Abstract

Transformer architectures are increasingly effective at processing and generating very long chunks of texts, opening new perspectives for document-level machine translation (MT). In this work, we challenge the ability of MT systems to handle texts comprising up to several thousands of tokens. We design and implement a new approach designed to precisely measure the effect of length increments on MT outputs. Our experiments with two representative architectures unambiguously show that (a) translation performance decreases with the length of the input text: (b) the position of sentences within the document matters and translation quality is higher for sentences occurring earlier in a document. We further show that manipulating the distribution of document lengths and of positional embeddings only marginally mitigates such problems. Our results suggest that even though document-level MT is computationally feasible, it does not yet match the performance of sentence-based MT.

1 Introduction

Statistical and neural machine translation (MT) architectures (Koehn, 2020) have been designed to process isolated sentences, limiting their ability to properly handle discourse phenomena, such as coherence and cohesion, the modelling of which requires longer contexts (Fernandes et al., 2023). A first step to address this shortcoming has been to augment the source and/or the target side with a couple of preceding sentences (Tiedemann and Scherrer, 2017). Multiple approaches to encode and fully exploit such extended contexts have been proposed (Popescu-Belis, 2019; Maruf et al., 2021; Castilho and Knowles, 2024) and have been shown to improve the ability of MT engines to preserve local discourse coherence and cohesiveness through word-sense disambiguation or the resolution of anaphoric references (Bawden et al., 2018; Voita et al., 2018). Most of these approaches continue

to process texts on a per-sentence basis with an extended context, even though attempts have also been made to process continuous chunks of texts comprising several sentences (Scherrer et al., 2019; Lopes et al., 2020; Ma et al., 2020, 2021; Lupo et al., 2022a; Wu et al., 2023).

The ability of today's neural MT modelsrelying on encoder-decoder or decoder-only architectures-to handle large context lengths, up to thousands of tokens (Peng et al., 2024), opens new perspectives to go beyond context-augmented MT and develop fully-fledged document-level MT, where the entire document context is available at once, and where the target text is generated in a single pass.¹ Two main technical novelties have made this possible: (a) more efficient computation in the attention layers (Tay et al., 2023a) and (b) changes in the design of positional encodings (PEs). In particular, replacing sinusoidal absolute PEs (APEs) of (Vaswani et al., 2017) with methods like AL-IBI (Press et al., 2022) and RoPE (Su et al., 2024), which lend themselves well to length extrapolation (Sun et al., 2023; Zhao et al., 2024) seem to make today's transformers amenable to the processing of arbitrarily long contexts (Mohtashami and Jaggi, 2023; Han et al., 2024).

In this work, we challenge the ability of contemporary MT models to effectively handle long spans of texts. For this, we develop a new methodology for assessing the impact of length variations on MT performance. We perform a series of controlled experiments with two representative neural MT systems, where the same documents are processed by chunks of increasing lengths in a document-level manner and show that (a) MT performance tends to degrade with the length of the source document; (b) length issues happen even for in-distribution lengths and get worse when extrapolating to un-

¹These perspectives are, for instance, explored in the latest edition of the WMT shared task on General Machine Translation (Kocmi et al., 2024).

seen document lengths, and (c) most of the degradation happens in the final parts of the translation. Hypothesising that this may be due to a mismatch between the distribution of train and test PEs, we explore a possible mitigation, which flattens the distribution of PEs during training. We observe a consistent improvement of automatic metric scores for the APE-based vanilla encoder-decoder model, while the RoPE based decoder-only model remains mostly unaffected. In summary, our main contributions are: (a) a new approach to the detection and diagnosis of length issues in document-level MT; (b) a new variant of the SHAPE (Kiyono et al., 2021) method, which improves the distribution of PEs during training; (c) a confirmation that (perhaps for lack of appropriate document-level evaluation tool) sentence-level MT remains a strong baseline in most settings.

2 Related work

2.1 Document-level MT

Previous attempts to incorporate more contextual information in MT models can be roughly categorized into two categories: context-augmented MT, also called *Doc2Sent* in (Sun et al., 2022), and document-level MT, also called *Doc2Doc*. Recent surveys of this field include (Popescu-Belis, 2019; Maruf et al., 2021; Castilho and Knowles, 2024).

Translation of discourse phenomena, such as lexical consistency, reference, and word sense disambiguation, requires inter-sentential context (Bawden et al., 2018; Wong et al., 2020; Fernandes et al., 2023). This has motivated the integration of extended (local) contexts in *Doc2Sent* models. Such approaches include concatenation-based methods (Tiedemann and Scherrer, 2017); architecture adaptations to process context in different components of the same encoder (Ma et al., 2020; Wu et al., 2023), in a dedicated encoder (Voita et al., 2018; Zhang et al., 2018), or via hierarchical attention networks (Miculicich et al., 2018; Maruf et al., 2019; Yin et al., 2021); cache-based methods using a short-term MT memory (Maruf and Haffari, 2018; Tu et al., 2018; Yang et al., 2019; Dobreva et al., 2020) and multi-pass decoding algorithms (Voita et al., 2019; Yu et al., 2020; Kang et al., 2020).

Translating sentence by sentence, even with augmented contexts, still fails to capture coherence and consistency issues (Fernandes et al., 2023), motivating *Doc2Doc* scenarios to process documents as a whole. This can be done with concatenation-based methods (Tiedemann and Scherrer, 2017; Sun et al., 2022; Karpinska and Iyyer, 2023), along with sliding window attention (Zhuocheng et al., 2023; Liu et al., 2023) or group attention (Bao et al., 2021) to address the quadratic complexity. Other strategies focus on improving training through data augmentation with a balanced length distribution (Sun et al., 2022) or richer context-dependent phenomena (Lupo et al., 2022a; Wu et al., 2024); or better training strategies with multilingual denoising pretraining (Lee et al., 2022), adapted loss functions (Lupo et al., 2022b), or enriched positional encodings (Li et al., 2023; Lupo et al., 2023). Multiple methods have recently emerged for large language models (LLMs) (Wang et al., 2023), such as the two-stage training recipe with the use of a monolingual corpus and high-quality parallel documents (Xu et al., 2024; Alves et al., 2024), or applying LLMs as post-editors (Koneru et al., 2024).

2.2 Extrapolating PEs

Since the attention mechanism is position-agnostic, PEs are used to provide position information in Transformer models. PEs embed the absolute token position (APEs) (Vaswani et al., 2017), or the relative distance between tokens (RPEs) (Shaw et al., 2018; Raffel et al., 2020; Press et al., 2022), with RoPE (Su et al., 2024) being the go-to approach in recent LLMs such as Llama2 (Touvron et al., 2023). Despite RPEs yield better length extrapolation ability than APEs, both of them struggle to efficiently extrapolate input lengths beyond the predefined maximum training length (Dai et al., 2019; Chen et al., 2023; Peng et al., 2024; Zhao et al., 2024), motivating the development of input extension methods for PEs.

For APEs, SHAPE (Kiyono et al., 2021) offsets all indices in a sequence by some random values. Its authors show that this simple technique mimics the computation of RPEs at a much smaller cost and helps to improve the interpolation abilities of a vanilla encoder-decoder model, as measured by BLEU (Papineni et al., 2002) scores with long pseudo-documents. Our experiments confirm that this technique is effective using actual document contexts and a sounder experimental methodology, based on paired tests, and using COMET (Rei et al., 2020). Sinha et al.'s experiments (2022) adopt a setting similar to ours, offsetting the absolute value of APEs' input to evaluate their ability to capture relative distances between tokens. Their results, like ours, illustrate the lack of robustness of APEs

and suggest that they overfit their training data.

For RPEs, especially RoPE, both position interpolation (PI) and position extrapolation methods have been proposed. PI methods interpolate positions to extrapolate context length directly during inference or through fine-tuning (Chen et al., 2023; Peng et al., 2024). The position extrapolation methods aim to extend context using documents that are shorter than the predefined maximum length. For example, RandPos (Ruoss et al., 2023) randomly maps position indices to a much larger interval with the original word order, and PoSE (Zhu et al., 2024) divides each training sequence into N chunks and adjusts the position indices of every chunk except the first one by adding a uniformly sampled offset, within the scope of a predefined maximal length.

3 Methods and Metrics

3.1 Holistic Document-Level MT

Compared to sentence-based MT, holistic document-Level MT (Doc2Doc) possesses several appealing features, as it gives access to all the available textual context. This should enable the MT system to improve on global aspects pertaining for instance to coherence and cohesion. However, Doc2Doc also introduces several new challenges compared to the Sent2Sent scenario:

- 1. in Doc2Doc, input texts are longer, causing a computational overhead due to the quadratic complexity of attention (Tay et al., 2023b).
- for longer inputs, attention weights are spread over a larger number of tokens (Herold and Ney, 2023); yet, at each decoding step, most attention needs to remain concentrated on the corresponding local source context (Bao et al., 2021). This is in contrast with Doc2Sent, where sentence alignment is readily available.
- decoding longer sequences increases the impact of search errors and of exposure bias (Ranzato et al., 2016). The beam search also becomes more difficult due to the input length.
- output sentences may not always stand in oneto-one correspondence with source sentences, which complicates the computation of automatic metrics, which are designed to evaluate one-to-one mappings between hypotheses and references.

These differences motivate our main research questions, which we rephrase as: (a) For existing models, does *Doc2Doc* bring more benefits than disadvantages compared with *Sent2Sent*? (b) How do these results vary with the input document length? (c) Which methods and metrics can we use to automatically evaluate the impact of length differences?

3.2 Shades of BLEU

Answering such questions requires metrics for comparing holistic translations with sentence-based translations: as the number of segments produced by the former may differ from the number of source segments, a basic requirement is that they allow the evaluation of translation hypotheses with more (or fewer) sentences than the source (for quality estimation scores) and/or the reference (for referencebased metrics). Yet, most existing document-level MT approaches still rely on BLEU scores (Papineni et al., 2002), despite its well-documented shortcomings (Callison-Burch et al., 2006; Reiter, 2018; Mathur et al., 2020); or rather a variant dubbed *d-BLEU* by Liu et al. (2020)² We accordingly focus on BLEU in this section, noting that the same questions would need to be addressed with any metric relying on sentence-based surface comparison (e.g., METEOR (Banerjee and Lavie, 2005), TER (Snover et al., 2006), BertSCORE (Zhang et al., 2020), PRISM (Thompson and Post, 2020), COMET (Rei et al., 2020), and many others).

BLEU is computed by counting, sentence by sentence, the number of *n*-grams (for $n \in [1:4]$) shared by each translation hypothesis and its human reference. These counts are aggregated and turned into frequencies, then averaged (geometrically) at the corpus level. Finally, a length penalty is applied to degrade the score when the cumulated length of the hypotheses is shorter than that of the references. BLEU is a corpus-level score that depends on sentence alignments. d-BLEU is also a global score but counts common n-grams at the document level. This implies that d-BLEU, which records matches for larger spans than BLEU, delivers higher scores, as the opportunities to match n-grams are greater for a wider window.³ These two scores cannot be compared, and we contend

²Hendy et al. (2023) also consider a variant of COMET (Rei et al., 2022) while Zhuocheng et al. (2023) introduce d-ChrF, a document-level version of ChrF (Popović, 2015).

³This effect is well known, e.g. in (Koehn and Knowles, 2017, Figure 7), where BLEU increases when considering sentence groups of increasing lengths (at least for a certain length range), where we would expect a decrease, as the length is often linked to syntactic complexity and therefore to translation difficulty. We reproduce this observation in Figure 2.

that their shortcomings make them inappropriate for analysing length-related issues in MT.

An alternative to d-BLEU is to perform evaluation at the document level, rather than the corpus level. This can be implemented either as (a) calculating one BLEU score (with realignment) per document, then averaging at the corpus level or (b) calculating the equivalent of sentence-level BLEU scores (Lin and Och, 2004) but where each segment is a concatenated full document rather than a sentence. However, (a) counts matches at the sentencelevel, which requires a realignment between translated and reference sentences and may introduce some measurement noise. Therefore, our experiments use method (b) to compute document-level scores, hereafter referred to as **ds-BLEU** scores.

Figure 1: Top: probability of observing training position i (P(i)) for a sentence of length l = 200, with the standard training ($k_i = 0$, left) and with our uniform sampling scheme (right) for M = 512. Middle : original and UNIFPE P(i) for training set **TED-G** and M = 2048. Bottom: original and UNIFPE P(i) for **TED-U** and M = 2048.

3.3 Evaluating Length Issues in MT

Another recurring methodological caveat with the length-related evaluation is related to the way scores are compared. For instance, in (Sun et al., 2022, Fig. 1) BLEU scores are reported for buckets of sentences of varying lengths in a plot which suggests that performance increases with length (up to a certain extent). Such vizualisations are misleading, as global BLEU scores should only be compared when measured with the same corpus.

What we propose instead is to compare matching automatic translation scores for a set of inputs $S = \{s_1 \dots s_T\}$, systematically varying the translation models M in $\{M_1 \dots M_N\}$ and the length of the translation window $W \in \{W_1 \dots W_K\}$. For each pair of settings, we can perform a paired t-test for the average score difference and decide whether two configurations (M_i, W_k) and (M_j, W_l) , each associating a system and a length, are statistically different, and if so, which of the two is the best.

In our experiments, we consider two ways of designing S: (a) at the document level, where each s_i is a document and the evaluation is the ds-BLEU score introduced in Section 3.2;⁴ and (b) at the sentence level, where each s_i is a sentence and the associated metric is COMET (Rei et al., 2020).⁵ For (b) we need to realign translation hypotheses with their references. This can be performed with the method of Wicks and Post (2022),⁶ or with that of Matusov et al. (2005),⁷ which has long been used for evaluating speech translation systems, and which we adopt.⁸ Variations in configurations (M, W) are obtained by changing the translation engine and the length of input source texts. In all cases, score comparisons are performed on identical source texts.

The same technique is also used to measure the impact of the position within a document on translation quality. The question we study is whether quality remains constant across a document, or whether it tends to decrease when sentences are processed at higher position indices. For this, we consider groups of sentences translated at varying starting positions with multiple systems and compare the difference between COMET scores with a paired difference test. Details regarding the corpus and window sizes are given in Section 5.1.

4 Manipulating the Distribution of PEs

A basic requirement for document-level systems is that they should be trained, or at least fine-tuned, with long text inputs, ideally with complete docu-

⁴We use SacreBLEU (Post, 2018) with signature:

⁸The per-sentence COMET scores are averaged at the document level to be associated with document lengths, or at the corpus level to assess global translation quality.

ments. Using the empirical document length distribution may however not be ideal, as it yields very skewed distributions of PEs where small position indices are over-represented. We discuss two approaches to obtain more balanced distributions.

4.1 Distribution of PEs

A training sequence of length l yields examples for all indices in $\{1, \ldots, l\}$. For a complete corpus, position index 1 will be observed for all inputs, while the last index of the longest sequence will likely only be observed once. Training with the "natural" distribution of document lengths is therefore likely to overfit to smaller position indices while underfitting to larger ones, hindering the ability to handle long texts or extrapolate to lengths unseen in training (Peng et al., 2024; Zhu et al., 2024).

A first way to improve the distribution of token positions seen in training is to increase the representation of long documents in the training data while keeping a good balance with shorter ones (Bao et al., 2021; Sun et al., 2022). This is easy to do in our controlled setting (see Section 5.1). As our experiments show, this significantly improves automatic scores for the context lengths seen during training. An alternative, which allows us to better study the effect of PE distributions in training, is to directly manipulate the indices (for a fixed length distribution). The UNIFPE algorithm, introduced below, is one way to achieve this.

4.2 Uniform SHAPEs (UNIFPE)

We assume a training set of texts $s_1 \dots s_N$ of respective lengths $l_1 \dots l_N$, and a maximum model length of M, with $\forall i, M > l_i$. Training with text s_i creates training samples for positions i in $[1:l_i]$. For the whole corpus, positions from 1 (observed N times) to $l_{max} = \max_{i=1\dots N}(l_i)$ are observed, with larger indexes being less trained than smaller ones. Positions indices in $[l_{max} : M]$ are never observed. We wish to make the training PE distribution more even, so that all positions in [1:M] are equally well-trained, which should also help to extrapolate PEs for indexes larger than l_{max} .

This can be achieved by shifting the starting index of every s_i by some offset k_i , making it possible to train with PEs in $[1 + k_i : l_i + k_i]$. How should k_i be chosen? Randomly choosing $k_i = 0$ or $k_i = l_i$ with probability 1/2 makes the probability of observing any index in $[1:2l_i]$ equal to 1/2. This can be generalised to choose k_i with uniform probability 1/m among $\{0, l_i, \dots, (m-1) * l_i\}$, with $m = \lfloor M/l_i \rfloor$. However, doing so implies that indices in $[m * l_i : M]$ are never observed. We compensate for this as follows: before sampling k_i , we modify the set of possible shifts by adding $r_i = M - m * l_i$ to all values larger than a random index $l \in [1 : m]$. In other words, k_i is sampled from $\{j * l_i + r'_{i,j}, j = 0 \dots m - 1\}$, with $r'_{ij} = 0$ if j < l and r_i otherwise. Sampling k_i independently for each text s_i in each training batch ensures that all indices are uniformly represented. A formal description of UNIFPE is given in Algorithm 1. Figure 1 illustrates the difference between always starting at position 1 ($\forall i, k_i = 0$) and using our UNIFPE strategy.

This approach is reminiscent of SHAPE (Kiyono et al., 2021); while SHAPE chooses the offset k_i uniformly at random in a fixed interval to simulate relative PEs, we sample k_i non-uniformly to ensure that all indexes are equally represented in training.

5 Experimental Settings

5.1 Datasets

For our experiments, we prepare multiple sets of parallel pseudo-documents based on the EN–FR part of the TEDtalks corpus (Cettolo et al., 2012).

Training and validation sets Our training set consists of pseudo-documents from both the training and validation splits of IWSLT-2016.⁹ Our goal is to simulate real corpora of parallel documents with source documents shorter than a certain length l_{max} – using $l_{max} = 1024$. We split all document pairs whose source side is longer than 1024 tokens into fragments.¹⁰ For each document pair, we iterate the following procedure: (1) sample a maximum pseudo-document length l'_i following the same Gaussian-like length distribution as the full TED talks with $l'_i < l_{max}$; (2) concatenate consecutive sentence pairs up to l'_i to form a training pseudo-documents s_i . The resulting distribution of document lengths is displayed in Figure 3. The development set is built similarly, using document pairs from IWSLT tst2010 and tst2011. We denote these training datasets as TED-G (G for Gaussian). As discussed in Section 4, we consider another dataset generation strategy, which produces a more balanced length distribution, for which we do as above but we sample uniformly:

 $l'_i \sim U(128, l_{max})$.¹¹ Fine-tuning with the resulting **TED-U** corpus allows us to contrast two distributions with differences in document length.

Test sets To evaluate MT systems for their ability to handle documents of varying sizes and extrapolate beyond the training samples, we build a series of test sets of increasing document lengths. For each document in IWSLT **tst2014**, **tst2015**, **tst2016** and **tst2017**, we accumulate consecutive sentence pairs into parallel pseudo-documents such that all resulting source texts have a length close to l_{max} , with $l_{max} \in \{256, 512, 1024, 1200, 1600, 2048\}$.¹² Contrarily to training sets, test sets are homogeneous in length. Statistics are in Table 1 with more details in Table 8. Evaluation is always performed with complete original talks, after concatenating and aligning all the corresponding parts.

5.2 Models

We used the UNIFPE algorithm to fine-tune two pre-trained MT systems that were not trained with TED talks. As UNIFPE is designed for APEs, we considered NLLB200-DISTILLED-600M¹³ or NLLB for short (Costa-jussà et al., 2024) as a representative encoder-decoder model based on APEs. NLLB is a 12-layer encoder-decoder multilingual MT model pre-trained in 200 languages. We used the *HuggingFace* implementation which relies on sinusoidal APEs (Vaswani et al., 2017). We denote MT systems trained on **TED-U** (resp. **TED-G**) as FT-NLLB-U (resp. FT-NLLB-G), and UNIF-NLLB-U (resp. UNIF-NLLB-G) when fine-tuning with UNIFPE.

We also experiment with an LLM-based architecture, TOWERBASE-7B¹⁴ (Alves et al., 2024) (TOWERBASE for short), derived from Llama2 using translation-related tasks. TOWERBASE uses RoPE (Su et al., 2024) to encode RPEs. As mentioned by Peng et al. (2024), they nonetheless encode some form of APE signal in some dimensions, and may therefore be also mildly impacted by the PE training distribution. We denote FT-TOWER-U (resp. FT-TOWER-G) and UNIF-TOWER-U (resp. UNIF-TOWER-G) the model fine-tuned on **TED-U** (resp. **TED-G**) without or with UNIFPE.

Both models were pretrained with large amounts of EN–FR data; we focus exclusively on the EN into FR direction. Details on fine-tuning and decoding parameters can be found in Appendix A.4.

6 Results and Analyses

6.1 Length Issues

We report the ds-BLEU (Table 2) and COMET (Appendix, Table 6) scores of the pretrained models NLLB and TOWERBASE for multiple testsets, varying the average input segment lengths from one sentence to the maximum input length used in training.¹⁵ For NLLB, we observe a drop of around 10 ds-BLEU points and about 0.2 COMET scores

¹⁴https://huggingface.co/Unbabel/ TowerBase-7B-v0.1

¹¹Short pseudo-documents continue to be slightly overrepresented, because the last pseudo-document in any given talk is often strictly shorter than the desired length l'_i .

 $^{^{12}\}mathrm{At}$ the end of each talk, we concatenate the last parallel sentences into the last pseudo-document if they are shorter than 50 to avoid exceedingly short parallel sequences.

¹³https://huggingface.co/facebook/

nllb-200-distilled-600M

¹⁵As explained in Section 3.2, these COMET scores require the realignment of target sentences with the reference.

Table 4: Average difference (and p-values) in **ds-BLEU** (top) evaluated on full TED talks and $100 \times COMET$ (bottom) evaluated on realigned sentences for NLLB. Left: scores without and with UNIFPE; right: scores of fine-tuning on **TED-U** (U) or **TED-G** (G).

when translating test sets of $l_{max} = 256$ instead of isolated sentences. Scores and their associated brevity penalties (BPs) only get worse with larger context lengths. For TOWERBASE, the decrease in BLEU is more progressive, with a sharp decline for all testsets for $l_{max} > 1024$. The related COMET scores plummet immediately with the context size of 256. Even though TOWERBASE is based on Llama2, which accepts inputs up to 4096 tokens, the continued-pretraining mostly uses isolated sentences, which introduces an inductive bias affecting its ability to translate long texts.

As expected, document-level fine-tuning (DLFT) has a strong positive impact (see Appendix, Table 11). However, the length issues remain.

Table 5: Average difference (and p-values) of $100 \times \text{COMET}$ -score evaluated on 794 sentence pairs, translated at different positions by NLLB-based systems (top) and TOWERBASE-based systems (bottom).

Length Bias We performed paired comparisons for the translation of our test sets with increasing text lengths for each MT system as presented in Section 3.3. Results are given in Table 3, where a positive difference (e.g. 9.2 for NLLB in line "sent-256") means that the translation of shorter segments (here: sentences) yield better scores than that of longer ones (256 tokens). Scores in the same column are comparable. Except for a handful of configurations, translating longer texts is never better than translating short ones. We conclude that in our experimental settings, the disadvantages associated with long inputs (Section 3.1) overwhelm the benefits of a complete context. These length issues result in large score degradations and are not easily fixed by simple manipulation of PEs. We also observe that results obtained with COMET and ds-BLEU sometimes disagree. These cases are rare, though, suggesting that our results are robust. **Document-level Tuning with UNIFPE** Again using the paired comparison methodology, we compare the performance of DLFT with and without UNIFPE. As shown in the left part of Table 4, finetuning using UNIFPE leads to steady improvements in translation scores for all test lengths, especially for systems fine-tuned with the unbalanced corpus (**TED-G**). The only exception is for sentence-level translations, which remain marginally better using standard DLFT than with UNIFPE. As Tables 11 to 15 show, these improvements remain moderate, and the length issues continue to strongly impact translation scores, especially for test documents of 1024 tokens or more.

For TOWERBASE, UNIFPE does not yield any significant difference with standard DLFT (see Appendix, Table 16), likely because this model relies on RPEs. From these comparisons, we conclude that UNIFPE partly resolves length issues for NLLB, but hardly changes the situation for TOWERBASE.

Impact of Data Distribution In the right part of Table 4, we evaluate the impact of the length distribution during fine-tuning for NLLB: the balanced distribution (TED-U) slightly but consistently underperforms the use of TED-G for short documents (fewer than 512 tokens), a trend that is reversed for longer documents with strong improvement (over 768 tokens). Manipulating the distribution of PEs with UNIFPE reduces the gap between the two finetuning corpora and makes the model more robust to document lengths rarely observed (or even unobserved) during fine-tuning. This analysis again reveals small differences between using ds-BLEU and COMET scores: in three cases out of 32 comparisons (marked in bold), one metric detects a difference that is non-significant for the other.

6.2 Position Bias

To investigate potential translation issues related to large position indices, we collected the 794 sentences that come from the final part of long talks and for which varying the window length also varied the position index. For each of them, we have seven translations, corresponding to positions $\{p_0^j, \ldots, p_6^i\}, j \in \{1, \ldots, 794\}$. The average values for $\{p_0^j, \ldots, p_6^i\}$ are $\{p_0, \ldots, p_6\} =$ [66, 173, 262, 335, 585, 779, 1477]. For this subset of sentences, we performed a paired t-test to compare the impact of the position on the translation score (using COMET as the only metric). We observe in Table 5 that in almost all comparisons but two, a small position index is preferable to a larger one. This suggests that one of the main challenges faced by *Doc2Doc* with large context lengths is to control the quality degradation for the final parts of the input text. Here again, UNIFPE slightly mitigates the problem for NLLB models, but no such improvement is observed for TOWERBASE.

6.3 Repeated *n*-grams in Translation

One obvious problem with holistic translations produced by NLLB is the generation of outputs that are too short. A closer look at translation outputs also reveals that outputs contain many instances of repeated texts, usually occurring in the final part of the translation. To quantify this problem, we compute the percentage of translations of pseudodocuments in which the repetition of a long *n*-gram (with $n \ge 10$) is detected. Detailed results are in Appendix, Table 9: for all systems and fine-tuning strategies, the percentage of repetitions increases with the length, a problem that seems (for large text lengths) slightly more severe for TOWERBASE, which has a much better BP, than NLLB.

7 Conclusion

In this work, we have studied the ability of current MT architectures to handle long input texts, ideally entire documents, and to translate them holistically. Our analyses are based on systematic comparisons of translation outputs computed with varying input lengths, which are then evaluated with two automatic metrics. They consistently show that, even when the test document lengths match that of the training set and remain within the model limits, the translation scores tend to decrease with the source length, a degradation that mostly impacts sentences occurring far from the document start. We also show that manipulating the training distribution of lengths or PEs has a positive effect for APE-based models, which vanishes in RoPE-based models like TOWERBASE. These results finally confirm the robustness of sentence-level baselines. They hint at the need to improve existing models to truly benefit from the potential of document-level MT, for instance by constraining the attention mechanism to simulate a form of sentence alignment, by improving the memorization capacities of existing architectures, or by ensuring that the generation algorithm does not eventually get trapped in repetition loops. These are some of the directions we wish to explore in future work.

8 Limitations

The empirical observations reported in this paper are only based on one single language direction, and one domain (TEDtalks). This experimental design is motivated by (a) the fact that French-English is considered an easy pair for MT, with large sets of parallel training data; (b) TEDtalks data are a standard benchmark for document-level MT, and crucially contain very long parallel documents, allowing us to implement our evaluation methodology on a large range of length values. Furthermore, these datasets are not included in the training data of our models. We contend that the length issues observed in these favorable conditions for two representative systems would only be worse for more difficult or less-resourced language pairs.

9 Ethics Statement

This study has been performed with standard benchmarks and open-weight models. We do not see any ethical problems with this work.

10 Carbon Impact Statement

The experiments were conducted on a private infrastructure using a single A100 SXM4 GPU, with a carbon efficiency of 0.432 kgCO₂eq/kWh. The average time required for fine-tuning and checkpoint selection was 14.21 hours for the four NLLB models, and 5.6 hours for the TOWERBASE models. The average emissions are estimated to be 2.45 kgCO₂eq for NLLB-based models and 0.97 kgCO₂eq for models derived from TOWERBASE, with no offset applied. These estimations were based on the Machine Learning Impact calculator¹⁶ (Lacoste et al., 2019).

A Appendix

A.1 The UNIFPE Algorithm

The UNIFPE algorithm sketched in Section 4.2 is formalised in Algorithm 1.

```
Data: l_i: The input length
Data: M: The target max context length
Data: List<sub>p_k</sub>: the distribution of p_k for each offset k
        in [0, M - l_i]
\operatorname{List}_{\operatorname{Pk}} \longleftarrow Initialized to 0 for each element
         |M/l_i| nb. of possible non-zero p_k
m \leftarrow
R_n \leftarrow the remainder of M divided by l_i
p_0 \leftarrow \frac{1}{m} the probability of each non-zero p_k
if M < 2l_i then
     \text{List}_{p_k} \longleftarrow p(k'=0) = 1 \text{ i.e. } p_{k=0} = 1
else
      k^* \longleftarrow a random integer in [0, m)
      for k \in [0, M - l_i] do
            if k \% l_i == 0 and k < k^* then
                 \text{List}_{p_k} \longleftarrow p(k'=k) = p_0
            end
            if (k - R_n) \% l_i == 0 and
              k^* < k \leq M - l_i then
               \text{List}_{\mathbf{p}_{\mathbf{k}}} \longleftarrow p(k'=k) = p_0
            end
      end
end
return List_{Pk}
```

Algorithm 1: UNIFPE: the pseudo-uniform position indices mapping algorithm.

A.2 A Call for Correctly Using BLEU Scores

As illustrated in Figure 2, d-BLEU and ds-BLEU are always larger than BLEU. When BLEU decreases due to the degradation of translation quality, d-BLEU remains stable because of the higher probability to find n-gram matches in longer sequences. In contrast, ds-BLEU consistently decreases when BLEU diminishes, as it applies a macro-average to compute the corpus-level score, which is more sensitive to the translation quality of each document

than d-BLEU. Therefore, d-BLEU, ds-BLEU and BLEU are not comparable and d-BLEU is not suitable for analysing length issues in document-level evaluation of MT.

Figure 2: BLEU, ds-BLEU and d-BLEU scores for IWSLT **tst2015**, translating and evaluating *pseudo-documents* of increasing lengths [256, 512, 768, 1204], using FT-NLLB-U (top) and UNIF-TOWER-U (bottom). Note that d-BLEU is computed for pseudo-documents while ds-BLEU is computed for concate-nated full talks.

A.3 Data Statistics and Other Details

The full data statistics are in Tables 7 and 8. All the full TED talks in our corpora start with the title, then the description and the talk before being split into pseudo-documents. Tags <description> and <title> are removed. When preparing our training and validation sets **TED-U** and **TED-G** (see Section 5.1), if concatenating the last sentence pair (x_n, y_n) into the current pseudo-document pair exceeds l_{max} , (x_n, y_n) will yield a single parallel sequence, to respect the maximum length l_{max} . The length distribution is illustrated in Figure 3.

A.4 Experimental Settings

This section presents detailed experiment settings for fine-tuning NLLB and TOWERBASE.

For NLLB, we fine-tuned the pretrained model with learning rate 5e - 4, 500 warm-up steps, 4 parallel pseudo-documents per batch and 32 gradient accumulation steps. An early stopping criterion

Figure 3: Source document length distribution in the training set of **TED-G** (top) and **TED-U** (bottom).

with a patience of 5 epochs is also applied, according to the d-BLEU evaluated on the validation set. For inference on test sets, the beam size is set to 5 and the batch size is set to 4.

For TOWERBASE, We performed supervised fine-tuning using QLoRA (Dettmers et al., 2023) and bfloat16.¹⁷ The batch size is 8 with 2 gradient accumulation steps. The learning rate is 2e - 5adjusted by a *cosine* schedule, without warm-up steps nor packing. We fine-tuned the model for two epochs and saved checkpoints every 50 steps in the second epoch. We then chose the checkpoint with the best d-BLEU on the validation set. The inference is performed without additional in-context

examples, with bfloat16 and greedy search.

A.5 Detailed Evaluation Results

The paired comparison and the complete BLEU and COMET scores for each test set are given in Tables 11 to 15.

Document-level Fine-tuning Table 11 reports average differences of automatic scores between fine-tuned MT systems and the corresponding pretrained models (NLLB or TOWERBASE), for varying test document lengths. ds-BLEUs are averaged over 52 complete TED talks and COMET scores are averaged over 5, 103 sentences. Finetuning significantly improves over base conditions for all lengths, with larger increases for longer test texts, where the baseline scores were initially very poor. Both metrics yield consistent conclusions, except for the sentence-level assessment of NLLB fine-tuned on **TED-U**, which is slightly worse than the baseline according to ds-BLEU (-0.8), but for which COMET detects no difference. For TOWER-BASE, DLFT is always beneficial.

Analysing the Repetitions The analysis of *n*-gram repetitions is given in Table 9.

Realignment Issues Since the COMET score is sentence-based, its computation requires a realignment between hypotheses and reference sentences in the Doc2Doc scenario. However, due to issues with long documents, translation hypotheses can be incomplete, resulting in empty alignment for some sentences. These untranslated sentences often occur in the final part of long documents. Table 10 displays the statistics of empty alignments across all the 5, 103 sentences. This issue is more severe for NLLB models than TOWERBASE models, which is consistent with the poor BP reported in Tables 12 and 13.

¹⁷The prompt for fine-tuning is "Translate the following text from English into French.\nEnglish: SRC\nFrench: TGT", and the zero-shot prompt for the pretrained model TOWER-BASE is "English: SRC\nFrench:".

Table 11: Average difference (and p-values) in ds-BLEU or $100 \times \text{COMET}$ between fine-tuned models (FT) and the corresponding pretrained models NLLB (top) and TOWERBASE (bottom). U and G denote the corpora **TED-U** and **TED-G** respectively. Positive values indicate that the fine-tuned model improves over the baseline.

Table 16: Average difference (and p-value of paired t-test) of ds-BLEU (top) evaluated on concatenated full TED talk and $100 \times \text{COMET}$ (bottom) evaluated on realigned sentences, between FT-TOWERBASE (FT) and UNIF-TOWERBASE (Unif) trained on **TED-U** (U) or **TED-G** (G).
