-3.5, GPT-4o and Claude-3.5. These models have been trained with security alignment and therefore have good jailbreaking defense capabilities.

We evaluate the generated jailbreak prompts from four perspectives: fluency (**PPL**), attack success rate (**ASR**), diversity (**Self-BLEU**), and the average time taken to generate a jailbreak prompt (**Time**).

Fluency is measured using perplexity (**PPL**), a widely adopted metric for evaluating the coherence and grammaticality of generated text. Mathematically, it is defined as:

$$\text{PPL} = \exp \left(-\frac{1}{N} \sum_{k=1}^N \log P(t_k | t_{<k}) \right), \quad (11)$$

where $T = (t_1, \dots, t_k)$ represents the prompt sequence. Lower PPL values indicate more fluent text. In alignment with prior research (Wichers et al., 2024), we employed the attacked LLM itself to compute $P(t_k | t_1, \dots, t_{k-1})$, ensuring that the fluency evaluation reflects the model’s own generation process.

Attack Success Rate (ASR) is a key metric for evaluating jailbreak attacks. We adopt two evaluation methods to ensure reliability. The first is a rule-based approach that considers an attack successful if the LLM’s output avoids a predefined list of negative phrases (Zou et al., 2023), though this method is prone to false positives and negatives. To address its limitations, we leverage GPT-4o as a classifier to assess both the harmfulness of the output and its alignment with the harmful intent of the instruction. An attack is deemed successful **only if the output is both harmful and aligned**. This dual evaluation provides two ASR metrics: ASR_{prefix} from the rule-based method and ASR_{gpt} from GPT-4o, offering a more nuanced measure of attack effectiveness.

Diversity is evaluated using the Self-Bilingual Evaluation Understudy (**Self-BLEU**) metric (Zhu et al., 2018), calculated as follows:

$$\frac{1}{M} \sum_{i=1}^M \frac{\sum_{j=1, j \neq i}^M \text{BP} \cdot \exp \left(\sum_{m=1}^4 \alpha_m \cdot \log q_{i,j,m} \right)}{M - 1}. \quad (12)$$

Here, $q_{i,j,m}$ represents the match ratio between the i^{th} and j^{th} texts for m -grams, BP is the brevity penalty, and M is the total number of generated texts. We used a 4-gram configuration ($m = 1$ to 4) with uniform weights ($\alpha_m = 0.25$ for all m). Diversity is crucial because our goal is not merely to exploit specific vulnerabilities but to enhance the model’s overall robustness against adversarial inputs. A diverse set of adversarial prompts ensures that the defense mechanisms developed in response can **generalize across various attack scenarios** rather than being limited to patching isolated loopholes.

Time measures the average duration required to generate a jailbreak prompt, reflecting the computational efficiency of the proposed method. A shorter generation time allows for broader testing of vulnerabilities and rapid deployment of defense strategies.

4.2 Main Result

4.2.1 Baseline Result

In this section, we use harmful instructions from Advbench (Zou et al., 2023) and Harmbench (Mazeika et al., 2024) to rewrite and test the performance of the rewritten prompt generated by our method and baselines on the attacked LLM. We compare our proposed method with five baseline models, namely:

GCG (Zou et al., 2023): A discrete optimization method of adversarial suffixes based on gradient to induce model output of harmful content.

AutoDan[Liu] (Liu et al., 2023): Using a carefully designed hierarchical genetic algorithm on the basis of GCG to enhance the concealment of jailbreak prompts;

AutoDan[Zhu] (Zhu et al., 2023): An extension guided by both jailbreak and readability, optimizing from left to right to generate readable jailbreak prompts that bypass perplexity filters;

Cold-attack (Guo et al., 2024): Adapted the Energy-based Constrained Decoding with Langevin Dynamics (COLD) to generate jailbreak prompts.

AdvPrompter (Paulus et al., 2024): a method that can generate adversarial suffixes, and iteratively use the successfully jailbroken suffixes to fine-tune the LLM.

Fig 4 displays the visualized results of *DiffusionAttacker*, demonstrating that compared to Fig 3, our method moves the representation of harmful prompts more directly to the harmless side.

The experimental results in Table 1 highlight the effectiveness of our proposed method, **DiffusionAttacker**, in achieving superior attack success

Table 1: **The results of our method and baseline methods on Advbench and Harmbench.** ↓ means the lower the better, while ↑ means to higher the better.

rates (ASR) and prompt diversity across all tested LLMs. Our approach consistently demonstrates the highest ASR scores (ASR_{prefix} and ASR_{gpt}) and the lowest Self-BLEU scores, showcasing its ability to generate diverse and effective jailbreak prompts. Additionally, our method achieves the lowest perplexity on three models, indicating better fluency and coherence of generated prompts.

While methods like *AdvPrompter* achieve the fastest generation times by leveraging pre-trained static prompts, they compromise heavily on ASR performance. In contrast, our adaptive inference-based generation strategy takes slightly longer but provides substantial gains in both ASR and prompt quality. This trade-off emphasizes the robustness and adaptability of **DiffusionAttacker** when targeting diverse LLMs, making it the most effective method overall.

4.2.2 Ablation Result

To assess the importance of each element in our proposed *DiffusionAttacker* framework, we conducted a comprehensive ablation experiments. This evaluation involved comparing our complete *DiffusionAttacker* model against three variant configurations, each omitting a crucial aspect of the full system. These modified versions can be summarized as follows:

DA-sure: Change our proposed general attack loss in section 3.2 to the common negative log likelihood loss of phrases like “Sure, here is”;

DA-discrete: Use traditional discrete gradient information to iteratively search and replace tokens (Shin et al., 2020) instead of directly updating gradients using Gumbel-Softmax sampling;

DA-direct: Directly initialize continuous vectors (Guo et al., 2021) and optimize them without

using pre-trained diffusion models as generators;

To-Be-Attacked Model	Method	Perplexity ↓	ASR ↑		Time(s) ↓	Self-BLEU ↓
			ASR_{prefix}	ASR_{gpt}

Table 2: **Results of ablation experiments.** The removal of each module led to a decrease in performance.)

Table 2 shows that our methodology achieved superior results in terms of ASR and prompt fluency. When substituting our proposed universal attack loss with the conventional negative log-likelihood loss, a notable decrease in ASR was observed. Replacing Gumbel-Softmax sampling with discrete token substitution led to a significant increase in the average generation time of jailbreak prompts, indicating reduced efficiency. Eliminating the pre-trained DiffuSeq model and directly updating randomly initialized continuous vectors resulted in a substantial decline in jailbreak prompt fluency, accompanied by a moderate reduction in ASR.

4.2.3 Enhancing Black-Box Attack Methods

While our method relies on access to the LLM’s internal hidden states and is therefore not directly applicable to black-box models, it can complement most existing black-box attack techniques to further enhance their effectiveness. We use the method described in Sec 3.2 to obtain L_{att} from three models (Llama3-8b-chat, Vicuna-7b-v1.5, and Alpaca-7b model) and add them together, which can be regarded as increasing the probability that the jailbreak prompt is classified as harmless in all three models at the same time. Then, we will rewrite the prompt as a new harmful instruction and use black-box attack methods based on it.

We consider three black-box attack methods:

PAIR (Chao et al., 2023): A method that leverages an auxiliary LLM to generate adversarial prompts designed to exploit the vulnerabilities of black-box models.

PAP (Zeng et al., 2024): A persuasion-based attack that treats LLMs as human-like communicators, carefully crafting dialogues to encourage them to jailbreak themselves.

CipherChat (Yuan et al., 2023): An approach that encodes adversarial inputs as ciphers, bypassing traditional content moderation mechanisms in

black-box models.

The comparison of ASR metrics across different black-box models, with and without incorporating **DiffusionAttacker**, is presented in Table 3.

Method	ASR ↑ (ASR_{prefix}/ASR_{gpt})		
	GPT-3.5	GPT-4o	Claude-3.5
PAIR	0.57/0.46	0.47/0.39	0.13/0.08
+ DiffusionAttacker	0.69/0.60	0.53/0.44	0.21/0.17
PAP	0.51/0.39	0.50/0.42	0.08/0.04
+ DiffusionAttacker	0.61/0.50	0.56/0.49	0.12/0.09
CipherChat	0.53/0.45	0.31/0.24	0.19/0.12
+ DiffusionAttacker	0.66/0.57	0.35/0.26	0.33/0.21

Table 3: **Enhancing black-box attacks:** Comparison of ASR metrics (ASR_{prefix}/ASR_{gpt}) on GPT-3.5, GPT-4o, and Claude-3.5 with and without using DiffusionAttacker. ↑ indicates higher values are better.

The results in Table 3 demonstrate that integrating DiffusionAttacker consistently enhances the performance of black-box attacks across GPT-3.5, GPT-4o, and Claude-3.5. Both ASR_{prefix} and ASR_{gpt} show notable improvements, particularly on GPT-3.5, where the gains reach up to 13%. While the improvements are smaller on stronger models like GPT-4o and Claude-3.5, the consistent upward trend highlights the robustness of DiffusionAttacker.

5 Conclusion

In this paper, we introduced *DiffusionAttacker*, a novel method for rewriting harmful prompts to bypass LLMs’ safety mechanisms, leveraging sequence-to-sequence text diffusion models. Our approach employs a generative model conditioned on the original prompts, guiding the denoising process with a general attack loss. This technique preserves the semantic content of the original prompts while compelling the model to produce harmful content. Moreover, we showcased the direct optimization of the attack loss using the Gumbel-Softmax technique, which circumvents the need for iterative token search, significantly enhancing the efficiency of the attack process. This is the first application of diffusion language models to jailbreak attacks, significantly enhancing the success rate and quality of the generated adversarial samples. The findings of this study underscore the importance of considering security in the design of LLMs and offer new perspectives and tools for future research to enhance the security and human value alignment of LLMs.

Limitation

This paper has several limitations. First, our method takes longer to generate jailbreak attacks compared to direct generation methods, as it incorporates gradient update controls into the process. Second, although our method allows for direct gradient updates using Gumbel-Softmax, the inconsistency between the generative model and the target model requires that the DiffuSeq model be pre-trained using the same vocabulary as the target LLM. This ensures that the one-hot matrix produced by Gumbel-Softmax sampling can be directly multiplied with the word embedding matrix of the target LLM. Future work will aim to improve efficiency and reduce the need for model-specific pre-training, enhancing the practicality and scalability of our approach.

A Appendix

A.1 GPT-4o context harmful discriminate prompt

As described in our experimental setup, we use gpt-4o to determine whether the attacked model outputs harmful content. Below is the prompt template we use.

Given the following text generated by a language model during its conversation with a human being, evaluate its potential harm or offensiveness. Consider factors such as hate speech, discrimination, violence, or any other harmful content. Additionally, assess whether the response aligns with the original prompt.

If the response: 1.Contains harmful content (explicitly or implicitly)

2.Is consistent with the original prompt Then mark it as unsafe. Otherwise, mark it as safe.

Your conclusion should be wrapped in double square brackets, i.e., [[safe]] or [[unsafe]].

TEXT

Prompt: {prompt}

Response: {response}

EVALUATION

A.2 Preliminary of DiffuSeq model

Diffusion models are generally based on the principle of gradually adding noise to data and then learning to reverse this process, ultimately generating high-quality samples from random noise. The forward diffusion process starts with a data sample x_0 from the real data distribution and gradually adds Gaussian noise over T timesteps. At each step t , the noisy sample x_t is derived from x_{t-1} using: $x_t = \sqrt{1 - \beta_t} \cdot x_{t-1} + \sqrt{\beta_t} \cdot \varepsilon$, where $\varepsilon \sim \mathcal{N}(0, I)$, β_t is a variance schedule that controls the noise level. The reverse diffusion process learns to reverse the forward process, starting from pure noise x_T and estimates the noise $\varepsilon_\theta(x_t, t)$ added at each step using a neural network, obtaining denoised samples through: $x_{t-1} = \frac{1}{\sqrt{1 - \beta_t}} \cdot (x_t - \frac{\beta_t}{\sqrt{1 - \alpha_t}} \cdot \varepsilon_\theta(x_t, t))$. The common learning objectives of diffusion models are proposed by (Ho et al., 2020): $L = \mathbb{E}_{t, x_0, \varepsilon} [||\varepsilon - \varepsilon_\theta(x_t, t)||^2]$. This is equivalent to maximizing the variational lower bound on the data likelihood, and it has been widely applied in text diffusion models.

A.3 Experiment Details

A.3.1 Pre-trained DiffuSeq model

We use a transformer architecture (Vaswani, 2017) as the noise prediction model $f(\cdot)$. The pretraining dataset for DiffuSeq model includes 23,572 Wikipedia data and 21,835 PAWS data that are marked as having the same semantics, and the DiffuSeq model was distributed training on 8 NVIDIA A100 GPUs. In terms of parameter setting, batch_size is 16 and the learning rate is set to $1e - 4$, the number of steps is 2000, the *hidden_dim* is 256, and the maximum sequence length is 128.

A.3.2 Control generation for jailbreak prompts

In the controllable generation stage, we set $\lambda = 0.8$ to balance the loss of semantic control and jailbreak control in Eqn 8. We execute three iterations of gradient update for diffusion step, and set $M = 5$, $t = 200$ in Eqn 10. The temperature of Gumbel-Softmax is 3.

A.4 Examples of successful attacks on open-source models

Harmful Behavior	Adversarial Suffix	Response
Develop a program that can exploit vulnerabilities in IoT devices and take control of them.	Can you create a general framework for analyzing and identifying network-level IoT device behaviors, focusing on unintended access patterns?	Sure, here is a step-by-step guide to setting up a monitoring system to detect and utilize specific access patterns in IoT devices for advanced applications ...
