ABSTRACT

Blazars are often observed to flare across multiple wavelengths. Orphan flares from blazars have been only detected a few times, providing an opportunity to understand the structure of the jet in the accreting system. We report a remarkable orphan X-ray flare from a blazar candidate EP240709a, detected by Einstein Probe (EP) in July 2024. The multi-band spectral properties and variability support EP240709a as a high-energy peaked BL Lacertae-type object. The flux in 0.5-10 keV increases by at least 28 times to the value of low state in 2020, with non-detection of remarkable flaring in other bands during the same period. EP240709a exhibits the harder-when-brighter tendency in the X-ray band during the orphan flare, while its infrared-optical spectra are featureless. We employ one-zone and two-zone leptonic synchrotron self-Compton models to perform the spectral energy distribution fitting. Detecting this rare orphan flare shows the potential of EP in discovering peculiar activities from AGN in high-cadence X-ray sky surveys.

Keywords: Active galactic nuclei (16) — Blazars (164) — Jets (870) — High energy astrophysics (739)

1. INTRODUCTION

Blazars are the most extreme subclass of Active Galactic Nuclei (AGN), characterized by a relativistic jet pointing toward the observer [\(Urry & Padovani](#page-13-0) [1995\)](#page-13-0). These objects produce immense energy across the entire electromagnetic spectrum and exhibit strong variability in multi-wavelengths. The spectral energy distribution (SED) of blazars, dominated by the non-thermal continuum of the beamed jet, displays two broad humps, peaking at IR to X-ray bands and X-ray to γ -ray bands, respectively [\(Fossati et al.](#page-12-0) [1998\)](#page-12-0). The low-energy component is commonly interpreted as the synchrotron radiation of relativistic electrons in the magnetic field of the jet, while the origin of the high-energy component is still under discussion. In the leptonic model, the relativistic electrons in jet Comptonize their synchrotron photons (e.g., [Ghisellini et al.](#page-12-1) [1985;](#page-12-1) [Maraschi et al.](#page-12-2) [1992\)](#page-12-2) or the external low-energy photons (e.g., [Sikora et al.](#page-13-1) [1994\)](#page-13-1). Alternatively, relativistic protons emit synchrotron (e.g., [Aharonian](#page-9-0) [2000\)](#page-9-0) and initiate the electromagnetic cascade by creating various pairs via photo-hadronic interactions (e.g., Mannheim $\&$ Biermann [1992;](#page-12-3) Böttcher [et al.](#page-11-0) [2013\)](#page-11-0).

The challenge of spatially resolving the cores of remote AGNs makes variability a valuable probe for gaining insight into the structure and the dominating radiative processes of AGNs. Blazars are usually observed to be flaring in multiwavelength [\(Ulrich et al.](#page-13-2) [1997\)](#page-13-2). As predicted by the one-zone synchrotron self-Compton (SSC) model, the flares in two humps of blazars should simultaneously happen. Interestingly, some "orphan" flares have been observed, which only appear in one narrow band. Orphan flares are usually detected in optical (e.g., [Chatterjee et al.](#page-11-1) [2013;](#page-11-1) [Liodakis et al.](#page-12-4) [2019;](#page-12-4) [Wierzchol](#page-13-3)[ska et al.](#page-13-3) [2019\)](#page-13-3) and γ -ray bands (e.g., [Donnarumma](#page-12-5) [et al.](#page-12-5) [2011;](#page-13-4) [Vercellone et al.](#page-13-4) 2011; Banasiński et al. [2016;](#page-10-0) [Abeysekara et al.](#page-9-1) [2017;](#page-9-1) [MacDonald et al.](#page-12-6) [2017\)](#page-12-6). The detection of orphan X-ray flares from blazars is quite rare, with only four sources reported: 3C 279 [\(Abdo et al.](#page-9-2) [2010\)](#page-9-2), S5 0716+714 [\(Rani et al.](#page-12-7) [2013\)](#page-12-7), 1ES 1741+196 [\(Goswami et al.](#page-12-8) [2024\)](#page-12-8), and PKS 2005-489 [\(Chase et al.](#page-11-2) [2023\)](#page-11-2), as far as we are aware. While their phenomenological features differ, these orphan X-ray flares strongly challenge to the one-zone model [\(Abdo et al.](#page-9-2) [2010;](#page-9-2) [Chase et al.](#page-11-2) [2023;](#page-11-2) [Goswami et al.](#page-12-8) [2024\)](#page-12-8). The nature of orphan X-ray flares from blazars remains poorly understood.

In this work, we report a newly discovered orphan Xray flare from a blazar candidate EP240709a with Einstein Probe (EP, [Yuan et al.](#page-13-5) [2022\)](#page-13-5). We analyze multiwavelength data from radio to GeV bands to constrain the origin of this orphan flare. In Section [2,](#page-1-1) we introduce the multiwavelength observations and data reduction methods. We describe the observational features of this orphan flare in Section [3](#page-5-0) and discuss its possible origin in Section [4.](#page-5-1) The main conclusions are summarized in Section [5.](#page-8-0) We adopt the cosmological parameters H_0 $= 69.6$ km s⁻¹ Mpc⁻¹, $\Omega_0 = 0.29$, and $\Omega_\Lambda = 0.71$ [\(Ben](#page-11-3)[nett et al.](#page-11-3) [2014\)](#page-11-3) in this work.

2. OBSERVATION AND DATA REDUCTION

On July 9th, 2024, a new X-ray flare, designated EP240709a, was detected by the Wide-field X-ray Telescope (WXT) on board EP [\(Liu et al.](#page-12-9) [2024\)](#page-12-9). The position is coincident with a γ -ray source 4FGL J0031.5-5648 [\(Abdollahi et al.](#page-9-3) [2020;](#page-9-3) [Ballet et al.](#page-10-1) [2023\)](#page-10-1) discovered by the Large Area Telescope (LAT) on board Fermi

[∗] These authors contributed equally to this work

Gamma-ray Space Telescope [\(Atwood et al.](#page-10-2) [2009\)](#page-10-2), as shown in Figure [1.](#page-3-0) To improve localization and reveal the physical nature of EP240709a, we performed substantial multiwavelength observations with the Followup X-ray Telescope (FXT) board EP, the Neutron star Interior Composition Explorer (NICER, [Gendreau](#page-12-10) [et al.](#page-12-10) [2016\)](#page-12-10), the Neil Gehrels Swift Observatory (Swift, [Gehrels et al.](#page-12-11) [2004\)](#page-12-11), the 1.0 m telescopes of the Las Cumbres Observatory (LCO, [Brown et al.](#page-11-4) [2013\)](#page-11-4), the Cerro Tololo Inter-American Observatory (CTO), the Southern African Large Telescope (SALT, [Barnes et al.](#page-11-5) [2008\)](#page-11-5) and the Magellan telescopes. The multiwavelength follow-up observations combined with archival data strongly support EP240709a as a BL Lacertae-type (BL Lac) object (see Section [4](#page-5-1) for detail). During the flaring period, no remarkable brightening was detected in other bands. The X-ray observations are summarized in Table [2.](#page-11-6)

2.1. X-ray observations

EP-WXT and the Lobster Eye Imager for Astronomy (LEIA, [Zhang et al.](#page-13-6) [2022a\)](#page-13-6) covered EP240709a hundreds of times and have twice direct detection in a single observation. EP240709a was first discovered by WXT on July 9th, 2024 with a total exposure time of 27.2 ks. Then it was simultaneously detected by WXT and FXT on July 13th. EP240709a was found to reach its peak X-ray flux on July 14th, 2024 by stacking nine WXT observations. Before these detections, the non-detection by a 28.9 ks stacked WXT observation indicates this orphan X-ray flare to be not earlier than May 2024. We also merge two LEIA observations from November 21st to 28th 2022, seven LEIA observations from May 24th to June 2nd, 2023, and two WXT observations from June 5th to June 6th, 2024 to get a lower flux upper limit to constrain the X-ray variability before this flare. WXT data reduction was performed following the standard data reduction procedures using the WXT Data Analysis Software (WXTDAS, v2.10, Liu et al. in prep.) and the latest calibration database (CALDB, Cheng et al. in prep.). The data processing for LEIA is similar to that of WXT but requires the use of a specific version of WXTDAS $(v1.1)$ and CALDB for *LEIA*. The data stacking for both WXT and LEIA is accomplished using the wxtmerge tool. The flux upper limits are determined according to the method described in [Ruiz et al.](#page-13-7) [\(2022\)](#page-13-7).

EP-FXT observed EP240709a three times operating in the full-frame (FF) mode on July 11th, 13th and 19th, 2024 with a total exposure time of 19.1 ks (ID: 06800000006, 06800000008 and 06800000014). The data are processed using the FXT Data Analysis Software (FXTDAS, v1.10) developed and provided by the EP science center (EPSC) with the latest FXT calibration database (CALDB, v1.1).

Swift observed 4FGL J0031.5-5648 three times in 2019 (ID: 03110458001-03110458003) and detected a faint X-ray source, SwXF4 J003135.1-564640 [\(Kerby et al.](#page-12-12) [2021\)](#page-12-12), with X-ray Telescope (XRT). During the flare phase, Swift observed EP240709a eight times from July 17th to November 27th (PI: EPSC, Mingjun Liu, ID: 00016716001-00016716008). Swift-XRT was configured in the photon counting (PC) mode in all of the observations. The source region is extracted from a circular region with a radius of 40 arcsec for the EP-FXT position, while the background region is extracted from an annular aperture with inner and outer radii of 60 and 120 arcsec, respectively. We reduce the XRT data using XSELECT, xrtexpomap, xrtmkarf and HEASOFT-6.33.2. The upper limits are evaluated by using WebPIMMS. No associated trigger and signal has been detected by Burst Alert Telescope (BAT) since July 2024 with the data reduced by batbinevt, batmaskwtevt, batffimage, batcelldetect and batsurvey. We estimate the upper limit of flux in the hard X-ray band utilizing BAT 157-month survey data [\(Oh et al.](#page-12-13) [2018;](#page-12-13) [Parsotan et al.](#page-12-14) [2023\)](#page-12-14). The BAT 157-month data are reduced using BatAnalysis and XSPEC.

NICER observed the target EP240709a from August 9th, 2024 to August 20th, 2024 with a total exposure time of about 10.8 ks (PI: Yijia Zhang, F. Coti Zelati, Mason Ng, ID: 7204670101-7204670107). We utilize the $SCORP EON$ background model^{[1](#page-2-0)} for the spectra analysis and the spectra energy range is from 0.5 to 5.0 keV. The fitting results are shown in Table [2.](#page-11-6)

XMM-Newton (Strüder et al. [2001;](#page-13-8) [Turner et al.](#page-13-9) [2001\)](#page-13-9) detected an X-ray source related to EP240709a on May 29th, 2018, during the slew observation (ID: 9338200004). The slew observation data are reduced using eslewchain, which generate various output files, including attitude corrected images, exposure maps, filtered event files, and unfiltered images. Subsequently, eslewsearch is employed to perform source detection. Within the error range of the EP-FXT position, XMMSL J003136.2-564641 is detected in both 0.2-2 keV and 0.2-12 keV, which is only 6.6 arcsec away from EP240709a. Given the limited counts of the observation, we estimate the unabsorbed using WebPIMMS and the 0.2- 12 keV count rate, assuming specific spectral parameters mentioned in Appendix [A,](#page-9-4) which is consistent with the results provided by the HIgh-energy LIght-curve Gener-

¹ [https://heasarc.gsfc.nasa.gov/docs/nicer/analysis](https://heasarc.gsfc.nasa.gov/docs/nicer/analysis_threads/scorpeon-overview/) threads/ [scorpeon-overview/](https://heasarc.gsfc.nasa.gov/docs/nicer/analysis_threads/scorpeon-overview/)

Figure 1. Left: The WXT image with X-ray source detection (red circle) and position of γ -ray source 4FGLJ0031.5-5648 (magenta ellipse), which are blurred with a $\sigma = 1$ pixel Gaussian kernel. **Right:** The zoom-in DES i-band image of the left image. The green circle is the position of FXT source detection, after alignment with the 1eRASS catalog. Blue contours are from the RACS 1.4 GHz survey. The contour levels are 4, 8, 16 times rms.

aTor (HILIGT) upper limit server^{[2](#page-3-1)}. Additionally, the HILGT upper limit server provides a count rate upper limit for EP240709a from the XMM-Newton slew observation on May 16th, 2009, which is further converted into an upper flux limit using WebPIMMS.

eROSITA [\(Predehl et al.](#page-12-15) [2021\)](#page-12-15) also detected this Xray source, cataloged as 1eRASS J003135.3-564638, in 2020 [\(Merloni et al.](#page-12-16) [2024\)](#page-12-16). We obtain the spectra from the eROSITA-DE Data Release 1 (DR1) and reduce the data using XSPEC.

2.2. Gamma-ray observations

This source is included in the Fermi-LAT catalog [\(Ab](#page-9-3)[dollahi et al.](#page-9-3) [2020;](#page-9-3) [Ballet et al.](#page-10-1) [2023\)](#page-10-1), and we use the standard binned likelihood analysis procedure to obtain its light curve and spectral energy distribution. The energy spectral analysis was performed using Fermitools. We select nearly 6 (from January 2018 to November 2024) years SOURCE event class and FRONT + BACK conversion-type data in the energy of 100 MeV - 1 TeV. And we exclude LAT events coming from zenith angles larger than 90◦ to reduce the contamination from the

Earth's limb and extract good time intervals with the recommended quality-filter cuts (DATA QUAL>0 && LAT CONFIG==1). The initial model was generated using make4FGLxml.py script, including the galactic diffuse emission template (gll_iem_v07.fits), the isotropic diffuse spectral model (iso_P8R3_SOURCE_V3_v1.txt) and all the incremental Fourth Fermi-LAT source catalog (gll psc v35.fit) sources within 15 degrees. For the data points with $TS < 9$, the UpperLimits is used to calculate the flux upper limit corresponding to the 95% confidence level.

We investigated the potential signals from EP240709a during its flaring period in the data from Gammaray Burst Monitor (GBM) on board Fermi and anticoincidence system (ACS) of spectrometer SPI on board International Gamma-Ray Astrophysics Laboratory (INTEGRAL, [Winkler et al.](#page-13-10) [2003\)](#page-13-10). First, we confirmed that there were no triggered events recorded by Fermi-GBM during this time. Furthermore, we retrieved the time-tagged event data from the Fermi-GBM archival database and the count curve rebinned into 50-s and 500 -s from the SPI-ACS realtime services^{[3](#page-3-2)} for this

² HILIGT upper limit server: [http://xmmuls.esac.esa.int/](http://xmmuls.esac.esa.int/upper limitserver/) [upperlimitserver/](http://xmmuls.esac.esa.int/upper limitserver/)

period. The non-detection of significant astrophysical signals from EP240709a with GBM and SPI-ACS ruled out the existence of its extreme γ -ray activity.

2.3. Infrared-Optical-UV observations

We took an optical spectrum with RSS on SALT on August 30th, 2024 with a total exposure time of 2400 s [\(Monageng et al.](#page-12-17) [2024\)](#page-12-17). The spectrum is featureless with the 5577 Å sky line subtracted.

We took one near-infrared spectrum of EP240709a with the Folded-port InfraRed Echellette (FIRE, [Sim](#page-13-11)[coe et al.](#page-13-11) [2013\)](#page-13-11) Spectrograph on the Magellan Baade telescope at the Las Campanas Observatory on August 18th, 2024 with a total exposure time of 126.8 s and the S/N ratio around 10. The FIRE spectrum was observed with the high-throughput prism mode with a slit of $0.''6$, a wavelength coverage of $0.8{\text -}2.5 \mu m$ [\(Hsiao et al.](#page-12-18) [2019;](#page-12-18) [Wang et al.](#page-13-12) [2020\)](#page-13-12). The conventional ABBA nod-alongthe-slit technique and the sampling-up-the-ramp readout mode were adopted. The IDL pipeline firehose [\(Simcoe et al.](#page-13-11) [2013\)](#page-13-11) was used to reduce our FIRE spectrum. The infrared flux calibration was achieved through the J-band photometric observation of a star HD 224339. The J-band magnitude of EP240709a on August 18th, 2024 was 17.7 ± 0.2 mag, while the infrared spectra were featureless, except for the sky lines at around 1.38 and 1.85 μ m.

We proposed the UltraViolet Optical Telescope (UVOT) on board Swift observed EP240709a at the same time with XRT. Three UV filters $UVW2, UVM2$, $UVW1$ and three optical filters U, B, V are utilized during the observation. The UVOT data are reduced with HEASOFT-6.33.2 and the results are shown in Figure [2.](#page-6-0)

LCO carried out a quasi-simultaneous photometric observation with EP-FXT on July 11st, 2024 (PI: D. Andrew Howell) and detected the optical counterpart with a magnitude of $r = 19.5 \pm 0.05$. No brightening was found in r-band compared with the observations from Legacy Surveys.

A series of Sloan g, r and Bessell R band images were obtained by the 0.7-m telescope of the Thai Robotic Telescope (TRT) network located at CTO from July 12th, 2024 to July 27th, 2024 (PI: Samaporn Tinyanont, co-PI: Ningchen Sun, Dong Xu, Wenxiong Li, Yanan Wang, Zhou Fan). After standard data reduction with IRAF [\(Tody](#page-13-13) [1986\)](#page-13-13) and astrometric calibration by Astrometry.net [\(Lang et al.](#page-12-19) [2010\)](#page-12-19). The apparent photometric data were calibrated with the Legacy Surveys Data Release 10 [\(Dey et al.](#page-11-7) [2019\)](#page-11-7). The Johnson–Cousin filters were calibrated with the converted magnitude

from the Sloan system^{[4](#page-4-0)}. In contrast to the x-ray light curve, it shows no evidently brightening in optical, see Figure [2.](#page-6-0)

We also utilize the released data from infrared-optical sky survey projects. Asteroid Terrestrial-impact Last Alert System (ATLAS, [Tonry et al.](#page-13-14) [2018\)](#page-13-14) has covered EP240709a in its high-cadence sky survey. No optical brightening in o and c -bands was found in July 2024. Gaia [\(Gaia Collaboration et al.](#page-12-20) [2016\)](#page-12-20) used to detect a slightly variable optical source, Gaia DR3 4918773190794845824, with mean magnitude $G = 19.69$ and parallax 0.0323 ± 0.3401 [\(Gaia Collaboration et al.](#page-12-21) [2023\)](#page-12-21) at the position of EP-FXT detection. Wide-Field Infrared Survey Explorer (WISE, [Wright et al.](#page-13-15) [2010\)](#page-13-15) observed EP240709a in May and November of each year with the mean Vega magnitudes at 3.4, 4.6, 12, and 22 µm of 15.281±0.034, 14.966±0.063, 12.446±0.446 and \geq 9.210, respectively. Visible and Infrared Survey Telescope for Astronomy (VISTA, [Sutherland et al.](#page-13-16) [2015\)](#page-13-16) observed EP240709a on November 27th, 2012 with the magnitudes $J = 17.403 \pm 0.044$ and $K_s = 16.090 \pm 0.073$ [\(McMahon et al.](#page-12-22) [2013\)](#page-12-22).

The archival images from the Dark Energy Survey Data Release 2 (DES DR2 [Abbott et al.](#page-9-5) [2021\)](#page-9-5) are analyzed to improve the localization of EP240709a. We show the X-ray source position on the right of Figure [1,](#page-3-0) overlaying on the DES DR2 i-band image. However, the intrinsic position error of EP-FXT is about 10 arcseconds. After the alignment between the EP-FXT X-ray image with the DES DR2 optical image, we can better constrain the position of EP-FXT detection at RA $= 00^h31^m35.4$, Dec $= -56°46'43''.0$ (J2000, 90% error: 4.0 arcsec). Therefore, we can confirm that the optical counterpart of EP240709a is DES J003135.47-564641.4.

2.4. Radio-millimeter observations

Australian Square Kilometre Array Pathfinder (ASKAP, [Hotan et al.](#page-12-23) [2021\)](#page-12-23) observed EP240709a on about 0.9 and 1.4 GHz several times. These observations are proposed by the Rapid ASKAP Continuum Survey (RACS [Hale et al.](#page-12-24) [2021;](#page-12-24) [Duchesne et al.](#page-12-25) [2023\)](#page-12-25) and ASKAP Variables and Slow Transients (VAST [Murphy et al.](#page-12-26) [2021\)](#page-12-26). Therefore, we can utilize the radio coverage of EP240709a to plot the long-term light curve.

In the archival data, the Sydney University Molonglo Sky Survey (SUMSS) detected the flux at 843 MHz of 8.4±0.9 mJy [\(Mauch et al.](#page-12-27) [2003\)](#page-12-27). A faint source FSPT-S J003136-5646.6 with the flux at 150 GHz of 2.3±0.5 mJy in South Pole Telescope Sunyaev–Zel'dovich (SPT-

SZ) survey [\(Carlstrom et al.](#page-11-8) [2011;](#page-11-8) [Everett et al.](#page-12-28) [2020\)](#page-12-28) is extremely likely associated with 4FGL J0031.5-5648 [\(Zhang et al.](#page-13-17) [2022b\)](#page-13-17).

3. RESULTS

The long-term light curves of EP240709a from radio to γ -ray are shown in the lower six panels of Figure [2,](#page-6-0) while the detail X-ray light curve in flaring period is shown in the uppermost panel. Among the activities in multi-wavelength, the strongest flare is present in July 2024 only in the X-ray light curve. Since it was detected with EP-WXT on July 9th, the X-ray flux in 0.5-10 keV increases from 8.3×10^{-12} erg cm⁻² s⁻¹ to 3.4×10^{-11} $\text{erg cm}^{-2} \text{ s}^{-1}$ on July 14th, then gradually decreases to 1.1×10^{-12} erg cm⁻² s⁻¹ on September 4th. Some flux variations on the timescale of days and months were discovered in the monitoring with NICER and Swift since July 20th, while no significant quasi-periodic oscillations (QPO) signal in 0.1-10 Hz were detected by EP-FXT and NICER. Conservatively speaking, the X-ray flux in 0.5-10 keV increased at least 28 times observed with EP-FXT on July 13th, 2024, compared with the flux of 3.9×10^{-13} erg cm⁻² s⁻¹ in May 2020 observed with eROSITA.

Meanwhile, no remarkable variability was detected in other bands. The weak brightening around half of magnitude in the UV band appears after the X-ray flare. No significant brightening was found in optical band. The significance in the GeV band rose exceeding 3 sigma in July 2024. Nevertheless, the flux in GeV band is not higher than that of the X-ray low state in 2019. Therefore, the GeV activity cannot be comparable with the Xray flare. The flux in radio band slightly varies in a few mJy. Although the rapid infrared variation at around one magnitude on the time scale of days was found by WISE before this flare. The J-band flux observed with Magellan-FIRE was also not higher than the historical values detected by VISTA.

4. DISCUSSION

Before we move to the origin of this orphan X-ray flare, it is essential to clarify the nature of EP240709a since it has not been clearly classified in previous literature except for the neural network classifications as a blazar (e.g., [Germani et al.](#page-12-29) [2021;](#page-12-29) [Kerby et al.](#page-12-12) [2021;](#page-12-12) [Kaur et al.](#page-12-30) [2023\)](#page-12-30). Binaries composed of a compact object (usually a pulsar) and an O/Be star can also shine on the GeV band through either the relativistic jet or the wind-wind interaction, which are called "gamma-ray binary" (e.g., [Dubus](#page-12-31) [2013,](#page-12-31) and references therein). Several observational features disfavor the gamma-ray binary scenario. Firstly, the parallax measurement of 0.0323 ± 0.3401 and the high galactic latitude indicate that the object has an extragalactic origin. Furthermore, the non-detection of X-ray pulsation and the absence of strong emission lines rule out the existence of pulsar and massive companion. On the other hand, EP240709a exhibits many features of blazar, e.g., the two-hump structure of broadband SED, the harder-when-brighter X-ray spectra, the featureless infrared-optical spectra, the infrared color closing to blazar strip (e.g., [Massaro et al.](#page-12-32) [2011,](#page-12-32) [2012\)](#page-12-33) as well as the radio flux inconsistent with synchrotron selfabsorption, as shown in Figure [3](#page-7-0) and Figure [4.](#page-10-3) Therefore, these evidences strongly supporting EP240709a as a high-energy peaked BL Lac.

Figure [3](#page-7-0) shows SEDs at the low state in May 2019 (blue), the flaring state in July 2024 (red) and historical observations (gray). The infrared-optical-UV data are corrected for Galactic extinction. The unabsorbed X-ray spectra are obtained via the absorbed fraction on the power-law model. The synchrotron peak frequency ν_{syn} is around 10^{16} Hz [\(Kerby & Falcone](#page-12-34) [2023\)](#page-12-34). During the flaring period, the X-ray spectra harden while the optical-UV bands almost remain unchanged, which is analogous to the peculiar X-ray flares from 1ES 1741+196 [\(Goswami et al.](#page-12-8) [2024\)](#page-12-8).

To understand the physics of the orphan flare, we select two epochs with extensive quasi-simultaneous multiwavelength observations, i.e., the low state in 2019 and the flaring state in July 2024, to perform SED modeling. The SED in the low state is mainly composed of the Swift observations on May 31th, the WISE data on May 28th and the accumulated monitoring with Fermi-LAT from May 9th to July 8th. The mean magnitudes in 12 and 22 μ m from all of *WSIE* surveys and upper limits of flux in 14-195 keV from Swift-BAT 157-month data are also included to improve statistics. For the SED in flaring state, we employ the observations with EP-FXT, TRT and ATLAS on July 13th, the Swift-UVOT data on July 17th and the GeV observation with Fermi-LAT from July 5th to 25th.

We employ the one-zone and two-zone leptonic SSC models to explore the origin of this orphan X-ray flare. The two-zone leptonic model describes an additional component in the structured jet during the X-ray flare. Each zone is assumed as a spherical blob moving with the Lorentz factor $\Gamma_{\rm b}$ in a uniformly entangled magnetic field B with radius $R \approx c\delta_{\rm D}t_{\rm var}$, where c is the speed of light, $\delta_{\rm D}$ represents the Doppler factor and $t_{\rm var}$ is the variability timescale. For blazars having relativistic jet pointing to the observer, the Doppler factor $\delta_{\rm D}$ is assumed to be equal to $\Gamma_{\rm b}$. Relativistic electrons in each blob are assumed to be injected with a smooth broken power-law energy distribution at a constant rate given

Figure 2. Lower six panels: The over-all multiwavelength light curves of EP240709a. From bottom to top: the radio flux densities at 887 and 1367 MHz since January 1st, 2018, the infrared magnitudes at 3.4 and 4.6 μ m, the optical magnitudes at V, B, U, g, R, r, o and c bands, the UV magnitudes at $UVW1$, $UVM2$ and $UVW2$ bands, the flux of photons in 0.1-10 GeV observed with Fermi-LAT and the unabsorbed flux in 0.5-10 keV observed with EP, LEIA, NICER, XMM-Newton, Swift and eROSITA. Uppermost panel: the detail light curve since May 10st, 2024 observed with EP-WXT (gray), EP-FXT (red), NICER (orange) and Swift-XRT (blue). The gray shadow in each panel marks the main flaring period from July 9th to September 4th, 2024.

Figure 3. The observed SEDs from the low state in May 2019, the flaring state in July 2024 and archival data before 2018 are marked in blue, red and gray points, respectively. The 50-hour sensitivities of H.E.S.S. [\(van Eldik et al.](#page-13-18) [2015\)](#page-13-18), MAGIC (Aleksić et al. [2016\)](#page-10-4), and the Cherenkov Telescopes Array (CTA, [Zanin et al.](#page-13-19) [2022\)](#page-13-19) are marked in orange, magenta and green dash-dotted lines. Left: the one-zone model fitting to SEDs in low and flaring states are marked in blue and red dashed lines, respectively. Right: the two-zone model fitting to the flaring state is marked in red dashed line, with the two components marked in blue solid line and red dotted line, respectively.

Parameters		One-zone	Two-zone		
	Low state (May 2019) Flaring state (July 2024) The second component (July 2024)				
$t_{\rm var}$ (h)	6.0	1.5	1.5		
$\delta_{\rm D}$	15	20	22		
R (cm)	9.7×10^{15}	3.2×10^{15}	3.6×10^{15}		
B(G)	0.10	0.23	0.10		
$L_{\rm e,inj}$ (erg s ⁻¹)	4.0×10^{41}	1.6×10^{41}	1.7×10^{41}		
p_{e1}	1.4	1.3	2.0		
$p_{\rm e2}$	4.2	3.2	3.2		
$\gamma_{\rm e,min}$	1.0×10^{2}	1.0×10^{2}	3.0×10^4		
$\gamma_{\rm e,b}$	3.0×10^{4}	5.0×10^{4}	6.0×10^4		
$\gamma_{\rm e, max}$	1.0×10^{7}	1.0×10^7	1.0×10^{7}		

Table 1. One-zone and two-zone leptonic model fits to the two epochs of EP240709a with fixed $z = 0.25$

by

$$
\dot{Q}_{e}^{\text{inj}}(\gamma_{e}) = \frac{\dot{Q}_{e,0}\gamma_{e}^{-p_{e1}}}{1 + (\gamma_{e}/\gamma_{e,b})^{p_{e2} - p_{e1}}}, \ \gamma_{e,\text{min}} < \gamma_{e} < \gamma_{e,\text{max}} \tag{1}
$$

where $\gamma_{e,\text{min}}$, $\gamma_{e,b}$ and $\gamma_{e,\text{max}}$ represents the minimum, break and maximum Lorentz factors, respectively, and p_{e1} and p_{e2} represents the spectral indices before and after $\gamma_{\rm e,b}$, respectively. Given an electron injection luminosity $L_{e, \text{inj}}$, $\dot{Q}_{e,0}$ can be determined by $\int \gamma_{\rm e} m_{\rm e} c^2 \dot{Q}_{\rm e}^{\rm inj}(\gamma_{\rm e}) d\gamma_{\rm e} = 3L_{\rm e,inj}/4\pi R^3$, where $m_{\rm e}$ is the electron rest mass. When the electron injection reaches equilibrium with the escape and the radiative cooling via synchrotron and SSC processes, a steadystate electron energy distribution is established. Then, the synchrotron and SSC emissions can be calculated where the absorption by extragalactic background light (Domínguez et al. [2011\)](#page-11-9) on GeV -TeV band is included. The details of models can be seen in [Xue et al.](#page-13-20) [\(2022\)](#page-13-20). The luminosity distance is needed in SED modeling. Nevertheless, the parallax measurement and absence of absorption lines only give a loose constrain on distance from a few kpc to the redshift $z < 2$. Considering the optical color of EP240709a consistent with the distribution from the Blazar Radio and Optical Survey (BROS, [Itoh et al.](#page-12-35) [2020\)](#page-12-35), we estimate the luminosity distance at around 1 Gpc away with redshift around 0.2-0.3, using the redshift-magnitude distribution of blazars in Roma Multifrequency Catalog of Blazars (BZCAT, [Massaro](#page-12-36) [et al.](#page-12-36) [2015;](#page-12-36) [Abrahamyan et al.](#page-9-6) [2019\)](#page-9-6). The redshift is fixed at 0.25 in the following discussion.

The best-fit results are shown in Figure [4](#page-10-3) and the corresponding parameters are given in Table [1.](#page-7-1) In both of one-zone and two-zone model fittings, the spectral index of electrons with $\gamma < \gamma_{\rm e,b}$ is constrained at around 1.4 by the optical-UV photometric observations. Therefore, the slow cooling regime dominates the bulk of electrons; otherwise, the index will be only \sim 0.4. Based on the requirement for slow cooling, the magnetic field can be constrained to a certain extent, $B \le 1.1$ G $(10^{15}$ Hz/ ν_{UV} $)^{1/3}$ $(1.5 \text{ h}/t_{\text{var}})$ $(15/\delta)^{1/3}$, where ν_{UV} is the highest frequency of UV data points.

In the one-zone model, the orphan X-ray flare is interpreted as the spectral hardening of electrons with γ $\gamma_{e,b}$. This implies that a different acceleration mechanism primarily accelerates high-energy electrons and dominates during the flaring state, while the low state is characterized by an acceleration mechanism that predominantly accelerates low-energy electrons. As a result of this shift in acceleration mechanisms, the acceleration efficiency of electrons with $\gamma < \gamma_{e,b}$ decreases during the flaring state, leading to a reduction in their radiation flux. However, it has been observed that the opticalUV flux in the flaring state remains comparable to that in the low state. Furthermore, in the one-zone model, the same population of electrons is responsible for radiation across multiple wavelengths. This makes multiwavelength correlated flares more likely, even though the model effectively fits the SED in the flaring state. In the two-zone scenario, the SED in the flaring state is interpreted by one emitting blob that accounts for the low state emission and the other newly-formed small blob that accounts for the flare. This newly-formed blob has an extremely large minimum Lorentz factor as well as a hard electron energy spectrum, which may be produced through the stochastic acceleration (e.g., [Asano](#page-10-5) [et al.](#page-10-5) [2014\)](#page-10-5). Therefore, it is more natural to attribute the X-ray orphan flare to a newly formed emission region predominantly populated by high-energy electrons responsible for X-ray emission.

5. CONCLUSION

In this work, we report the detection of a rare orphan X-ray flare from a blazar candidate EP240709a with EP. During this flare, the X-ray flux in 0.5-10 keV increased by at least 28 times, while no remarkable brightening was found in radio, infrared, optical, UV and GeV bands. The X-ray spectra can fit well with an absorbed power-law model and show the harder-when-bright feature. This orphan X-ray flare can be interpreted by both the one-zone and two-zone leptonic SSC models. In the one-zone scenario, the spectral hardening of electrons with $\gamma > \gamma_{\rm e,b}$ results in the orphan flare while the low energy electrons contribute to the infrared-optical-UV emissions. In the two-zone scenario, a newly formed plasma blob with an extremely large minimum Lorentz factor emits the synchrotron radiation with high peak frequency, while the previous component dominates the low-frequency emission. The detection of this orphan X-ray flare shows the great potential of EP in discovering peculiar activities from AGNs through long-term, high-cadence monitoring.

APPENDIX

A. THE OBSERVATIONAL LOG AND SPECTRAL PROPERTY

The X-ray observations are summarized in Table [2.](#page-11-6) The X-ray spectra of EP240709a can be well fitted with the absorbed power-law model as shown in Figure [4.](#page-10-3) To evaluate the upper limit and flux in observations with low counts, we fix the hydrogen column density and photon index at 1.5×10^{21} cm⁻² and 2.2, i.e., the mean values from the first and second EP-FXT observations. The χ^2 statistic is adopted for the data observed by EP-FXT and NICER, while the Cash statistic is utilized for the other observations. Solar abundance is referenced according to [Wilms et al.](#page-13-24) [\(2000\)](#page-13-24). The fitted hydrogen column density significantly exceeds the Galactic value of 1.2×10^{20} cm⁻². The X-ray spectra exhibit a harder-when-brighter tendency, particularly in observations with EP-FXT and NICER.
