Abstract

Graph neural networks (GNNs) have emerged as an effective tool for fraud detection, identifying fraudulent users, and uncovering malicious behaviors. However, attacks against GNN-based fraud detectors and their risks have rarely been studied, thereby leaving potential threats unaddressed. Recent findings suggest that frauds are increasingly organized as gangs or groups. In this work, we design attack scenarios where fraud gangs aim to make their fraud nodes misclassified as benign by camouflaging their illicit activities in collusion. Based on these scenarios, we study adversarial attacks against GNN-based fraud detectors by simulating attacks of fraud gangs in three real-world fraud cases: spam reviews, fake news, and medical insurance frauds. We define these attacks as multi-target graph injection attacks and propose MonTi, a transformer-based Multi-target one-Time graph injection attack model. MonTi simultaneously generates attributes and edges of all attack nodes with a transformer encoder, capturing interdependencies between attributes and edges more effectively than most existing graph injection attack methods that generate these elements sequentially. Additionally, MonTi adaptively allocates the degree budget for each attack node to explore diverse injection structures involving target, candidate, and attack nodes, unlike existing methods that fix the degree budget across all attack nodes. Experiments show that MonTi outperforms the state-of-the-art graph injection attack methods on five real-world graphs.

Introduction

Recent endeavors have highlighted the power of Graph Neural Networks (GNNs) for fraud detection (Dou et al. 2021; Xu et al. 2022). In fraud detection tasks, complex interactions of fraudsters can be effectively modeled using graphs, and frauds are typically represented as nodes corresponding to individuals with malicious intentions. GNN-based fraud detection methods aim to determine whether the nodes are fraudulent or benign. Meanwhile, it has been reported that adversarial attacks can cause GNNs to malfunction across various domains, including recommender systems and social network analysis (Chen et al. 2022a; You et al. 2023; Huang and Li 2023; Shao et al. 2023; Wang et al. 2023a). Those works consider vanilla GNNs as victim models,

e.g., GCN (Kipf and Welling 2017), GraphSAGE (Hamilton, Ying, and Leskovec 2017), and GAT (Veličković et al. 2018). On the other hand, various tailored GNNs for fraud detection have recently been developed to filter the camouflaged fraudsters, such as CARE-GNN (Dou et al. 2020), PC-GNN (Liu et al. 2021), and GAGA (Wang et al. 2023c). However, vulnerabilities of these GNN-based fraud detectors to adversarial attacks remain unexplored.

It has been recently observed that frauds are increasingly organized into gangs or groups exhibiting collusive patterns to carry out fraudulent activities more effectively with reduced risk (Wang et al. 2023b; Yu et al. 2023; Ma et al. 2023). For example, in the medical insurance domain, fraudsters may collaborate with doctors or insurance agents to obtain fake diagnoses. On online review platforms, fraudsters could create multiple fake reviews using different IDs. On social media platforms, fraudsters can spread misinformation by using multiple fake accounts. We design these three attack scenarios where fraud gangs attack GNN-based fraud detectors to make them misclassify the fraud nodes as benign. Furthermore, to simulate the scenarios, we create datasets and target sets that consist of fraud nodes grouped based on metadata or relations in real-world graphs.

In this work, the adversarial attack on GNN-based fraud detectors by fraud gangs is defined as a multi-target graph injection attack. We adopt a graph injection attack, as it is more feasible than a graph modification attack, which re-

quires privileged access to alter existing structures (Chen et al. 2022b). As illustrated in Figure 1, in our attack scenarios, a fraud gang attempts to deceive the detector by injecting malicious nodes (i.e., attack nodes) into the original graph, causing their fraud nodes to be misclassified by increasing the scores of being benign. We consider a black-box evasion attack, where the attacker can access only the original graph, partial labels, and a surrogate model, and the attack occurs during the victim model’s inference phase (Sun et al. 2023).

Existing methods (Tao et al. 2021; Zou et al. 2021; Wang et al. 2022) have focused on adversarial attacks for randomly grouped target nodes. However, fraud nodes are often organized into gangs to camouflage their illicit activities. While the existing methods have investigated attacks where vanilla GNNs are employed as victim models, GNN-based fraud detectors are tailored to address heterophily induced by fraud nodes, making them more difficult to attack than vanilla GNNs. To overcome the limitations of these existing methods in our scenario, we propose MonTi, a transformer-based Multi-target one-Time graph injection attack model.

MonTi significantly differs from the existing graph injection attack methods in several aspects, as summarized in Table 1. The existing methods, such as TDGIA (Zou et al. 2021), Cluster Attack (Wang et al. 2022), and G²A2C (Ju et al. 2023), inject multiple attack nodes sequentially, fixing the graph structure at each step. Those approaches fix the degree budget across all attack nodes due to the lack of information about future steps, limiting their flexibility and efficiency. In contrast, MonTi injects all attack nodes at once, adaptively assigning the degree budget for each attack node to explore diverse structures among target, candidate, and attack nodes. Furthermore, the existing methods, including G-NIA (Tao et al. 2021), overlook interactions within target nodes and among attack nodes, which are crucial for modeling the intricate relationships within a fraud gang and attack nodes. Additionally, the existing methods sequentially generate attributes and edges of attack nodes, only considering a one-way dependency, which fails to model collusive patterns of fraud gangs. On the other hand, MonTi employs a transformer encoder to effectively capture interdependencies within target and attack nodes, and between attributes and edges. Our contributions are summarized as follows:

- To the best of our knowledge, our work is the first study to investigate the vulnerabilities of GNN-based fraud detectors and also the first study on graph injection attacks for multiple target nodes organized by groups.
- We propose a graph injection attack method MonTi, which generates attributes and edges of all attack nodes at once via the adversarial structure encoding transformer.
- MonTi can explore adversarial injection structures comprehensively by generating adversarial edges with adaptive degree budget allocation for each attack node.
- Experimental results demonstrate that MonTi substantially outperforms the state-of-the-art graph injection attack methods on five real-world graphs.¹

Table 1: Comparison of graph injection attack methods. We mark whether victim models are vanilla GNNs (Van) or GNN-based fraud detectors (Frd); target nodes are randomly grouped (Rnd) or fraud gangs (Frd); multiple attack nodes are injected sequentially (Seq) or at once (One); degree budget per attack node is fixed (Fix) or adaptively assigned (Ada); attribute-edge interdependency is considered or not.

Related Work

Graph-based Fraud Detection The majority of graph-based fraud detection methods adopt GNNs and define this task as a problem of classifying nodes into two categories: fraud or benign (Huang et al. 2022; Shi et al. 2022; Chai et al. 2022; Li et al. 2022b,a). In fraud graphs, fraud nodes are much fewer than benign nodes, resulting in a class imbalance problem. In addition, fraud nodes tend to connect with or imitate the attributes of benign nodes to hide their malicious activities. Such behavior introduces heterophily (Zhu et al. 2020), which causes vanilla GNNs to fail in detecting fraud nodes. To address the class imbalance and heterophily in fraud graphs, recent approaches have introduced learnable neighborhood samplers (Dou et al. 2020; Liu et al. 2021), utilized Beta wavelet transform (Tang et al. 2022; Wu et al. 2023) and proposed group aggregation strategies (Wang et al. 2023c; Duan et al. 2024). Despite the recent advancements, vulnerabilities of GNN-based fraud detectors to adversarial attacks have not yet been studied.

Adversarial Attacks on Graphs It has been shown that even a few adversarial modifications on graphs can significantly degrade the performance of GNNs (Zügner, Akbarnejad, and Günnemann 2018; Bojchevski and Günnemann 2019; Zügner and Günnemann 2019; Ma et al. 2021; Ma, Deng, and Mei 2022; Lin, Blaser, and Wang 2022). Graph injection attacks have emerged focusing on more practical settings, where attackers inject new malicious nodes instead of modifying existing nodes and edges (Wang et al. 2020a; Sun et al. 2020). Recent developments include learning attribute and edge generators to target unseen nodes (Tao et al. 2021), introducing defective edge selection strategies (Zou et al. 2021), regarding graph injection attacks as clustering tasks (Wang et al. 2022), and employing the advantage actor-critic framework (Ju et al. 2023). More detailed discussions on related work are provided in Appendix A.

Problem Definition

An undirected attributed graph is defined as $G = (\mathcal{V}, \mathcal{E}, \mathcal{X})$ where \mathcal{V} is a set of n nodes, $\mathcal{E} \subset \mathcal{V} \times \mathcal{V}$ is a set of edges, and \mathcal{X} is a set of D -dimensional node attribute vectors. For a node $v \in \mathcal{V}$, we represent its attribute vector as $\mathbf{x}_v \in \mathcal{X}$ and

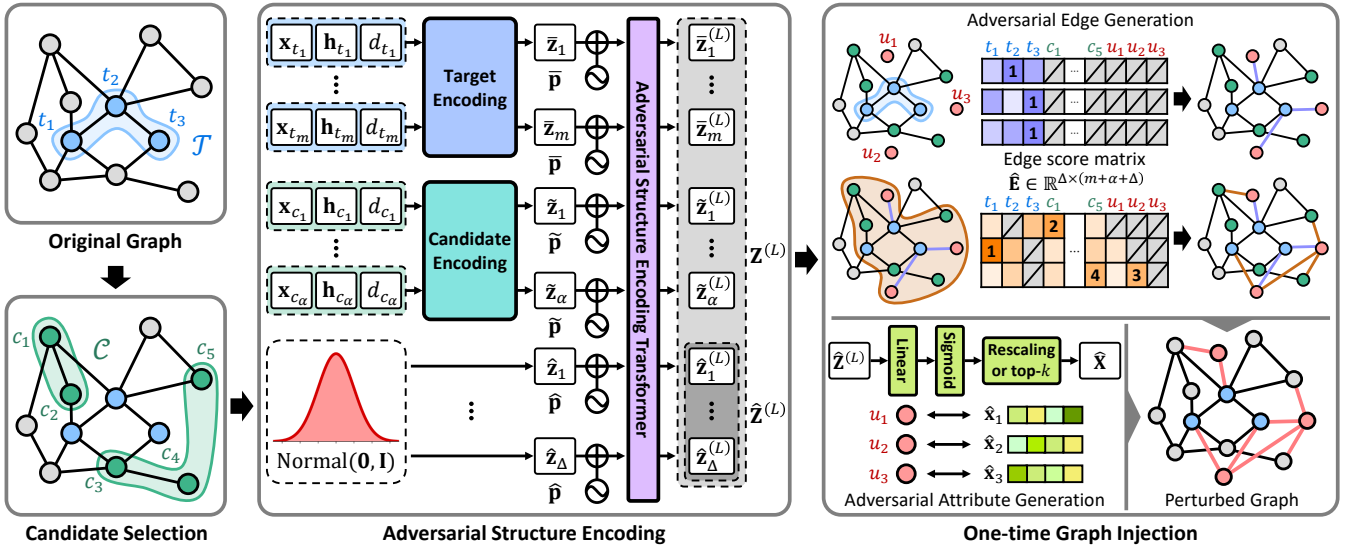

Figure 2: Overview of MonTi. Given the original graph and the target set, MonTi selects candidate nodes among K -hop neighbors of target nodes utilizing a learnable scoring function. Then, MonTi calculates the intermediate node representations of target, candidate, and attack nodes by the adversarial structure encoding transformer. Based on those intermediate representations, adversarial attributes and edges for injection are simultaneously generated.

its label as $y_v \in \{0, 1\}$ where $y_v = 1$ indicates v is a fraud and $y_v = 0$ indicates v is benign. $\mathcal{Y} = \{y_v | v \in \mathcal{V}\}$ denotes a set of node labels. We represent a GNN-based fraud detector as $f_\theta(\cdot)$ where θ indicates learnable parameters. The fraud score vector $\mathbf{s}_v \in \mathbb{R}^2$ and the predicted label $\hat{y}_v \in \{0, 1\}$ are calculated by $\mathbf{s}_v = f_\theta(G, v) = \text{MLP}(\Phi(G, v))$ and $\hat{y}_v = \arg \max_i s_{v,i}$ where MLP is a multi-layer perceptron, $\Phi(\cdot)$ denotes a GNN encoder and $s_{v,i}$ denotes the i -th element of \mathbf{s}_v . We formulate the objective function of the fraud detector as $\max_\theta \sum_{v \in \mathcal{V}} \mathbb{I}(\hat{y}_v = y_v)$ where $\mathbb{I}(\cdot)$ is an indicator function. Most GNN-based fraud detectors utilize label information based on domain-specific knowledge, employing (semi-)supervised approaches (Dou et al. 2020; Liu et al. 2022). As the first study of adversarial attacks against GNN-based fraud detectors, we assume that graphs are single-relational, in line with existing studies of adversarial attacks on graphs (Tao et al. 2021; Zou et al. 2021; Wang et al. 2022; Ju et al. 2023).

A graph injection attack injects attack nodes \mathcal{V}_{in} with attributes \mathcal{X}_{in} and adversarial edges $\mathcal{E}_{\text{in}} \subset (\mathcal{V}' \times \mathcal{V}') \setminus (\mathcal{V} \times \mathcal{V})$ into the original graph $G = (\mathcal{V}, \mathcal{E}, \mathcal{X})$ where $\mathcal{V}' = \mathcal{V} \cup \mathcal{V}_{\text{in}}$. We define the perturbed graph as $G' = (\mathcal{V}', \mathcal{E}', \mathcal{X}')$ where $\mathcal{E}' = \mathcal{E} \cup \mathcal{E}_{\text{in}}$ and $\mathcal{X}' = \mathcal{X} \cup \mathcal{X}_{\text{in}}$. The multi-target graph injection attack against a GNN-based fraud detector aims to make fraud nodes in the target set $\mathcal{T} \subset \mathcal{V}$ misclassified. For a node $v \in \mathcal{V}$, let $\mathbf{s}'_v = f_{\theta^*}(G', v)$ where $\theta^* = \arg \min_\theta \mathcal{L}_{\text{train}}(f_\theta, G, \mathcal{D})$, $\mathcal{L}_{\text{train}}$ is a training loss of $f_\theta(\cdot)$, and $\mathcal{D} \subset \mathcal{Y}$ is a node label set for training. The objective function of the multi-target graph injection attack is:

$$\min_{G'} \sum_{t \in \mathcal{T}} \mathbb{I} \left(\arg \max_i s'_{t,i} = y_t \right) \text{ st. } |\mathcal{V}_{\text{in}}| \leq \Delta, |\mathcal{E}_{\text{in}}| \leq \eta \quad (1)$$

where Δ and η denote node and edge budgets, respectively.

Multi-target One-time Graph Injection Attack

We propose MonTi (Figure 2), a graph injection attack model with a transformer-based architecture. MonTi utilizes self-attention to capture interactions among target, candidate, and attack nodes, simultaneously generating attributes and edges of attack nodes to reflect their interdependencies. In addition, by generating edges of all attack nodes at once, MonTi enables flexible budget allocation for each node.

Adversarial Structure Encoding

Three types of contexts can affect multi-target graph injection attacks: target nodes $\mathcal{T} = \{t_1, \dots, t_m\}$, attack nodes $\mathcal{V}_{\text{in}} = \{u_1, \dots, u_\Delta\}$, and candidate nodes. We define $\mathcal{N}^{(K)} \subset \mathcal{V}$ as a set of K -hop neighbors of the target nodes, excluding the target nodes themselves. From $\mathcal{N}^{(K)}$, we select α nodes to form a set of candidate nodes $\mathcal{C} = \{c_1, \dots, c_\alpha\} \subset \mathcal{N}^{(K)}$. The neighborhood of target nodes provides information on how to propagate malicious messages within a GNN-based architecture. MonTi employs multi-head self-attention to learn intermediate representations for nodes in \mathcal{T} , \mathcal{V}_{in} , and \mathcal{C} to capture interactions among these contexts, distinguishing their respective roles.

Candidate Selection The size of $\mathcal{N}^{(K)}$ can drastically increase depending on the target nodes, making it computationally inefficient and challenging to find the optimal G' . Therefore, when the number of possible candidate nodes exceeds the threshold n_c , MonTi selects candidate nodes to narrow the search space with a learnable scoring function \mathcal{J} ; otherwise, all nodes are considered as candidate nodes. To incorporate the class distribution learned by GNN architectures, MonTi utilizes a surrogate GNN model pretrained on the original graph. MonTi calculates candidate scores for

all $v \in \mathcal{N}^{(K)}$ by integrating node attributes and graph topology with those of the target nodes using the surrogate GNN:

$$\mathcal{J}(G, v) = \text{MLP}(\sigma([\mathbf{q}_v \parallel \mathbf{m}_v \parallel \mathbf{h}_v \parallel \mathbf{h}_{\mathcal{T}}])) \quad (2)$$

where $\mathbf{q}_v = \text{MLP}(\mathbf{x}_v) \in \mathbb{R}^{D_H}$, D_H is the dimension of node representation, $\mathbf{m}_v = \text{MLP}([d_v \parallel \beta_v]) \in \mathbb{R}^{D_H}$, d_v is the degree of node v , β_v is the number of target nodes directly connected to v , $\mathbf{h}_v = \Phi^*(G, v) \in \mathbb{R}^{D_H}$, Φ^* is a pretrained GNN encoder of the surrogate model, $\mathbf{h}_{\mathcal{T}} = \text{READOUT}(\{\mathbf{h}_t \mid t \in \mathcal{T}\}) \in \mathbb{R}^{D_H}$, $\text{READOUT}(\cdot)$ is a pooling function, \parallel is a horizontal concatenation, and σ is the activation function. We adopt the mean operation as a pooling function. Based on the calculated scores, the top- n_c nodes are selected as candidate nodes. To solve the optimization problems of discrete selection in MonTi, we adopt the Gumbel-Top- k technique (Jang, Gu, and Poole 2017; Kool, Hoof, and Welling 2019) coupled with the straight-through estimator (Bengio, Léonard, and Courville 2013).

Target and Candidate Encoding To exploit the structural information of target and candidate nodes, we introduce learnable encodings with three different factors of each node v related to the attack: raw attributes \mathbf{x}_v , degree d_v , and the GNN representation \mathbf{h}_v . We employ the raw attributes to explicitly take into account the node itself. The node degree is utilized to indirectly measure the susceptibility of the node to the change of its neighbors. We use the GNN representation to capture an inherent class distribution learned by the surrogate GNN and topological information of the node. With a learnable target encoding function $\bar{\mathcal{P}}$, a target encoding $\bar{\mathbf{z}}_i = \bar{\mathcal{P}}(\mathbf{x}_{t_i}, d_{t_i}, \mathbf{h}_{t_i})$ for a target node $t_i \in \mathcal{T}$ is computed by projecting and integrating all three factors:

$$\bar{\mathbf{z}}_i = \text{MLP}(\sigma([\overline{\mathbf{W}}\mathbf{x}_{t_i} + \overline{\mathbf{b}}_1] \parallel [\overline{\mathbf{w}}d_{t_i} + \overline{\mathbf{b}}_2] \parallel \mathbf{h}_{t_i})) \quad (3)$$

where MLP transforms the input into \mathbb{R}^{D_H} , $\overline{\mathbf{W}} \in \mathbb{R}^{D_H \times D}$, $\overline{\mathbf{w}} \in \mathbb{R}^{D_H}$, $\overline{\mathbf{b}}_1 \in \mathbb{R}^{D_H}$, $\overline{\mathbf{b}}_2 \in \mathbb{R}^{D_H}$. Similarly, we compute a candidate encoding $\tilde{\mathbf{z}}_i = \tilde{\mathcal{P}}(\mathbf{x}_{c_i}, d_{c_i}, \mathbf{h}_{c_i})$ for a candidate node $c_i \in \mathcal{C}$ where $\tilde{\mathcal{P}}$ denotes a learnable candidate encoding function. Note that the parameters of $\bar{\mathcal{P}}$ and $\tilde{\mathcal{P}}$ are distinct.

Adversarial Structure Encoding Transformer We propose to adopt the transformer (Vaswani et al. 2017) encoder to learn the intermediate node representations of the target, candidate, and attack nodes for adversarial attribute and edge generation. Each attack node $u_i \in \mathcal{V}_{\text{in}}$ is initialized with the representation $\hat{\mathbf{z}}_i \in \mathbb{R}^{D_H}$ sampled from a standard Gaussian distribution. The input sequence for the adversarial structure encoding transformer is defined as $\mathbf{Z}^{(0)} = [\bar{\mathbf{Z}}^{(0)} \parallel \tilde{\mathbf{Z}}^{(0)} \parallel \hat{\mathbf{Z}}^{(0)}] = [\bar{\mathbf{z}}_1 \cdots \bar{\mathbf{z}}_m \parallel \tilde{\mathbf{z}}_1 \cdots \tilde{\mathbf{z}}_\alpha \parallel \hat{\mathbf{z}}_1 \cdots \hat{\mathbf{z}}_\Delta]$ where $\bar{\mathbf{Z}}^{(0)}$, $\tilde{\mathbf{Z}}^{(0)}$, and $\hat{\mathbf{Z}}^{(0)}$ denote the input sequence corresponding to the target, candidate, and attack nodes, respectively. We then add learnable positional encodings $\bar{\mathbf{p}}$, $\tilde{\mathbf{p}}$, $\hat{\mathbf{p}} \in \mathbb{R}^{D_H}$ to the corresponding node representations. Subsequently, $\mathbf{Z}^{(0)}$ is processed through an L -layer transformer encoder with n_h heads to obtain the final representations $\mathbf{Z}^{(L)} = [\bar{\mathbf{Z}}^{(L)} \parallel \tilde{\mathbf{Z}}^{(L)} \parallel \hat{\mathbf{Z}}^{(L)}]$. To mitigate noise from attack nodes whose edges are not formed yet, we optionally mask the attack nodes when calculating target and candidate node representations, treating this masking as a hyperparameter.

Adversarial Attribute Generation

To generate the attributes of attack nodes, we project $\hat{\mathbf{Z}}^{(L)}$ into D -dimensional space: $\mathbf{F} = \text{sigmoid}(\mathbf{W}_a \hat{\mathbf{Z}}^{(L)} + \mathbf{b}_a) \in \mathbb{R}^{D_H \times \Delta}$ where $\mathbf{W}_a \in \mathbb{R}^{D \times D_H}$ and $\mathbf{b}_a \in \mathbb{R}^D$. Depending on whether the raw attributes are continuous or discrete, \mathbf{F} is transformed into the malicious attributes in different ways.

For continuous attributes, we rescale \mathbf{F} by using the min-max vectors of raw attributes $\mathbf{x}_{\text{min}}, \mathbf{x}_{\text{max}} \in \mathbb{R}^D$ derived from the original graph. The adversarial attribute vector $\hat{\mathbf{x}}_i$ for the attack node $u_i \in \mathcal{V}_{\text{in}}$ is computed by $\hat{\mathbf{x}}_i = \mathbf{F}_i \odot (\mathbf{x}_{\text{max}} - \mathbf{x}_{\text{min}}) + \mathbf{x}_{\text{min}}$ where $\mathbf{F}_i \in \mathbb{R}^D$ denotes the i -th column vector of \mathbf{F} , and \odot denotes the element-wise product operator.

We adopt the Gumbel-Top- k technique to optimize discrete choices, such as candidate selection, discrete attribute generation, and edge generation. Following (Tao et al. 2021; Nguyen Thanh et al. 2023), we additionally utilize the exploration parameter ϵ to control the randomness. The Gumbel-Softmax for the discrete attribute generation is defined as:

$$\text{Gumbel-Softmax}(\mathbf{F}_i, \epsilon)_j = \frac{\exp((F_{ij} + \epsilon N_j)/\tau)}{\sum_{j'=1}^D \exp((F_{ij'} + \epsilon N_{j'})/\tau)} \quad (4)$$

where F_{ij} is the j -th element of \mathbf{F}_i , $N_j = -\log(-\log(U_j))$, $U_j \sim \text{Uniform}(0, 1)$ is a Uniform random variable, and τ is the temperature parameter. The Gumbel-Top- k function \mathcal{G}^a for discrete attribute generation is defined as:

$$\mathcal{G}^a(\mathbf{F}_i) = \arg \text{top-}k \underset{j}{\text{Gumbel-Softmax}}(\mathbf{F}_i, \epsilon)_j \quad (5)$$

where $\arg \text{top-}k$ function returns the indices corresponding to the k highest values of the input. Here, we set k as λ , the average count of non-zero values in the node attributes of the entire graph. Finally, the j -th element of $\hat{\mathbf{x}}_i$ becomes $\hat{x}_{ij} = \mathbb{I}(j \in \mathcal{G}^a(\mathbf{F}_i))$. We employ the straight-through estimator to optimize the discrete selection processes, allowing for gradient-based optimization with discrete elements.

Adversarial Edge Generation

To generate all adversarial edges at once within the edge budget η , we construct an edge score matrix and apply the Gumbel-Top- k . First, we project $\mathbf{Z}^{(L)}$ into edge score space:

$$\begin{aligned} \mathbf{R} &= \mathbf{W}_e \mathbf{Z}^{(L)} + \mathbf{b}_e = [\bar{\mathbf{R}} \parallel \tilde{\mathbf{R}} \parallel \hat{\mathbf{R}}] \\ &= [\bar{\mathbf{r}}_1 \cdots \bar{\mathbf{r}}_m \parallel \tilde{\mathbf{r}}_1 \cdots \tilde{\mathbf{r}}_\alpha \parallel \hat{\mathbf{r}}_1 \cdots \hat{\mathbf{r}}_\Delta] \\ &= [\mathbf{r}_1 \cdots \mathbf{r}_M] \end{aligned} \quad (6)$$

where $\mathbf{W}_e \in \mathbb{R}^{D_H \times D_H}$, $\mathbf{b}_e \in \mathbb{R}^{D_H}$, $\bar{\mathbf{R}} \in \mathbb{R}^{D_H \times m}$, $\tilde{\mathbf{R}} \in \mathbb{R}^{D_H \times \alpha}$, $\hat{\mathbf{R}} \in \mathbb{R}^{D_H \times \Delta}$, m is the number of target nodes, α is the number of candidate nodes, Δ is a node budget, and $M = m + \alpha + \Delta$. We define the edge score e_{ij} between an attack node $u_i \in \mathcal{V}_{\text{in}}$ and a node $v_j \in \mathcal{T} \cup \mathcal{C} \cup \mathcal{V}_{\text{in}}$ as the cosine similarity between their representations. Then, the edge score matrix $\hat{\mathbf{E}} \in \mathbb{R}^{\Delta \times M}$ can be written as $\hat{\mathbf{E}} = \hat{\mathbf{D}}^{-1} \hat{\mathbf{R}}^T \mathbf{R} \hat{\mathbf{D}}^{-1}$ where $\mathbf{D} = \text{diag}(\|\mathbf{r}_1\|, \dots, \|\mathbf{r}_M\|)$, and $\hat{\mathbf{D}} = \text{diag}(\|\hat{\mathbf{r}}_1\|, \dots, \|\hat{\mathbf{r}}_\Delta\|)$. To guarantee that every attack node is directly connected to the original graph, we generate at least a single edge for each attack node to one of the target nodes by applying Gumbel-Top- k with $k = 1$. For all remaining possible edges, we apply Gumbel-Top- k across the entire $\hat{\mathbf{E}}$ with $k = \eta - \Delta$. Note that edge scores corresponding to self-loops and duplicated edges are masked.

Training of MonTi

Following the previous works in graph injection attacks (Tao et al. 2021; Wang et al. 2022), we define the loss function for MonTi based on C&W loss (Carlini and Wagner 2017):

$$\min_{G'} \mathcal{L}(f_{\theta^*}, G', \mathcal{T}) = \frac{1}{|\mathcal{T}|} \sum_{t \in \mathcal{T}} \max(s'_{t,1} - s'_{t,0}, 0) \quad (7)$$

where $\mathbf{s}'_t = f_{\theta^*}(G', t) \in \mathbb{R}^2$, and $s'_{t,i}$ denotes the i -th element of \mathbf{s}'_t . We focus on increasing normal scores and decreasing fraud scores of target nodes to align with our attack scenarios. In line with our emphasis on black-box attack settings, the loss is calculated using a surrogate model.

Experiments

We compare MonTi with the state-of-the-art graph injection attack baselines on five real-world graphs.

Datasets Our experiments on multi-target graph injection attacks cover three real-world datasets: *GossipCop-S*, *YelpChi*, and *LifeIns*. *GossipCop-S* and *YelpChi* have continuous node attributes, whereas *LifeIns* contains discrete ones. Using *GossipCop* (Shu et al. 2020), which includes news articles and their Twitter engagements (Shu et al. 2020), we create *GossipCop-S* by following (Wu and Hooi 2023), linking articles tweeted by the same multiple users. *YelpChi* (Rayana and Akoglu 2015; Mukherjee et al. 2013) is a review graph where nodes represent reviews. *LifeIns* is a medical insurance graph based on real-world data provided by an anonymous insurance company. In *LifeIns*, nodes correspond to claims, and edges represent relationships pre-defined by domain experts. In experiments, we use $p\%$ of nodes as training sets, setting $p = 40$ for *GossipCop-S* and *YelpChi*, and $p = 10$ for *LifeIns*. The remaining nodes are split into validation and test sets with a ratio of 1:2, following the conventional setting in the GNN-based fraud detection (Tang et al. 2022). We create the training, validation, and test target sets with fraud nodes belonging to each split. Each target set represents a fraud gang organized based on metadata or relations in each dataset. The statistic of datasets for multi-target attacks is summarized in Table 2. More detailed descriptions of the datasets are in Appendix B.

Although MonTi is designed for multi-target attacks, we present benchmark results for single-target attacks on *OGB-Prod* (Hu et al. 2020) and *PubMed* (Sen et al. 2008) in Appendix E.1. Despite not being specifically designed for single-target attacks, MonTi achieves the highest misclassification rates on both datasets. This demonstrates the effectiveness of MonTi’s transformer-based architecture, which captures intricate interactions around a target node via adversarial structure encoding.

Budgets Due to the diverse sizes and substructures of target sets, node and edge budgets should be allocated according to the characteristics of each target set. We also impose limits on the budgets since excessively large budgets can lead to highly noticeable and easy attacks. The node budget Δ for each target set is defined as $\Delta = \max(\lfloor \rho \cdot \min(B, \bar{B}) + 0.5 \rfloor, 1)$ where ρ is a parameter to control node budgets, $B = |\mathcal{N}^{(1)} \cup \mathcal{T}|$, and \bar{B} is

	$ \mathcal{V} $	#Frauds	#Target Sets	$ \mathcal{E} $	D
<i>GossipCop-S</i>	16,488	3,898	2,438	3,865,058	768
<i>YelpChi</i>	45,900	6,656	1,435	3,846,910	32
<i>LifeIns</i>	122,792	1,264	380	912,833	1,611

Table 2: Statistic of datasets for multi-target attacks.

the average value of B across all target sets within the dataset. The edge budget η for each target set is calculated as $\eta = \Delta \cdot \max(\lfloor \min(d_{\mathcal{T}}, \xi \cdot \bar{d}) + 0.5 \rfloor, 1)$ where $d_{\mathcal{T}}$ is the average node degree of the target set, ξ is a parameter to control edge budgets, and \bar{d} is the average node degree of all nodes in the graph. Unless specifically stated otherwise, we set $\rho = 0.05$, $\xi = 0.1$ for *GossipCop-S*, $\rho = 0.05$, $\xi = 0.5$ for *YelpChi*, and $\rho = 0.2$, $\xi = 0.5$ for *LifeIns*. A detailed explanation of the rationale behind defining the budgets and analysis of the effect of ρ and ξ is provided in Appendix E.2.

Fraud Detectors, Baselines, and Implementation Details

We consider following models as surrogate and victim models: GCN (Kipf and Welling 2017), GraphSAGE (Hamilton, Ying, and Leskovec 2017), GAT (Veličković et al. 2018), CARE-GNN (Dou et al. 2020), PC-GNN (Liu et al. 2021), and GAGA (Wang et al. 2023c). Since we focus on graph injection evasion attacks where attack nodes are injected into the original graph during the inference phase, we exclude fraud detectors that cannot handle the nodes added after training, such as BWGNN (Tang et al. 2022), SplitGNN (Wu et al. 2023), and DGA-GNN (Duan et al. 2024). We use GNIA (Tao et al. 2021), TDGIA (Zou et al. 2021), Cluster Attack (Wang et al. 2022), and G²A2C (Ju et al. 2023) as attack baselines. Further details on the experimental environment and implementation details of the fraud detectors and attack baselines are available in Appendix C, and implementation details of MonTi are described in Appendix D.

Performance of Multi-target Attacks

Table 3 presents the results of multi-target attacks when the types of surrogate and victim models are the same. We repeat all experiments five times and report the average and standard deviation of the misclassification rates of all target sets weighted by their sizes, as the size varies across different target sets. `Clean` represents the misclassification rates on the original clean graphs. We see that GNN-based fraud detectors are more robust than vanilla GNNs due to their ability to handle heterophily. MonTi shows the best attack performance across all datasets, as it can search adversarial structures more extensively than other methods.

Table 4 shows the results in a more realistic and challenging scenario where GCN is the surrogate model and CARE-GNN, PC-GNN, and GAGA are victim models. MonTi outperforms all baselines, even when merely using GCN as the surrogate model. This demonstrates that MonTi effectively generalizes its attacks by comprehensively capturing and leveraging the interdependencies between node attributes and edges, as well as among target, candidate, and attack nodes. More detailed analyses are provided in Appendix E.3.

Ablation Studies and Efficiency Analysis of MonTi

Table 5 shows the results of ablation studies on *GossipCop-S* for MonTi with the same settings as in Table 4. We replace the adversarial attribute and edge generation methods with random generation. For attributes, nodes are randomly selected from the original graph, and their attributes are assigned to attack nodes (random attributes). For edges, connections are randomly created among target, candidate, and attack nodes (random edges). We remove the learnable positional encodings $\bar{\mathbf{p}}$, $\tilde{\mathbf{p}}$, and $\hat{\mathbf{p}}$ (w/o pos. encoding) and modify MonTi to select the candidates randomly (random candidates). Lastly, we fix the degree budget for each attack node (fixed budget). In conclusion, the original MonTi shows the best performance, demonstrating the importance of each component of MonTi for effective graph injection attacks. More ablation studies are presented in Appendix E.4.

We also compare MonTi with attack baselines in terms of runtime and memory usage on *GossipCop-S*, *YelpChi*, and *LifeIns*, using GCN as the surrogate model and GAGA as the victim model in Appendix E.5. Overall, MonTi is the most efficient in terms of runtime while maintaining moderate memory usage. This is because MonTi effectively

narrows the search space through candidate selection and adopts efficient matrix operations to inject all attack nodes at once. In addition, the complexity analysis of MonTi is provided in Appendix E.6.

Case Study: Effects of the Size of Fraud Gangs

To analyze vulnerabilities of GNN-based fraud detectors regarding the size of fraud gangs, we categorize target sets in *GossipCop-S* into three groups based on $B = |\mathcal{N}^{(1)} \cup \mathcal{T}|$, which reflects the size of the fraud gang. Table 6 presents the multi-target attack performance of G-NIA and MonTi for each category, using GCN as the surrogate model. The results show that the disparity in misclassification rates before and after the attack widens with increasing the size of gangs (B). This highlights the threats that large-scale fraud gangs pose to GNNs. Specifically, CARE-GNN and PC-GNN, which only filter node-level camouflages, are more vulnerable to relatively large fraud gangs ($B > 10$) compared to GAGA. Notably, the performance gap between G-NIA and MonTi becomes larger as the size of gangs increases, suggesting that MonTi can explore the complex structures that could be formed by large fraud gangs more

	CARE-GNN	PC-GNN	GAGA
Clean	48.02	55.62	21.68
random attributes	78.18	77.81	25.70
random edges	79.64	81.40	39.33
w/o pos. encoding	86.12	86.98	40.21
random candidates	88.25	88.38	39.13
fixed budget	87.28	88.66	42.17
MonTi	88.78	89.90	43.70

Table 5: Ablation studies of MonTi on *GossipCop-S* with surrogate GCN. We report misclassification rates (%).

	CARE-GNN	PC-GNN	GAGA
$B \leq 10$ (#Sets = 277)			
Clean	48.04%	54.46%	16.39%
G-NIA	49.17%	54.53%	17.75%
MonTi	58.69%	61.63%	27.95%
$10 < B \leq 1000$ (#Sets = 316)			
Clean	51.30%	58.35%	11.59%
G-NIA	56.47%	63.73%	15.18%
MonTi	83.39%	86.44%	27.97%
$B > 1000$ (#Sets = 316)			
Clean	55.00%	61.41%	28.66%
G-NIA	65.52%	70.45%	33.21%
MonTi	98.70%	98.22%	56.14%

Table 6: Multi-target attack performance on *GossipCop-S* using GCN as the surrogate model, with target sets categorized into three groups based on B . #Sets denotes the number of target sets within each category.

comprehensively than G-NIA.

To analyze cases where G-NIA fails but MonTi succeeds, we show a case study on *GossipCop-S* using target sets with $B > 1000$ and GCN as the surrogate model. We visualize the latent node representations computed by GAGA before and after the attack using t-SNE (Van der Maaten and Hinton 2008) in Figure 3 and Appendix E.7. Blue circles indicate the representations of target nodes before the attack, and orange diamonds indicate those after the attack. A blue circle and an orange diamond that correspond to the same target node are connected. Below each t-SNE visualization, we provide misclassification rates before and after the attack, the size of the target set, and B . G-NIA results in minor changes in target node representations, leading to a small increase in misclassification rates. In contrast, MonTi significantly shifts the representations from the fraud to the benign area, effectively making most target nodes misclassified.

Discussion on Defenses against MonTi

Our research aims to investigate the vulnerabilities of GNN-based fraud detectors and highlight their risks by simulating attacks of fraud gangs in practical settings. In particular, our findings suggest that GNN-based fraud detectors are especially susceptible to large-scale group attacks, which could undermine their reliability in real-world applications. We discuss potential approaches that could be beneficial to safeguarding against such threats. Our promising approach is to

Figure 3: The t-SNE visualization of the changes in the latent representations of target nodes computed by GAGA on *GossipCop-S*, incurred by G-NIA (Left) and MonTi (Right).

extend existing graph adversarial defense methods (Zhang and Zitnik 2020; Zhang et al. 2021b), such that those methods can be applied to GNN-based fraud detectors by identifying collusive patterns of fraudulent nodes. For instance, rather than solely focusing on individual nodes to detect malicious behavior, considering how the neighborhood structure around target nodes is partitioned into distinct groups could provide more effective defenses against attacks of fraud gangs. Additionally, incorporating adversarial training (Jin et al. 2020; Sun et al. 2023) with generative models could also be helpful in developing community-aware GNN-based fraud detectors. We believe that these approaches can mitigate the impact of gang-level attacks and improve the robustness of GNN-based fraud detection methods.

Conclusion and Future Work

We investigate adversarial attacks against GNN-based fraud detectors with various practical scenarios and real-world datasets. To the best of our knowledge, our work is the first study to explore such attacks against GNN-based fraud detectors and graph injection attacks for multiple target nodes formed by fraud gangs. We define this task as a multi-target graph injection attack and propose MonTi, a new adversarial attack model that injects all attack nodes at once. MonTi employs adaptive degree budget allocation for each node to explore diverse injection structures. Furthermore, MonTi simultaneously generates attributes and edges of attack nodes, considering the interdependency between them. Extensive experiments on five real-world graphs show that MonTi outperforms state-of-the-art graph injection attack methods in both multi- and single-target settings. For future work, we will extend MonTi to multi-relational graphs (Kim, Choi, and Whang 2023), as considering multiple relation types can be beneficial to effective fraud detection. We also plan to examine our work in inductive settings (Lee, Chung, and Whang 2023) where both victim and attack models do not observe test nodes and their connections during training. Moreover, we will theoretically investigate MonTi in terms of generalization bounds (Lee, Hwang, and Whang 2024).

Appendix

A Detailed Discussions on Related Work

A.1 Graph-based Fraud Detection

Graph-based fraud detection aims to identify entities associated with illicit activities by considering graph structures. It has been widely applied across various practical scenarios, such as detecting fake news (Wu and Hooi 2023; Dou et al. 2021; Xu et al. 2022), identifying spam reviews (Dou et al. 2020; Liu et al. 2021), and uncovering insurance frauds (Ma et al. 2023). Recently proposed fraud detection methods have adopted GNNs to detect malicious activities by aggregating the neighborhood information (Dou et al. 2020; Liu et al. 2021; Shi et al. 2022; Li et al. 2022b,a; Wang et al. 2023c). These GNN-based fraud detection methods define this task as a problem of classifying nodes into two categories: fraud or benign.

In fraud graphs, fraud nodes are much fewer than benign nodes, resulting in a class imbalance problem. In addition, fraud nodes tend to connect with benign nodes or imitate attributes of benign nodes to conceal their malicious activities. Such behavior introduces heterophily (Zhu et al. 2020), which makes vanilla GNNs challenging to distinguish between fraud and benign nodes. The class imbalance problem and heterophily in graphs have been raised as significant challenges in GNN-based fraud detection. CARE-GNN (Dou et al. 2020) defines this phenomenon as camouflage and addresses it by employing a neighborhood selector with reinforcement learning. FRAUDRE (Zhang et al. 2021a) introduces an imbalance-oriented classification module to address the training bias resulting from the large number of benign nodes. PC-GNN (Liu et al. 2021) devises a neighborhood sampler based on a learnable distance function, and a label-balanced graph sampler to choose neighbors for aggregation. BWGNN (Tang et al. 2022) and SplitGNN (Wu et al. 2023) alleviate the heterophily utilizing the Beta Wavelet in the lens of the spectral domain. Several methods have also been proposed to explicitly distinguish and separately leverage heterophilic and homophilic edges (Shi et al. 2022; Li et al. 2022b,a). GAGA (Wang et al. 2023c) proposes the group aggregation strategy that leverages observable labels, neighbor distances, and relationships, using a transformer encoder. DGA-GNN (Duan et al. 2024) addresses the non-additivity of node features by proposing decision tree binning encoding and introduces a dynamic grouping strategy to improve group distinguishability.

Despite the recent advancements, vulnerabilities in these GNN-based fraud detectors have not yet been studied. In this work, we investigate adversarial attacks against GNN-based fraud detectors in real-world scenarios. We focus on graph injection evasion attacks where attack nodes are injected into the original graph during the inference phase. Thus, we have excluded the following fraud detection methods from our experiments, as their inability to handle the nodes added after training hinders a fair comparison with other GNN-based fraud detectors: BWGNN (Tang et al. 2022) and SplitGNN (Wu et al. 2023) employ graph spectral filters that rely on the eigenvectors and eigenvalues of the graph laplacian matrix, which limits their ability to handle new nodes added after training. DGA-GNN (Duan et al. 2024) introduces a dynamic grouping mechanism to enhance the distinguishability of grouped messages. However, since this mechanism groups nodes based on predictions generated during training, it cannot handle new nodes added after training.

A.2 Adversarial Attacks on Graphs

Taxonomies of Adversarial Attacks on Graphs: Attack Stage and Attackers' Knowledge It has been recently highlighted that vanilla GNNs are vulnerable to adversarial attacks (Bojchevski and Günnemann 2019; Ma et al. 2021; Lin, Blaser, and Wang 2022; Ma, Deng, and Mei 2022). Adversarial attacks on graphs can be carried out in various settings depending on the problem setting (Jin et al. 2020; Sun et al. 2023; Wang et al. 2023a). In terms of the attack stage, the attack can be categorized as either a poisoning attack or an evasion attack. A poisoning attack injects malicious data into the training set, which causes the victim model to malfunction (Jin et al. 2020; Sun et al. 2023). However, given the massive scale and accessibility of training data, the poisoning attack has been considered as highly cost-inefficient and challenging (Wang et al. 2023a). On the other hand, an evasion attack introduces defects into the victim model solely during the inference phase, which makes it more realistic for attacks against GNN-based fraud detectors.

The attack can be also classified as either a white-box or black-box attack, depending on the attacker's knowledge. In a white-box attack, it is assumed that the attacker can access all information about the architecture and parameters of the victim model (Sun et al. 2023). However, acquiring such details about the victim model is practically challenging. In contrast, a black-box attack is more feasible since it supposes that the attacker cannot directly access the victim model (Zou et al. 2021). To conduct attacks in the most realistic setting, we adopt a black-box evasion attack setting for our study of multi-target graph injection attacks against GNN-based fraud detectors.

Graph Modification Attacks and Graph Injection Attacks It has been shown that even a few adversarial modifications on graphs can significantly degrade the performance of GNNs (Zügner, Akbarnejad, and Günnemann 2018; Zügner and Günnemann 2019; Ma et al. 2021; Ma, Deng, and Mei 2022; Lin, Blaser, and Wang 2022). For instance, Nettack (Zügner, Akbarnejad, and Günnemann 2018) generates adversarial perturbations on node attributes and edges while preserving the node degree distribution. Meta-attack (Zügner and Günnemann 2019) modifies the graph structure using meta-gradients, under constraints of the unnoticeability. Graph injection attacks have emerged focusing on more practical settings, where attackers inject new malicious nodes instead of modifying existing nodes and edges (Wang et al. 2020a; Sun et al. 2020). NIPA (Sun et al. 2020) employs reinforcement learning to inject malicious nodes, while AFGSM (Wang et al. 2020a) adapts the fast gradient

sign method to efficiently inject nodes. However, although both NIPA and AFGSM involve injection attacks, their poisoning attack setting requires retraining the victim model on the attacked graph, which might be demanding in real-world scenarios.

Meanwhile, graph injection evasion attack methods have recently been proposed, offering a more feasible alternative to graph poisoning attacks (Tao et al. 2021; Zou et al. 2021; Wang et al. 2022; Ju et al. 2023). For example, G-NIA (Tao et al. 2021) jointly learns attribute and edge generators to attack unseen target nodes, whereas TDGIA (Zou et al. 2021) determines where to connect attack nodes using the defective edge selection strategy and then optimizes the features of the injected nodes. Cluster Attack (Wang et al. 2022) regards graph injection attack as a clustering task, clustering target nodes by adversarial vulnerability, assigning attack nodes to each cluster, and optimizing their attributes. G²A2C (Ju et al. 2023) aims to alleviate the discrepancies between surrogate and victim models, based on the advantage actor-critic framework. In our experiments, we have employed attack methods that align with the multi-target graph injection attack under a black-box evasion attack setting, such as G-NIA, TDGIA, Cluster Attack, and G²A2C.

Comparison between Existing Graph Injection Attack Methods and MonTi Despite the recent progress in graph injection attack methods, they still have several limitations when applied to multi-target attacks against GNN-based fraud detectors. First, the existing methods, such as G-NIA (Tao et al. 2021), TDGIA (Zou et al. 2021), Cluster Attack (Wang et al. 2022), and G²A2C (Ju et al. 2023), assign the fixed degree budget to each attack node or inject attack nodes sequentially. This limits their flexibility and efficiency in exploring diverse structures, as it requires to fix the degree budget across all attack nodes due to a lack of information about future steps. Second, the existing methods focus on single-target (Ju et al. 2023) or single-injection attacks (Tao et al. 2021). As a result, they often overlook interactions within target nodes and among attack nodes, which are crucial for modeling the intricate relationships within a fraud gang and attacking target nodes. Third, the existing methods sequentially generate attributes and edges of attack nodes, considering a one-way dependency, which fails to accurately model collusive patterns of fraud gangs. In contrast, MonTi addresses these limitations by 1) injecting all attack nodes at once, adaptively assigning the degree budget for each attack node to explore diverse structures among target, candidate, and attack nodes, 2) employing a transformer encoder to effectively capture interdependencies within target and attack nodes, and 3) simultaneously generating attributes and edges of attack nodes to capture their interdependency.

B Details about Datasets for Multi-target Attacks

We have created datasets and target sets consisting of fraud nodes which are grouped based on their metadata or relations in real-world graphs: *GossipCop-S*, *YelpChi*, and *LifeIns*. Detailed descriptions of each graph and the process of generating the target sets are provided below, and statistic of the three datasets is presented in Table 7. Notably, our datasets are substantially larger and denser than those typically used in the previous graph adversarial attack studies (Tao et al. 2021; Zou et al. 2021; Wang et al. 2022; Ju et al. 2023). Our datasets include *GossipCop-S* (16,488 nodes, 3,865,058 edges), *YelpChi* (45,900 nodes, 3,846,910 edges), and *LifeIns* (122,792 nodes, 912,833 edges). In contrast, among the datasets used in our attack baselines, the largest is *PubMed* (Sen et al. 2008) (19,717 nodes, 44,338 edges), and the densest is *Wiki-CS* (Mernyei and Cangea 2020) (11,701 nodes, 216,123 edges). In experiments, we extract the largest connected component of each dataset. We set the percentage of training nodes p , the parameter to control node budgets ρ , and the parameter to control edge budgets ξ for each dataset based on its characteristics to ensure that the attacks are performed under realistic and challenging conditions. Further details on ρ and ξ are provided in Appendix E.2.

GAGA	0.8803	0.9570	0.7470	0.8962	0.8845	0.9313

Table 8: Fraud detection performance of victim models on clean *GossipCop-S*, *YelpChi*, and *LifeIns*. We report F1-macro and AUC. For both F1-macro and AUC, higher values indicate better performance.

GossipCop-S The original *GossipCop* dataset contains news articles and the social user engagements of the news articles from Twitter (Shu et al. 2020). We generate *GossipCop-S* by utilizing users’ social engagements with the news articles to create an undirected weighted graph by referring to (Wu and Hooi 2023). In *GossipCop-S*, nodes represent news articles and edges are created when multiple users tweet two news articles. Note that we retain only the edges with the top 5% engagements to prevent the graph from being excessively dense. While removing edges, we preserve the minimum spanning tree to maintain the connectivity of the graph. Fake news articles are defined as fraud nodes. When fake news articles are tweeted by the same user, we consider this as collusive behavior to spread misinformation. Thus, we group the fake news articles tweeted by the same user into a target set.

YelpChi The *YelpChi* dataset (Rayana and Akoglu 2015; Mukherjee et al. 2013) is a review graph where nodes represent reviews, and edges are created based on three different types of relations: (1) the reviews are written by the same user, (2) the reviews have the same star rating for the same product, and (3) the reviews are written within the same month for the same product. In *YelpChi*, fake reviews are defined as fraud nodes. We consider fake reviews written by the same user, or fake reviews for the same product within the same month as evidence of collusive fraudulent behaviors. Thus, we group the fake reviews of the same user or the fake reviews for the same product within the same month into a target set.

LifeIns The *LifeIns* dataset is a medical insurance graph generated based on claim data collected by an anonymous insurance company. In *LifeIns*, nodes correspond to claims, and edges represent relationships predefined by domain experts. We group fraud claims into a target set, guided by domain experts of the insurance company that provided the data. Due to the request from the company, we are unable to provide further details.

C More Details about Fraud Detectors and Attack Baselines

All experiments, except those on *LifeIns*, are conducted using GeForce RTX 2080 Ti, RTX 3090, or RTX A6000 with Intel(R) Xeon(R) Gold 6330 CPU @ 2.00GHz, running on Ubuntu 18.04.5 LTS. Experiments on *LifeIns* are performed on an Amazon EC2 G4dn.metal instance with eight Nvidia T4 GPUs and 384GB RAM. Implementation details of the fraud detectors and attack baselines are described below.

C.1 Details about Surrogate and Victim Fraud Detection Models

We consider following models as surrogate and victim models: GCN (Kipf and Welling 2017), GraphSAGE (Hamilton, Ying, and Leskovec 2017), GAT (Veličković et al. 2018), CARE-GNN (Dou et al. 2020), PC-GNN (Liu et al. 2021), and GAGA (Wang et al. 2023c). We train all the methods with two different initialization seeds utilizing the Adam optimizer (Kingma and Ba 2015) by following the strategy used in (Zou et al. 2021); the models initialized with the first seed serve as surrogate models, while those initialized with the second seed are employed as victim models. The weighted cross entropy is employed as the loss function to address the class imbalance issue. We conduct validation every 10 epochs up to a maximum of 1000 epochs, applying early stopping with the patience of 100. For all methods, we set the hidden dimension to 64 and the batch size to 1,024. The performance of victim models on clean graphs, measured in terms of F1-macro and AUC, is reported in Table 8. F1-macro provides a balanced measure of precision and recall for all classes, while AUC evaluates the model’s ability to distinguish between fraud and benign classes. For both F1-macro and AUC, higher values indicate better performance.

The general GNNs, GCN, GraphSAGE, and GAT, are implemented with two layers, followed by a 2-layer MLP classifier, using Deep Graph Library (Wang et al. 2020b) and PyTorch (Paszke et al. 2019). To find the optimal hyperparameters for these methods, we perform a grid search, exploring learning rates in $\{0.01, 0.001\}$ and weight decay values in $\{0.001, 0.0001\}$. The mean aggregator is adopted as the aggregation function of GraphSAGE. For GAT, we utilize multi-head attention and tuned the number of attention heads in $\{2, 8\}$.

For CARE-GNN, PC-GNN, and GAGA, we set the hyperparameters of them by following the official codes or descriptions provided in the methods’ original publications. Additionally, the original implementation of GAGA for generating and updating

group sequences of nodes does not utilize efficient operations like sparse matrix or tensor operations, leading to substantial computational overheads. Therefore, based on sparse matrix and tensor operations, we implement an efficient method to update group sequences of the attacked target nodes, strictly maintaining the functionality of the original implementation.

C.2 Details about Attack Baselines

We use the following methods as baselines for graph injection attack methods: G-NIA (Tao et al. 2021), TDGIA (Zou et al. 2021), Cluster Attack, and G²A2C (Ju et al. 2023). We set the hyperparameters of the baselines, including the maximum number of epochs and patience settings, based on the official code or as outlined in the original publications of the methods.

G-NIA (Tao et al. 2021) G-NIA is originally designed to inject a single attack node. Therefore, we extend G-NIA to enable the injection of multiple attack nodes, making it suitable for multi-target graph injection attacks. Meanwhile, as the sequential injection approach causes out-of-memory issues, we adopt the one-time injection approach, which concatenates random noise vectors from the standard normal distribution to the input of the attribute generation module.

TDGIA (Zou et al. 2021) Since the official implementation of TDGIA only supports attacks on datasets with continuous node attributes, we extend TDGIA by introducing the discrete feature optimization through the top- k operation and straight-through estimator (Bengio, Léonard, and Courville 2013) to enable attacks on *LifeIns* dataset whose node attributes are discrete.

Cluster Attack (Wang et al. 2022) Cluster Attack learns to inject attack nodes by directly querying the victim model. However, since access to the victim model is not feasible in our scenario, we instead adopt an alternative version of Cluster Attack that utilizes gradients from a surrogate model, as implemented in the official code.

G²A2C (Ju et al. 2023) The original G²A2C is only capable of single-target attacks. Therefore, we extend G²A2C to enable multi-target attacks. Following G-NIA (Tao et al. 2021), we employ the mean of representations of target nodes as a representation of the target set and utilize it as the input for the adversarial node generator. For the adversarial edge sampler and the value predictor, we adjust them to consider all nodes in the target set. Extra rewards, which are originally given for each successful attack on a single target node, are weighted by the overall attack success rate across all target nodes in the target set.

D Implementation Details of MonTi

MonTi is implemented using Deep Graph Library (Wang et al. 2020b) and PyTorch (Paszke et al. 2019). To identify the optimal hyperparameters of MonTi, we perform a grid search, which includes whether MonTi adopts the attack node masking strategy or not. Our search covers learning rates in $\{0.01, 0.001\}$, weight decay in $\{0.001, 0.0001\}$, dropout rates in $\{0, 0.1, 0.2\}$, and dimensions of the feed-forward network of the adversarial structure encoding transformer in $\{512, 2048\}$. Key parameters of MonTi are set as follows: the number of neighbor hops for candidate node selection $K = 2$, the maximum number of candidates $n_c = 128$, the number of layers $L = 6$, the number of heads $n_h = 4$, and the hidden dimension $D_H = 64$. We apply exponential decay to temperature τ and exploration parameter ϵ , reducing them from 10 to 0.01 at a decay rate of 0.63 per epoch. MonTi is trained using the Adam optimizer (Kingma and Ba 2015) over 100 epochs, applying early stopping with a patience of 10. In the case of single node injection, where the node budget $\Delta = 1$, the representation of the attack node $\hat{\mathbf{z}}_1$ is initialized to the zero vector. For single-target attack experiments, which utilize multi-class node classification datasets, we optimize MonTi using the C&W loss (Carlini and Wagner 2017; Tao et al. 2021; Wang et al. 2022) which is the multi-class version of our loss function.

E Complete Experimental Results and Additional Analyses

This section presents more experimental results and analyses, expanding those summarized or mentioned in the main paper.

E.1 Results of Single-target Attacks

Although MonTi is designed for multi-target attacks, we present benchmark results for single-target attacks on *OGB-Prod* (Hu et al. 2020) and *PubMed* (Sen et al. 2008) using GCN as the surrogate and victim models to verify that MonTi is also applicable in general scenarios. The *OGB-Prod* is a co-purchasing network of Amazon products. The *PubMed* is a citation network from the PubMed database. For the single-target attack experiments, we set the node budget $\Delta = 1$ and edge budget $\eta = 1$, following (Tao et al. 2021; Ju et al. 2023). In this setting, we additionally consider the following baselines: Random (Tao et al. 2021), Nettack (Zügner, Akbarnejad, and Günnemann 2018) with a randomly initialized attack node (denoted by Rand+Nettack), NIPA (Sun et al. 2020), and AFGSM (Wang et al. 2020a). Following the experimental setup of (Ju et al. 2023), we use the sub-graph and data splits distributed by G-NIA (Tao et al. 2021) for *OGB-Prod*, and public splits for *PubMed*. Results are presented in Table 9. `Clean` represents the misclassification rates of the victim GCN measured on the original clean graph. The results labeled as “(obtained from (Ju et al. 2023))”, such as Rand+Nettack, NIPA, and AFGSM, are obtained from (Ju et al. 2023), whereas the other results (i.e., `Clean`, Random, G-NIA, TDGIA, G²A2C, and MonTi) were obtained by running the methods by ourselves. For the results obtained from (Ju et al. 2023), we also present `Clean` (obtained from (Ju et al. 2023)), which denotes the misclassification rates of the victim GCN on the original clean graph that have been reported in (Ju et al. 2023). Despite not being specifically designed for single-target attacks, MonTi achieves the highest misclassification rates on both datasets. This demonstrates the effectiveness of MonTi’s transformer-based architecture, which captures intricate interactions around a target node via adversarial structure encoding.

	<i>OGB-Prod</i>	<i>PubMed</i>

G ² A2C	92.3±0.5	<u>82.0±0.0</u>
MonTi	96.4±1.1	85.3±1.1

Table 9: Single-target attack performance on *OGB-Prod* and *PubMed* with GCN as the surrogate and victim models. We report misclassification rates (%). `Clean` represents the misclassification rates of the victim GCN measured on the original clean graph. The results labeled as “(obtained from (Ju et al. 2023))”, such as Rand+Nettack, NIPA, and AFGSM, are obtained from (Ju et al. 2023), whereas the other results (i.e., `Clean`, Random, G-NIA, TDGIA, G²A2C, and MonTi) were obtained by running the methods ourselves. For the results obtained from (Ju et al. 2023), we also present `Clean` (obtained from (Ju et al. 2023)), which denotes the misclassification rates of the victim GCN on the original clean graph that have been reported in (Ju et al. 2023).

E.2 Budget Constraints for Multi-target Attacks: Formulation and Implications

Rationales behind the Formulation of Budget Constraints This section explains the rationale for determining the total budget for a target set. Previous studies have determined budget constraints for a target set based on the degree of each target node (Tao et al. 2021) or by setting the fixed budget constraints with constant values (Zou et al. 2021; Wang et al. 2022; Ju et al. 2023). For attacks of fraud gangs, we can consider that the degrees of target nodes in a target set reflect the size and amount of available resources of the corresponding gang. Thus, the budget constraints for each target set have to be proportional to the overall degrees of the nodes in the target set. However, in multi-target attack scenarios where target nodes often share neighboring nodes, relying solely on the sum or average degree of the target nodes can make the budgets too large due to overlapping neighbors. To address this issue, we define the budgets based on the size of the one-hop neighbor set for each target set $B = |\mathcal{N}^{(1)} \cup \mathcal{T}|$. In addition, we also impose limits on the budgets since excessively large budgets can lead to highly noticeable and easy attacks. For each target set, the node budget Δ is defined to be proportional to the number of direct neighbors and constrained not to exceed the average level:

$$\Delta = \max(\lfloor \rho \cdot \min(B, \bar{B}) + 0.5 \rfloor, 1) \quad (8)$$

where ρ is a parameter to control node budgets and \bar{B} is the average value of B across all target sets. The edge budget η for each target set is determined based on both Δ and the average node degree of the target set, ensuring that the average node degree of the attack nodes remains below a predefined threshold relative to the average node degree of the entire graph:

$$\eta = \Delta \cdot \max(\lfloor \min(d_{\mathcal{T}}, \xi \cdot \bar{d}) + 0.5 \rfloor, 1) \quad (9)$$

where $d_{\mathcal{T}}$ is the average node degree of the target set, ξ is a parameter to control edge budgets, and \bar{d} is the average node degree of all nodes in the graph. In our main experiments for multi-target attacks, we have determined the budget constraints, Δ and η , by setting ρ and ξ for each dataset considering its characteristics, and applied the same budget constraints for all attack methods. We set $\rho = 0.05$, $\xi = 0.1$ for *GossipCop-S*, $\rho = 0.05$, $\xi = 0.5$ for *YelpChi*, and $\rho = 0.2$, $\xi = 0.5$ for *LifeIns*.

Analysis of the Effects of Varying ρ and ξ To examine the influence and tendency of different budget constraints, we conduct additional experiments by varying the values of parameters to control budgets: ρ and ξ . Figure 4 shows the attack performance of MonTi under varying budgets on *GossipCop-S* with GCN as the surrogate model and CARE-GNN, PC-GNN, and GAGA as the victim models. For all cases, we see that misclassification rates initially increase sharply with a rise in budget, then seem to converge without significant further changes.

E.3 Results of Multi-target Attacks

The results of the multi-target attack experiments on *GossipCop-S*, *YelpChi*, and *LifeIns* are shown in Tables 3 and 4. We see that GNN-based fraud detectors are generally more robust against attacks than vanilla GNNs due to their ability to handle heterophily. For example, CARE-GNN and PC-GNN employ a similarity-based neighborhood selection, which can be beneficial in alleviating the influence of injected attack nodes. Among the GNN-based fraud detectors, GAGA is relatively robust

Figure 4: Multi-target attack performance of MonTi on *GossipCop-S* using GCN as the surrogate model with varying node (Left) and edge budgets (Right).

	<i>GossipCop-S</i>		<i>YelpChi</i>		<i>LifeIns</i>	
	Before Attack	After Attack	Before Attack	After Attack	Before Attack	After Attack
CARE-GNN	18.72	18.65 ± 0.08	22.89	22.86 ± 0.02	0.52	0.52 ± 0.00
PC-GNN	24.54	24.48 ± 0.07	17.16	17.13 ± 0.02	0.52	0.52 ± 0.00
GAGA	8.76	8.73 ± 0.06	15.19	15.18 ± 0.01	0.42	0.42 ± 0.00

Table 10: Misclassification rates (%) of non-target test nodes before and after attacks by MonTi on *GossipCop-S*, *YelpChi*, and *LifeIns* using GCN as the surrogate model and CARE-GNN, PC-GNN, and GAGA as victim models.

in general; GAGA alleviates the impacts of attack nodes through group aggregation by treating the attack nodes as unlabeled nodes.

MonTi shows the best attack performance among all attack methods across all datasets since MonTi can more extensively search for adversarial structures, including connections among attack nodes. We conduct independent samples t-tests with the significance level of 0.05 comparing MonTi with the best-performing baselines for the results reported in Tables 3 and 4. MonTi outperforms all baselines in 25 cases, with statistically significant differences (with p-values less than 0.05) in 21 cases. The performance variation of MonTi across datasets can be attributed to their distinct characteristics. For example, *GossipCop-S* has a denser structure and larger fraud gangs than the other graphs. This allows attackers to explore diverse injection structures, leading to more effective attacks. Also, the datasets differ in their node feature characteristics. For example, *GossipCop-S* and *YelpChi* use continuous features, which allow attackers to flexibly generate node attributes. In contrast, *LifeIns* contains discrete features that inherently limit the possible values for attack node features, posing challenges for all attack methods. While MonTi’s performance varies across datasets, MonTi consistently outperforms all baselines. Furthermore, we evaluate MonTi’s impacts on non-target nodes across all datasets. Table 10 presents the misclassification rates of non-target test nodes before and after attacks by MonTi, using GCN as the surrogate model and CARE-GNN, PC-GNN, and GAGA as victim models. The results demonstrate that MonTi’s attacks have negligible impacts on the classification of non-target nodes. This is because MonTi injects only a limited number of nodes around a target set, resulting in minimal impacts on non-target nodes.

Among the attack baseline methods, G-NIA exhibits relatively superior performance among the graph injection attack baselines since G-NIA can process the target nodes in the same target set together, unlike TDGIA and Cluster Attack. However, G-NIA oversimplifies interactions within target nodes by just using the mean representation of the target nodes and does not consider possible connections among attack nodes, resulting in significantly lower misclassification rates than MonTi. Meanwhile, TDGIA and Cluster Attack appear to encounter challenges in performing attacks. Since the defective edge selection strategy of TDGIA overlooks that edges can be formed among attack nodes, TDGIA struggles to consider appropriate connections among attack nodes in a sequential injection process. Cluster Attack faces a challenge in specifying the proper number of clusters for target sets with varying sizes. In addition, for discrete features, Cluster Attack applies perturbations to each element of features and computes the loss. As a result, on the *LifeIns* dataset, which has numerous feature dimensions and nodes, the computation time exceeds 5 days (N/A). In most settings, G²A2C encounters Out of Memory (OOM) errors, highlighting its limitations in scalability, which come from storing complete episodes of sequential injections.

	CARE-GNN	PC-GNN	GAGA
Clean	48.02	55.62	21.68
random attributes	78.18	77.81	25.70
random edges	79.64	81.40	39.33
w/o pos. encoding	86.12	86.98	40.21
w/o degree	87.33	88.06	38.40
shared parameters	87.76	86.66	39.57
w/o candidates	88.20	88.96	40.67
random candidates	88.25	88.38	39.13
fixed budget	87.28	88.66	42.17
MonTi	88.78	89.90	43.70

Table 11: Ablation studies of MonTi on *GossipCop-S* with GCN as the surrogate model. We report misclassification rates (%). Clean represents the misclassification rates of the victim models measured on the original clean graph. Overall, the original MonTi shows the best attack performance, demonstrating the importance of each component of MonTi.

E.4 Additional Ablation Studies of MonTi

Table 11 shows the results of ablation studies for MonTi on *GossipCop-S*, utilizing CARE-GNN, PC-GNN, and GAGA as victim models and GCN as the surrogate model. We replace the adversarial attribute and edge generation methods with random generation. For attributes, nodes are randomly selected from the original graph, and their attributes are assigned to attack nodes (random attributes). For edges, connections are randomly created among target, candidate, and attack nodes (random edges). The attack performance of MonTi significantly degrades when the random generation strategy is used. We also remove the learnable positional encodings \bar{p} , \hat{p} , and \hat{p} (w/o pos. encoding) and degree information (w/o degree). Furthermore, we set the parameters to be shared between target and candidate encodings (shared parameters). In addition, we modify MonTi to exclude candidate nodes during the entire process (w/o candidates) and to select the candidates randomly (random candidates). Lastly, we fix the degree budget for each attack node (fixed budget). While not as substantial as observed when replacing attribute and edge generation with the random strategy, there is a noticeable decline in performance when removing or modifying any of these modules. Overall, the original MonTi shows the best attack performance, demonstrating the importance of each component of MonTi in achieving effective graph injection attacks.

E.5 Efficiency Analysis

We measure the total training, inference, and running times, as well as the maximum GPU memory usage for each attack method on *GossipCop-S*, *YelpChi*, and *LifeIns* using GCN as the surrogate model and GAGA as the victim model, as shown in Table 12. Experiments on *GossipCop-S* and *YelpChi* were conducted using GeForce RTX 3090 24GB, while experiments on *LifeIns* were performed using NVIDIA T4 GPU. Note that as TDGIA and Cluster Attack are algorithm-based methods, which require optimization for each attack, they only have inference times. We measure the maximum GPU memory usage using `torch.cuda.max_memory_allocated()`. We mainly compare MonTi with G-NIA, which is the best-performing baseline. Across all datasets, training MonTi requires significantly less time than G-NIA (e.g., 1,581 vs. 14,757 seconds on *GossipCop-S*). The inference time of MonTi is comparable to or slightly better than G-NIA. Since MonTi and G-NIA are model-based methods which are generalizable to unseen nodes based on trained parameters, their inference times are significantly less than those of TDGIA and Cluster Attack. The total runtime of MonTi ranges from 11% to 93% of that required by baselines across different datasets. In terms of memory efficiency, MonTi shows moderate GPU memory usage compared to baselines, while G²A2C encounters Out of Memory errors in all settings. MonTi effectively narrows the search space through candidate selection and adopts efficient matrix operations to inject all attack nodes at once. Especially, the candidate selection mechanism significantly reduces the number of nodes involved in transformer computations of MonTi by focusing solely on target nodes and a subset of their K -hop neighbors, rather than processing the entire graph. Although MonTi requires more memory storage than algorithm-based methods such as TDGIA and Cluster Attack, MonTi operates much faster and shows superior attack performance compared to TDGIA and Cluster Attack.

E.6 Complexity Analysis of MonTi

In this section, we analyze the computational complexity of MonTi’s forward pass. We do not consider the operations using the pretrained GNN encoder as these operations can be precomputed. The candidate selection process has a complexity of $O(|\mathcal{N}^{(K)}| + m)$ where $m := |\mathcal{T}|$ is the number of target nodes and $\mathcal{N}^{(K)}$ is a set of K -hop neighbors of the target nodes excluding the target nodes themselves. Note that K is a tunable hyperparameter that allows us to control the trade-off between computational cost and the exploration range of candidate nodes. The complexity of the adversarial structure encoding step is

		G-NIA	TDGIA	Cluster Attack	G ² A2C	MonTi
<i>GossipCop-S</i>	Training Time	14,757 ± 1,166 s	-	-	-	1,581 ± 336.3 s
	Inference Time	123.4 ± 0.61 s	9,874 ± 212.6 s	3,686 ± 59.52 s	-	119.2 ± 0.34 s
	Total Runtime	14,880 ± 1,166 s	9,874 ± 212.6 s	3,686 ± 59.52 s	-	1,700 ± 336.0 s
	Max. GPU Mem. Usage	13.1 ± 0.00 GiB	2.43 ± 0.00 GiB	2.17 ± 0.00 GiB	OOM	6.21 ± 0.01 GiB
<i>YelpChi</i>	Training Time	7,574 ± 3,454 s	-	-	-	1,365 ± 342.9 s
	Inference Time	56.85 ± 0.95 s	1,397 ± 171.2 s	1,158 ± 29.51 s	-	52.84 ± 0.34 s
	Total Runtime	7,631 ± 3,455 s	1,397 ± 171.2 s	1,158 ± 29.51 s	-	1,417 ± 342.9 s
	Max. GPU Mem. Usage	1.69 ± 0.14 GiB	2.19 ± 0.00 GiB	2.17 ± 0.00 GiB	OOM	1.86 ± 0.00 GiB
<i>LifeIns</i>	Training Time	1,348 ± 304.3 s	-	-	-	139.7 ± 14.4 s
	Inference Time	10.91 ± 0.08 s	3,171 ± 86.16 s	N/A	-	13.72 ± 0.46 s
	Total Runtime	1,359 ± 304.4 s	3,171 ± 86.16 s	N/A	-	153.4 ± 14.64 s
	Max. GPU Mem. Usage	3.54 ± 0.00 GiB	3.85 ± 0.00 GiB	-	OOM	3.51 ± 0.00 GiB

Table 12: Efficiency analysis results on *GossipCop-S*, *YelpChi*, and *LifeIns* using GCN as the surrogate model and GAGA as the victim model. OOM indicates an Out of Memory error. N/A denotes that experiments were not completed within 5 days.

$O((m + \alpha + \Delta)^2)$ for transformer-based encoding. The one-time graph injection has a complexity of $O(\Delta \cdot (m + \alpha + \Delta))$, which is absorbed into the adversarial structure encoding complexity. Therefore, MonTi’s overall complexity is:

$$O(|\mathcal{N}^{(K)}| + (m + \alpha + \Delta)^2) \quad (10)$$

where $(m + \alpha + \Delta) \ll |\mathcal{V}|$. The computational cost of candidate selection does not grow fast since target nodes representing fraud gangs are often locally close, resulting in considerable overlap among neighboring nodes. For comparison, we analyze G-NIA, the best-performing baseline. G-NIA consists of attribute generation with $O(m + \Delta)$ complexity and edge generation with $O(\Delta \cdot (|\mathcal{N}^{(1)}| + m))$ complexity. Thus, G-NIA’s overall complexity is:

$$O(\Delta \cdot (|\mathcal{N}^{(1)}| + m)) \quad (11)$$

While MonTi’s complexity mainly depends on $|\mathcal{N}^{(K)}|$, which can be controlled through the hyperparameter K , the complexity of G-NIA is determined by the product of $|\mathcal{N}^{(1)}|$ and node budget Δ . We can see that the complexities of MonTi and G-NIA are affected by the dataset characteristics and chosen values of K and Δ . However, as shown in Appendix E.5, MonTi is significantly more efficient than G-NIA in runtimes and memory usage in our experiments.

E.7 More Examples of Visualization of Large-Scale Attack Cases

Figure 5 illustrates additional cases using the same settings as those of Figure 3 in the main paper: on *GossipCop-S* using target sets with $B > 1000$, GCN as the surrogate model, and GAGA as the victim model. We visualize the latent node representations computed by GAGA before and after the attack using t-SNE (Van der Maaten and Hinton 2008). Blue circles indicate the representations of target nodes before the attack, and orange diamonds indicate those after the attack. A blue circle and an orange diamond that correspond to the same target node are connected. Below each t-SNE visualization, we provide misclassification rates of GAGA for the corresponding target set before and after the attack, the size of the target set, and $B = |\mathcal{N}^{(1)} \cup \mathcal{T}|$. These supplementary cases provide further validation of our findings. Specifically, MonTi substantially shifts the representations of target nodes from the fraud region to the benign region, leading to a significant increase in the number of targets being misclassified. In contrast, G-NIA induces only minor changes in target node representations, minimally increasing misclassification rates consequently. The first three figures in the upper row in Figure 5 show that although G-NIA shifts the representations of some target nodes, this does not lead to an increase in misclassification rates.

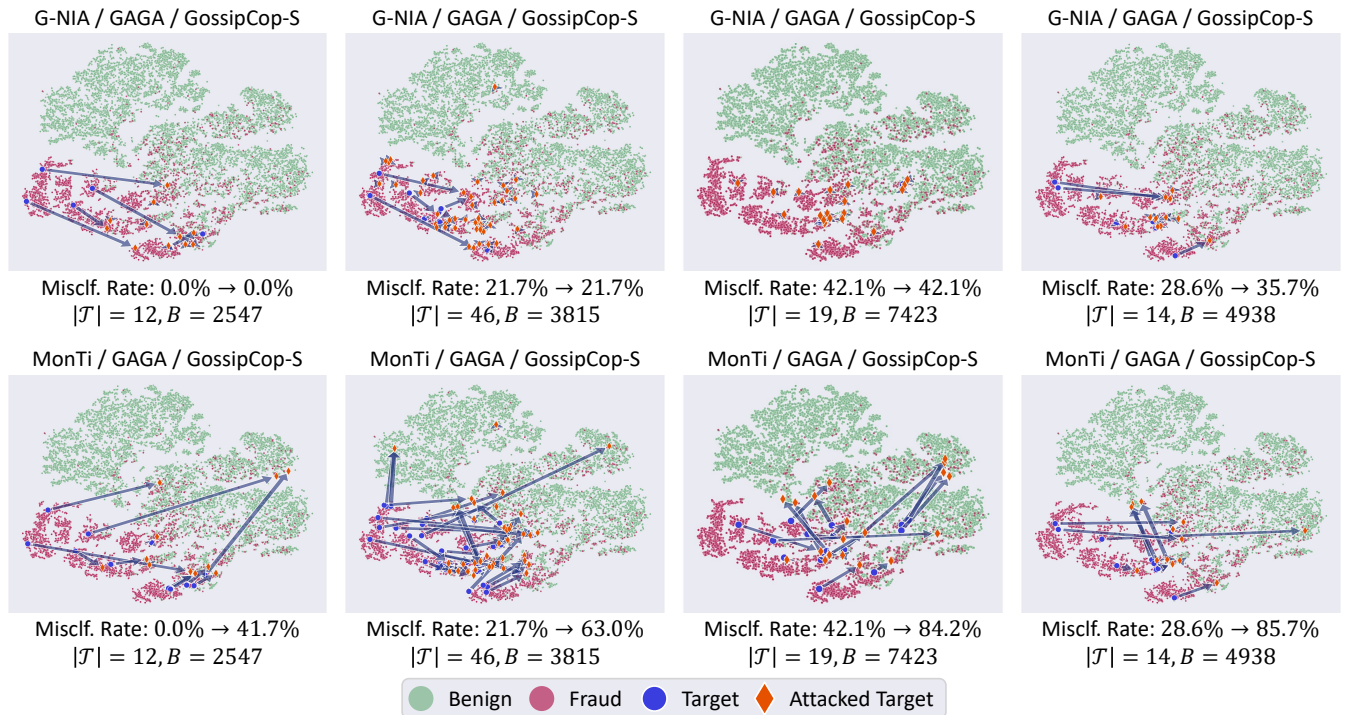

Figure 5: The t-SNE visualization of the changes in the latent representations of target nodes computed by GAGA on *GossipCop-S*, incurred by G-NIA (Upper) and MonTi (Lower). A blue circle and an orange diamond corresponding to the same target node are connected. For each figure, we also provide misclassification rates of GAGA for the corresponding target set before and after the attack, the size of the target set, and $B = |\mathcal{N}^{(1)} \cup \mathcal{T}|$. While G-NIA induces only minor changes in the representations of target nodes, MonTi significantly shifts the representations.
