ABSTRACT

BL Lacertae is a unique blazar for which the X-ray band can cover either the synchrotron or the inverse Compton, or both parts of the broadband spectral energy distribution. In the latter case, when the spectral upturn is located in the X-ray range, it allows contemporaneous study of the low- and high-energy ends of the electron distribution function.

In this work, we study spectral and temporal variability using X-ray and optical observations of the blazar performed with the *Neil Gehrels Swift* Observatory from 2020 to 2023. The large set of observational data reveals intensive flaring activity, accompanied by spectral changes in both spectral branches.

We conclude that the low-energy and high-energy ends of the particle distribution function are characterised by similar variability scales. Additionally, the hard X-ray observations of BL Lacertae performed with the Nuclear Spectroscopic Telescope Array (*NuS-TAR)* confirm a concave spectral curvature for some epochs of the blazar activity and reveal that it can be shifted up to energies of as high as 8 keV.

The time-resolved spectral analysis allows us to disentangle X-ray spectral variability features of the synchrotron from inverse Compton components. Despite significant variability of both spectral components, we find only small changes in the position of the spectral upturn.

The different slopes and shapes of the X-ray spectrum of BL Lacertae demonstrate that the classification of this source is not constant, and BL Lacertae can exhibit features of either high-, intermediate-, or low-energy peaked blazar in different epochs of observation. This also indicates that the spectral upturn for this blazar can be located not only in the X-ray range of 0.3-10 keV, but also at lower or higher energies.

Key words. galaxies: active – galaxies: jets – galaxies: individual: BL Lacertae – γ rays: galaxies

1. Introduction arXiv:2412.18680v1 [astro-ph.HE] 24 Dec 2024

Blazars, a class of active galactic nuclei (AGN) composed of BL Lacertae-(BL Lac)-type objects and flat-spectrum radio quasars (FSRQs), include sources characterised by a polarised and highly variable non-thermal emission. The emission of blazars is believed to be dominated by non-thermal radiation originating from a jet pointing towards the observer [\(Begelman](#page-7-0) [et al. 1984\)](#page-7-0). The emission of blazars is observed at all frequencies, from radio to high- and very high-energy γ rays (e.g. [Wag-](#page-8-0)[ner 2009;](#page-8-0) [Vercellone et al. 2011;](#page-8-1) [H.E.S.S. Collaboration et al.](#page-8-2) [2013,](#page-8-2) [2014;](#page-8-3) [Wierzcholska et al. 2015;](#page-8-4) [Wierzcholska & Wag](#page-8-5)[ner 2020\)](#page-8-5). The broadband spectral energy distribution (SED) of blazars has a typical structure with two prominent bumps. The low-energy bump is attributed to synchrotron radiation of relativistic electrons from the jet, while the origin of the highenergy bump is still under debate (see e.g. [Maraschi et al. 1992;](#page-8-6) [Kirk et al. 1998;](#page-8-7) [Aharonian 2000;](#page-7-1) [Atoyan & Dermer 2003;](#page-7-2) [Mücke et al. 2003;](#page-8-8) [Böttcher et al. 2013\)](#page-7-3). The most common explanation for this double structure is the synchrotron self-Compton model (SSC; e.g. [Maraschi et al. 1992;](#page-8-6) [Kirk et al.](#page-8-7) [1998\)](#page-8-7), where the origin of the high-energy bump is attributed to inverse Compton radiation scattered by the same population of relativistic electrons. Alternatively, the high-energy peak can be interpreted within the context of hadronic models. In these scenarios, the high-energy radiation originates from processes such as a proton synchrotron emission, synchrotron, and Compton emission from secondary decay products of charged pions, or π_0 decay (see e.g. [Aharonian 2000;](#page-7-1) [Mücke et al. 2003;](#page-8-8) [Böttcher et al. 2013\)](#page-7-3).

Among BL Lac-type blazars, high-, intermediate-, and low-energy peaked objects can be distinguished, and are known as HBL, IBL, and LBL objects, respectively (see e.g. [Padovani & Giommi 1995;](#page-8-9) [Fossati et al. 1998;](#page-7-4) [Abdo et al.](#page-7-5) [2010\)](#page-7-5). Correspondingly, the X-ray spectrum of the different sub-classes of BL Lac objects covers different components of the broadband SED. For HBL-type blazars, in the broadband SED, the X-ray spectrum is a part of the synchrotron domain. For LBL-type blazars, the X-ray spectrum belongs to the inverse Compton bump. In the case of IBL-type sources, the Xray emission usually covers either the synchrotron component or the inverse Compton component, or both. The spectral upturn in the X-ray domain has been reported for several IBLtype sources, such as BL Lacertae [\(Tanihata et al. 2000;](#page-8-10) [Rava](#page-8-11)[sio et al. 2002;](#page-8-11) [Donato et al. 2005;](#page-7-6) [Wierzcholska & Wagner](#page-8-12) [2016\)](#page-8-12), W Comae [\(Tagliaferri et al. 2000;](#page-8-13) [Donato et al. 2005;](#page-7-6) [Wierzcholska & Wagner 2016\)](#page-8-12), S5 0716+71 [\(Cappi et al.](#page-7-7) [1994;](#page-7-7) [Giommi et al. 1999;](#page-8-14) [Tagliaferri et al. 2003;](#page-8-15) [Donato et al.](#page-7-6) [2005;](#page-7-6) [Ferrero et al. 2006;](#page-7-8) [Wierzcholska & Siejkowski 2015;](#page-8-16) [Wierzcholska & Wagner 2016;](#page-8-12) [Wierzcholska & Siejkowski](#page-8-17) [2016\)](#page-8-17), AO 0235+16 [\(Raiteri et al. 2006\)](#page-8-18), OQ 5310 [\(Taglia-](#page-8-15) [ferri et al. 2003\)](#page-8-15), 3C 66A [\(Donato et al. 2005;](#page-7-6) [Wierzcholska &](#page-8-12) [Wagner 2016\)](#page-8-12), and 4C+21.35[\(Wierzcholska & Wagner 2016\)](#page-8-12).

Studies of X-ray observations of different blazars have revealed strong variability in this energy regime, with different amplitudes of variability and on different timescales (e.g. [Sem](#page-8-19)[bay et al. 1993;](#page-8-19) [Tanihata et al. 2000;](#page-8-10) [Sembay et al. 2002;](#page-8-20) [Zhang](#page-8-21) [et al. 2002,](#page-8-21) [2005\)](#page-8-22). Also, for several HBL blazars, a so-called 'harder-when-brighter' behaviour manifests as hardening of the spectral index with increasing flux level (e.g. [Pian et al.](#page-8-23) [1998;](#page-8-23) [Zhang et al. 2005,](#page-8-22) [2006;](#page-8-24) [H.E.S.S. Collaboration 2012;](#page-8-25) [Wierzcholska et al. 2019\)](#page-8-26). This feature is not common to all subclasses of blazars. In the case of IBL-type blazars in particular, in which X-ray spectra are due to different processes, the variability patterns are expected to be more complex.

BL Lacertae, a blazar at a redshift of $z = 0.069$ [\(Miller](#page-8-27) [& Hawley 1977\)](#page-8-27), is the prototype of the BL Lacertae class of blazars. This particular source is classified as either LBL [\(Nils](#page-8-28)[son et al. 2018\)](#page-8-28) or IBL [\(Ackermann et al. 2011\)](#page-7-9). The source has been observed in all energy regimes, starting from radio up to very high-energy γ rays, with several multiwavelength campaigns targeting the blazar (e.g. [Bertaud et al. 1969;](#page-7-10) [Made](#page-8-29)[jski et al. 1999;](#page-8-29) [Villata et al. 2004;](#page-8-30) [Papadakis et al. 2007;](#page-8-31) [Vil](#page-8-32)[lata et al. 2009;](#page-8-32) [Raiteri et al. 2013;](#page-8-33) [Agarwal & Gupta 2015;](#page-7-11) [MAGIC Collaboration et al. 2019\)](#page-8-34). Several X-ray campaigns performed with instruments such as HEAO–1, Einstein, Ginga, ROSAT, ASCA, *Beppo*SAX, RXTE, and *Swift* revealed significant spectral and temporal variability of BL Lacertae.

In the present work, we aim to characterise the spectral and temporal X-ray variability of BL Lacertae based on recent (2020-2023) *Swift* observations of the blazar. Additional information about the X-ray properties of the blazar is added thanks to *NuSTAR* data. The paper is organised as follows: Section [2](#page-1-0) describes the data used and our analysis techniques. Sections [3-](#page-1-1) [6](#page-5-0) focus on the description of the spectral and temporal variability of BL Lacertae, and we outline our conclusions in Sect. [7.](#page-5-1)

2. Observations and data analysis

Swift-XRT and Swift-UVOT observations

The *Neil Gehrels Swift* Observatory (hereafter *Swift*; [Gehrels](#page-7-12) [et al. 2004\)](#page-7-12) launched in November 2004 is a multiwavelength space observatory equipped with three instruments: the Burst Alert Telescope (BAT; [Barthelmy et al. 2005\)](#page-7-13), the X-ray Telescope (XRT; [Burrows et al. 2005\)](#page-7-14), and the Ultraviolet/Optical Telescope (UVOT; [Roming et al. 2005\)](#page-8-35), allowing observations in X-ray, ultraviolet, and optical energy ranges.

Our detailed spectral and temporal analysis focuses on observations collected in the period of 2020-2023, corresponding to the ObsIDs of 00030720231-00035028001. The Xray data in the energy range of 0.3-10 keV collected with *Swift*/XRT were analysed using 6.31.1 of the HEASOFT pack-age^{[1](#page-1-2)}. The data were recalibrated using the standard procedure xrtpipeline. For the spectral fitting, XSPEC v.12.13.1 was used [\(Arnaud 1996\)](#page-7-15). All data were binned to have at least one count per bin.

We used version 6.31.1 of the HEASOFT package to analyse the optical and ultraviolet observations of *Swift*/UVOT in six bands, namely UVW2 (188 nm), UVM2 (217 nm), UVW1 (251 nm), U (345 nm), B (439 nm), and V (544 nm). The instrumental magnitudes were calculated using uvotsource, including all photons from a circular region with a radius of 5".

The background was determined from a circular region with a radius of 10" near the source region not contaminated with the signal from nearby sources. The flux conversion factors as provided by [Poole et al.](#page-8-36) [\(2008\)](#page-8-36) were used. All data were corrected for the dust absorption using the reddening $E(B - V) =$ 0.2821 as provided by [Schlafly & Finkbeiner](#page-8-37) [\(2011\)](#page-8-37). The ratios of the extinction to reddening, $A_{\lambda}/E(B-V)$, for each filter were provided by [Giommi et al.](#page-7-16) [\(2006\)](#page-7-16).

NuSTAR observations

The Nuclear Spectroscopic Telescope Array (*NuSTAR*) is a satellite instrument dedicated to observations in the hard Xray regime up to 79 keV [\(Harrison & NuStar Team 2013\)](#page-8-38). All observations were performed in the SCIENCE mode. The raw data were processed with the *NuSTAR* Data Analysis Software package (NuSTARDAS, released as part of HEASOFT 6.31.1) using the standard nupipeline task. Instrumental response matrices and effective area files were produced with the nuproducts procedure. The spectral analysis was performed for the channels corresponding to the energy band of 3-79 keV.

NuSTAR observed BL Lacertae seven times. All these observations are listed in Tabl[e1](#page-2-0) and marked as N1-N7. We note here that BL Lacertae was observed twice with *NuSTAR* in 2012; however, due to its very short duration, the first observation is neglected in these studies. Table [1](#page-2-0) also includes information about simultaneous observations performed with *Swift*/XRT, if available.

3. Long-term X-ray light curve of BL Lacertae

Figure [1](#page-2-1) presents the long-term light curve of BL Lacertae in the energy range of 0.3-10 keV based on all *Swift*/XRT observations performed between 2005 and 2023. The light curve presented in Fig. [1](#page-2-1) demonstrates significant temporal variability of the source. In particular, the average count rate of the entire period of observations is 0.5±0.1 counts s⁻¹, while between 2020 and 2023 (the shaded area in Fig[.1\)](#page-2-1) this value is 1.0±0.1 counts s[−]¹ . The observations performed before 2020 are characterised by a count rate of 0.4 ± 0.1 counts s⁻¹. This indicates significantly higher fluxes in the period of 2020-2023 compared to previous years, that is, higher by a factor of 2. The highest point in the X-ray light curve is significantly above the others with the count rate being about 12 counts s⁻¹. That corresponds to the *Swift*/XRT observation performed on October 6, 2020. We note here that no intra-observation variability was detected in this extraordinary observation of BL Lacertae.

4. Spectral and temporal variability

X-ray observations

Between 2020 and 2023, BL Lacertae was observed more than 160 times with *Swift*/XRT in the energy range of 0.3-10 keV (ObsIDs of 00030720231-00096565004). In order to characterise all 2020-2023 observations in terms of spectral and temporal properties, we analysed each of these observations as described above, and fitted them using two spectral models: a single power-law model and a log-parabola, both with the Galactic column density value of N_H=3.03 · 10²⁰ cm⁻² as provided by [Willingale et al.](#page-8-39) [\(2013\)](#page-8-39).

The models mentioned above are as follows:

¹ [http://heasarc.gsfc.nasa.gov/docs/software/](http://heasarc.gsfc.nasa.gov/docs/software/lheasoft) [lheasoft](http://heasarc.gsfc.nasa.gov/docs/software/lheasoft)

(5) ID of *Swift*/XRT observations simultaneous to the *NuSTAR* one. (6) Duration of *Swift*/XRT observation (in seconds). (7) Date of *Swift*/XRT observation.

Fig. 1. Long-term (2005-2023) X-ray light curve of BL Lacertae in the energy range of 0.3-10 keV, including all *Swift*/XRT observations of BL Lacertae. The shaded area indicates 2020-2023 observations. The coloured vertical lines indicate *NuSTAR* observations of BL Lacertae as discussed in Sect[.6.](#page-5-0)

– a single power-law model, defined as

$$
\frac{dN}{dE} = N_p \left(\frac{E}{E_0}\right)^{-\gamma},\tag{1}
$$

– a logarithmic parabola (or curved power law), defined as

$$
\frac{dN}{dE} = N_l \left(\frac{E}{E_0}\right)^{-(\alpha+\beta\log(E/E_0))}.\tag{2}
$$

The power-law model is characterised by the normalisation N_p and the spectral index Γ (at energy E_0), while the logparabola model is described with the normalisation N_l , the curvature parameter β , and the spectral index α (at energy E_0). In both cases, the scale energy E_0 is fixed at 1 keV. The goodness of both fitted models is compared using the F-test (e.g. [Bevington](#page-7-17) [& Robinson 2003\)](#page-7-17). We note here that logparabola models are only preferred when β is negative, that is, a spectral upturn is observed in the range of the 0.3-10 keV band.

Figure [2](#page-3-0) presents a light curve of BL Lacertae in the energy range of 0.3-10 keV for the period of 2020-2023. Different coloured points are used to denote the preferred spectral model used to describe the spectrum of a single observation, as follows:

- 1. green points show spectra for which the logparabola model with β <0 is preferred;
- 2. red points show spectra for which the power-law model is preferred and γ <2;
- 3. blue points show spectra for which the power-law model is preferred and $\gamma > 2$.

Based on the coloured SED, (1) refers to the X-ray spectrum covering both the synchrotron and inverse Compton components. While cases (2.) and (3.) correspond to the situation when the X-ray spectrum dominates either the inverse Compton or synchrotron component only. As shown in Fig. [2,](#page-3-0) the curved power-law model with a negative curvature is the best description of more than half of the X-ray spectra. This spectral shape confirms the presence of both synchrotron and inverse Compton components in the energy range studied. The red coloured spectra, which describe the inverse Compton spectrum only, are in the minority and are only preferred for the low X-ray fluxes of BL Lacertae.

The highest point in the light curve corresponds to the flux of $(3.32\pm0.04)\cdot10^{-10}$ erg cm⁻²s⁻¹ and this is the largest X-ray flux measure with XRT so far for BL Lacertae.

The models power-law and logparabola) used to describe the spectral shapes of *Swift*/XRT observations are shown in Fig. [3.](#page-3-1) The same colour coding is used as in the case of Fig. [2.](#page-3-0)

Figure [4](#page-3-2) shows the relation between the 0.3-10 keV flux measured for each XRT observation of BL Lacertae and the corresponding photon index: γ or α for a power-law or logparabola fit, respectively. In order to check the relation between these two quantities, the Pearson correlation coefficient is calculated for all data points and for a subset of blue points only. The results are 0.40 ± 0.04 and 0.54 ± 0.10 , respectively, indicating a lack of correlation for the entire dataset, but a weak correlation when only a subset is taken into account.

Fig. 2. Long-term light curve of BL Lacertae presenting the 2020-2023 monitoring of the source in the energy range of 0.3-10 keV. Green, red, and blue points indicate different spectral shapes as defined in Sect. [4.](#page-1-3) The vertical lines and numbers indicate the intervals studied in Sect[.5.](#page-4-0) Intervals N4-7 marked with coloured vertical lines correspond to the same intervals as those marked in Fig[.1.](#page-2-1)

Fig. 3. Spectral energy distributions for different activity states of BL Lacertae. Each spectrum represents one *Swift*/XRT observation of the blazar. The same colour coding as in Fig[.2](#page-3-0) is used.

Ultraviolet and optical observations

Together with X-ray observations, *Swift* observed BL Lacertae simultaneously in the UV and optical wavebands. Figure [6](#page-4-1) presents a comparison of X-ray and optical fluxes in the energy range of 0.3-10 keV and the B band. Each data point corresponds to one observation. Significant variability is seen in both energy regimes, as presented in the light-curve plots (see Figs[.2](#page-3-0) and [5](#page-3-3) for reference). The flux changes seen in the Xray and optical band, however, are not identical. Figure [6](#page-4-1) also shows that two distinct trends are present. The X-ray and optical fluxes are correlated for high optical fluxes above $2 \cdot 10^{-10}$ erg cm⁻²s⁻¹, and the opposite trend is present below this value. The exceptional X-ray activity observed on October 6, 2020, has no counterpart in the optical range.

Spectral variability

A spectral power-law index (Γ*syn*) describing a low-energy bump of the broadband SED is calculated between an optical B point and the low-energy end of the X-ray spectrum; that is, the X-ray model flux at 0.3 keV. Here, Γ*syn* is defined as follows:

Fig. 4. Comparison of the X-ray flux in the energy range of 0.3-10 keV and the corresponding photon index for all 2020-2023 observations of BL Lacertae.

Fig. 5. Long-term light curve of BL Lacertae presenting the 2020- 2023 monitoring of the source in the optical B band.

$$
\Gamma_{syn} = \frac{\log F_X - \log F_O}{\log E_X - \log E_O},\tag{3}
$$

where E_X is the energy of the X-ray point, E_O is the energy of an optical point, and F_X and F_O are X-ray and optical fluxes,

Fig. 6. Comparison of the optical and corresponding X-ray fluxes. Plot based on the data presented in Fig[.2](#page-3-0) and Fig. [5.](#page-3-3)

Fig. 7. Comparison of Γ*syn* as a function of the X-ray model flux at 0.3 keV. The colour-coding (same as in Fig. [2\)](#page-3-0) denotes the different models describing the spectral shapes.

respectively. We note here that $E_X = 0.3 \text{ keV}$, while $E_O =$ 2.85 eV. Also, F_X and F_O are normalised by keV cm^{-2} s⁻¹, while E_X and E_O are normalised by keV.

Figure [7](#page-4-2) shows a comparison between the Γ*syn* index and the X-ray flux at 0.3 keV. The same colour coding as in Fig[.2](#page-3-0) is used to indicate the preferred spectral models of the single X-ray spectra, and the green colour corresponds to the curved spectra with a negative curvature parameter, while the powerlaw spectra are denoted with red and blue points. A clear linear trend is present for blue and green points, while the outliers in the plot are all denoted with red points. This indicates that Γ*syn* is correlated with the X-ray flux in the case where the Xray spectrum covers mainly or only the synchrotron part of the SED. Red points —which do not follow the trend— fully describe the high-energy part of the SED. Interestingly, Γ*syn* is not correlated with the X-ray model flux at 10 keV.

A comparison of Γ*syn* as a function of the X-ray photon index describing the *Swift*/XRT spectrum is shown in Fig. [8.](#page-4-3) The spectral index used here is either γ or α depending on the spectral model preferred to describe the X-ray spectrum

Fig. 8. Comparison of Γ_{syn} as a function of X-ray spectral index (γ or α depending on the spectral model used). The colour coding (same as in Fig[.2\)](#page-3-0) denotes the different models describing the spectral shapes.

of BL Lacertae. A linear trend is present for green and blue points, while the red points do not follow this relation, which is similarly to in the case of Fig. [7.](#page-4-2) Again, this relation linking Γ*syn* and the X-ray photon index is not followed by the red points but is followed by a few of the blue points.

5. Time-resolved spectral variability

To investigate the spectral variability in greater detail, the longterm X-ray light curve of BL Lacertae was divided into shorter intervals characterised by similar flux levels and consisting of a sufficient number of observations to constrain spectral parameters with accuracy and allow investigation of their evolution. The division into ten intervals is presented in Fig. [2](#page-3-0) and the intervals are numbered for clarity. In the figure, interval 11 is also marked. For this subset of observations, the X-ray spectrum is well described with a power-law model with a photon index of 1.82 ± 0.04 .

The spectral analysis of each of the intervals selected includes spectral fitting with a logparabola model and a double power-law model. In both cases, the Galactic absorption was also included in the spectral model. Table [2](#page-6-0) and Fig. [9](#page-5-2) present the variations of spectral parameters derived for the spectral fits.

The photon index of the low-energy component changes between 2.7 and 3.6, while that of the high-energy component varies between 0.8 and 1.8. Also, the crossing point of two spectral components moves to higher energies with increasing total flux. However, the range of detected values of the crossing point of 1.3-2.1 keV is small.

The relative contribution of the synchrotron component, which is 12−45% depending on the activity state of BL Lacertae, shows that the X-ray spectrum of BL Lacertae is dominated by the high-energy (inverse Compton) component. The contribution of the low-energy component is the largest for interval 3, which is the epoch where the source is in its highest state.

The separation of synchrotron and inverse Compton components allows a comparison of the variability in the two components.

Fig. 9. Spectral variations during the observation period. Each spectrum is derived for the interval defined in Fig. [2.](#page-3-0) Two spectral models, namely a log-parabola and double power law, as well as data points are shown in each plot. The spectral parameters of each plot are given in Table [2.](#page-6-0)

A first test investigating whether the low-energy end of the inverse Compton component reveals any significant variability within the data set. For this purpose, the low-energy component a fixed value of a photon index and normalisation is used and the parameters of the high-energy component are left free. Different values of the photon index and normalisation were tested, including all the possibilities listed in Table [2.](#page-6-0) Such a spectral fitting in all cases, however, resulted in reduced χ^2
values of significantly higher than 1 and large residuals at the values of significantly higher than 1, and large residuals at the high-energy end of the spectrum, discrediting such a scenario.

Fig. 10. The models of spectral energy distributions of BL Lacertae obtained based on *NuSTAR* and *Swift*/XRT simultaneous observations. Different colours denote separate epochs of observations as defined in Tabl[e1.](#page-2-0) Data points for each set of observations are denoted with the same colours.

6. Hard X-ray observations of BL Lacertae with NuSTAR

Additional information about X-ray spectra of BL Lacertae can be obtained thanks to hard X-ray observations performed with *NuSTAR*. As listed in Table [1,](#page-2-0) there are six observations of *NuSTAR* with exposure longer than 1ks. For five of them, there are also simultaneous XRT observations, allowing us to constrain the X-ray emission of the blazar in the energy band starting from 0.3 up to 70keV.

In the case of all six *NuSTAR* and simultaneous *Swift*/XRT observations, both models: a single power-law and logparabola were used. The preferred model was selected using the Ftest. Based on the test for all cases, the X-ray emission of BL Lacertae is best represented with a curved power-law model in four cases (N2, N3, N4, and N7) and a single powerlaw model in the others. Where a power-law model is preferred, the hard X-ray spectrum is only able to clearly describe the inverse Compton part of the spectrum, and there is no indication of the presence of a spectral upturn in this energy regime. We also note here that, for the N4 epoch, the curvature seen in the spectrum is marginal and a point of spectral upturn is also not clearly indicated. In the case of epochs N2, N3, and N7 *Swift*/XRT-*NuSTAR* joint spectra describe both spectral components of BL Lacertae. However, all three epochs differ in terms of spectral curvature and the position of the crossing point. For N2 and N7, a crossing point is located above 2 keV and a curvature parameter is between (-0.2) and (-0.1), while in the case of N3, the spectral curvature is more significant, with $\beta = -0.5$, and the crossing point is at E=8 keV. The N3 epoch corresponds to rather low activity of the blazar (see Fig[.1\)](#page-2-1). Thus, the location of the crossing point for this epoch is significatly higher than the crossing points observed for the *Swift*/XRT observations.

7. Summary

In this work, we present an analysis of long-term X-ray and optical observations of the blazar BL Lacertae. Numerous obser-

Table 2. Results of the time-resolved spectral analysis of the *Swift* data.

vations of the source performed with *Swift*/XRT, *Swift*/UVOT, and *NuSTAR* revealed different activity states of this AGN.

Studies of X-ray, optical, and ultraviolet observations of BL Lacertae have confirmed the strong temporal variability of the source, which is associated with spectral changes. Based on the long-term X-ray observations collected with *Swift*/XRT, the difference between the lowest and the highest count rates observed is 12 cts s[−]¹ , which is 24 times more than the average count rate. Large changes in the flux are also present in the optical and ultraviolet domains. The highest X-ray point reported, which corresponds to the observations performed on October 6, 2020, represents the historical maximum of the *Swift*/XRT monitoring of BL Lacertae. However, we note that the optical flux measured simultaneously in X-rays corresponds to a high state of the source, but does not represent the historical optical maximum.

Our analysis of the long-term behaviour of BL Lacertae based on *Swift*/XRT observations collected in 2006-2023 shows that the largest activity of the blazar started in 2020 and continued in the following years. Our detailed analysis of the X-ray observations collected from 2020 to 2023 with *Swift*/XRT reveals significant spectral and temporal variability of the source, and a complex behaviour during this period of intensive observations. Similarly, in the optical frequencies, the 2020-2023 fluxes are significantly higher than in the previous years (see e.g. the optical monitoring of BL Lacertae with the ATOM telescope [Wierzcholska et al. 2015\)](#page-8-4).

The large set of X-ray observations performed with the two X-ray instruments *Swift*/XRT and *NuSTAR* allows simultaneous measurements of the high- and low-energy ends of the particle distribution function for this source. In the X-ray energy range of 0.3-10 keV, significant variability can be seen both in the synchrotron and inverse Compton branches in terms of amplitude and variability scales. The amplitude of this variability is similar for synchrotron and inverse Compton ranges. Given the similar variability scales observed in both the synchrotron and inverse Compton branches, radiative cooling does not dominate the variability characteristics of BL Lacertae.

The spectral model describing single X-ray observations is either a power-law or logparabola model, depending on the epoch of the observation. The case of the curved model corresponds to the situation where the transition between the synchrotron and inverse Compton component is visible in the energy range of 0.3-10 keV. The spectral curvatures described by the β parameter in the model range between –0.1 and –0.8 indicate changes in the slope of the spectral components. For the curved power-law model, for all cases, the spectral upturn is located below 2 keV. However, given the variety of the X-ray spectra, which exhibit either synchrotron or inverse Compton or both spectral components with the spectral upturn, we note that the crossing energy for BL Lacertae can be outside the energy band of 0.3-10 keV. In particular, for the power-law spectra with a photon index of smaller than 2, the spectral upturn is located below 0.3 keV, while for the power-law spectra with a photon index larger than 2, the spectral upturn is located above 10 keV.

Given this characteristic, BL Lacertae is a unique example of a source exhibiting features of HBL-, IBL-, and LBL-type blazars, depending on the epoch of the observation. This occurs because the photon index and curvature of the spectrum change between epochs. The X-ray spectrum of BL Lacertae can either cover the synchrotron branch of the broadband SED, the inverse Compton one, or both, which correspond to the HBL-, LBL-, or IBL-type blazar characteristics, respectively. Interestingly, in the low state of the source, the blazar exhibits an X-ray spectrum with an LBL-like character, while for higher fluxes the source shows either HBL-like or IBL-like features in its X-ray spectrum.

The IBL-like characteristic of BL Lacertae confirms that the energy range of 0.3-10 keV is a region where two spectral components, synchrotron and inverse Compton, meet each other, which was already reported in previous studies focusing on BL Lacertae. These studies reported the spectral transition

of the synchrotron and inverse Compton component at energies below 2 keV. In particular, [Tanihata et al.](#page-8-10) [\(2000\)](#page-8-10) reported the spectral break at about 1 keV. [Donato et al.](#page-7-6) [\(2005\)](#page-7-6) found the transition point of the spectral components at 0.5 keV. The recent studies by [Wierzcholska & Wagner](#page-8-12) [\(2016\)](#page-8-12) showed that regardless of the epoch of observation, the spectral break is located at 1 keV. At the same time, both spectral components change in slope and flux normalisation. In the present work, we report similar values of the crossing point based on *Swift*/XRT observations of synchrotron and inverse Compton components ranging between 1.3 and 2.0 keV and being almost constant within the uncertainties, regardless of significant changes in flux and photon index.

A two-component model was also preferred for joint XMM-Newton-*NuSTAR* observations of the source, with a crossing point located at approximately 2 keV [\(Peirson et al.](#page-8-40) [2023\)](#page-8-40). The simultaneous IXPE observations during this campaign resulted in the first detection of X-ray polarisation in BL Lacertae, which the authors found to be possibly related to the larger contribution of the synchrotron component to the X-ray spectrum of the blazar. The X-ray polarisation was not detected in the previous, low-state observations of BL Lacertae with IXPE [\(Middei et al. 2023\)](#page-8-41).

To characterise spectral changes in the low-energy end of the electron distribution function, we used the Γ*syn* parameter, which we calculated for each individual X-ray point during the 2020-2023 epoch. A comparison of Γ*syn* and X-ray flux at 0.3 keV revealed a linear relation for those spectra, which correspond to mainly the synchrotron component, except in the case of the X-ray slopes, which characterise the inverse Compton part of the SED. Also, a comparison of Γ*syn* as a function of the X-ray photon index revealed a similar feature. A linear trend is present for all points that correspond to spectra representing synchrotron components. These comparisons confirm that BL Lacertae is a blazar for which the X-ray band of 0.3-10 keV can correspond to different bumps on the SED.

The comparison of the X-ray flux and corresponding photon index revealed that the harder-when-brighter relation is not present at any point during the entire set of 2020-2023 observations. The colour coding used revealed that spectra with different characteristics (different colours) are clustered in the figure.

The dense monitoring of BL Lacertae performed with *Swift* allowed us to perform time-resolved spectral analysis, focusing on intervals of the blazar's activity. These studies confirm the location of the spectral upturn in the *Swift*/XRT band. The analysis of time-resolved spectra also revealed strong temporal variability associated with spectral changes. The position of the crossing point varies with temporal changes but remains confined to a small range of energies. We reject the hypothesis that only one spectral component varies with time while the other remains constant. Furthermore, in the case of the highest Xray fluxes observed, the largest contribution of the low-energy component during these observations supports the scenario according to which the flaring activity of BL Lacertae is mainly caused by the high-energy tail of the synchrotron component. A similar trend was reported in the case of another IBL-type blazar, S5 0716+714 [\(Ferrero et al. 2006\)](#page-7-8).

Different activity states of BL Lacertae were also observed with *NuSTAR*. These hard X-ray observations of BL Lacertae confirm that its X-ray spectrum exhibits different properties, including the situation where it covers only the inverse Compton bump, and the presence of a crossing point in the hard Xray regime. The concave curvature of the *NuSTAR*-*Swift*/XRT spectrum of the blazar was well constrained and there was no need for an additional absorption component below 2 keV. We also note here that in the case of two observations performed with *NuSTAR*, a crossing point is located at the energy of about 2 keV, while in one case the upturn is at about 8 keV, which is the highest upturn energy reported for this blazar. *NuSTAR* observations of BL Lacertae do not support the hypothesis that a spectral crossing point is moving to higher energies with increasing flux.

We note here, however, that for the X-ray spectra provided by the integrated *Swift*/XRT observations, the upturn point changes its position only in a limited range of energies and does not reach energies as high as in the case of *NuSTAR* spectra. This may be the result of the averaging of the long-term observations effect. We conclude that the energy crossing point moves to higher energies only for short periods of the observations. These higher energies of the spectral upturn are also not reproduced in the single-observation spectra of *Swift*/XRT data because of insufficient temporal resolution.

Acknowledgements. The project is co-financed by the Polish National Agency for Academic Exchange. This research has made use of the *NuSTAR* Data Analysis Software (NuSTARDAS) jointly developed by the ASI Space Science Data Center (SSDC, Italy) and the California Institute of Technology (Caltech, USA). The authors acknowledge the use of public data from the *Swift* data archive. The authors gratefully acknowledge Polish high-performance computing infrastructure PLGrid (HPC Center: ACK Cyfronet AGH) for providing computer facilities and support within computational grant no.
