ABSTRACT

We present the Active Galactic Nuclei (AGN) catalog from the fourth data release (HDR4) of the Hobby-Eberly Telescope Dark Energy Experiment Survey (HETDEX). HETDEX is an untargeted spectroscopic survey. HDR4 contains 345,874 Integral Field Unit (IFU) observations from January 2017 to August 2023 covering an effective area of 62.9 deg². With no imaging pre-selection, our spectroscopic confirmed AGN sample includes low-luminosity AGN, narrow-line AGN, and/or red AGN down to $g \sim 25$. This catalog has 15,940 AGN across the redshifts of $z = 0.1 \sim 4.6$, giving a raw AGN number density of 253.4 deg⁻². Among them, 10,499 (66%) have redshifts either confirmed by line pairs or matched to the Sloan Digital Sky Survey Quasar Catalog. For the remaining 5,441 AGN, 2,083 are single broad line AGN candidates, while the remaining 3,358 are single intermediate broad line (full width at half maximum, FWHM $\sim 1200 \text{ km s}^{-1}$) AGN candidates. A total of 4,060 (39%) of the 10,499 redshift-confirmed AGN have emission-line regions 3σ more extended than the image quality which could be strong outflows blowing into the outskirts of the host galaxies or ionized intergalactic medium.

Keywords: galaxies: Active Galactic Nuclei

1. INTRODUCTION

The Hobby-Eberly Telescope Dark Energy Experiment Survey¹ (HETDEX; Gebhardt et al. 2021) is a groundbreaking survey designed to map the large-scale structure of the universe and constrain the nature of dark energy at cosmic noon through the observation of Lyman Alpha Emitters (LAEs) and other extragalactic populations. However, beyond its cosmological ob-

jectives, HETDEX offers unique opportunities to probe active galactic nuclei (AGN) within its untargeted spectroscopic survey. Its integral field unit (IFU) configuration enables the untargeted spectroscopic observations with no imaging pre-selections. This allows the identification of AGN, including populations that are typically underrepresented in traditional surveys, such as the low-luminosity AGN, narrow-line AGN, and/or red quasars at z>1. These AGN, which are usually rejected by the imaging pre-selections in traditional surveys, can be efficiently revealed using IFU surveys (e.g. Jarvis et al. 2005; Gavignaud et al. 2006; Liu et al. 2022a,b).

AGN are pivotal in understanding the co-evolution of galaxies and their central supermassive black holes (SMBHs). They serve as laboratories for studying

^{*} NASA FINESST Fellow

¹ https://hetdex.org/

phenomena such as galaxy feedback, accretion physics, and the role of ionizing radiation in the intergalactic medium. HETDEX, with its large field of view and untargeted spectroscopic approach, is particularly suited to addressing challenges in AGN science, such as uncovering extended Lyman Alpha blobs (LABs) around AGN. The spatially resolved spectra can help understand the origins of the extended emission-line regions around AGN and quantify the potential mass exchanges between the central SMBHs and their host galaxies.

The second HETDEX Data Release (HDR2) AGN catalog is discussed in Liu et al. (2022a,c). In this paper, we release the 15,877 AGN identified from the fourth HETDEX Data Release (HDR4), which includes observations from January 2017 through August 2023. Section 2 provides an overview of the HETDEX observations and data release history. Section 3 introduces the identification methods of AGN detections. Since HETDEX is an IFU survey, a single AGN can be detected with multiple fiber detections. Section 4 discusses how we deal with duplicate detections and generate the unique AGN catalog. Section 5 discusses the completeness of this catalog. Section 6 presents the statistics of the catalog (redshift and g-band magnitudes). Section 7 provides details of the data construction of the catalog file. Section 8 summarizes this catalog release.

2. OBSERVATIONS, DATA REDUCTIONS, AND DATA RELEASE HISTORY

HETDEX is an untargeted spectroscopic survey aiming at mapping the 1.88 < z < 3.52 universe and measure its expansion rate to 1\% precision by providing the redshifts of a million Lyman-Alpha Emitters (LAEs) over 540 deg². The untargeted spectroscopic observations with no imaging pre-selections are acquired by the Visible Integral-field Replicable Unit Spectrograph (VIRUS; Hill et al. 2021). VIRUS has $78.51'' \times 51''$ IFUs spanning on the central 18' field of view of the 22' focal plane on the 10-meter Hobby-Eberly Telescope (HET; Ramsey et al. 1998). The survey began from January 2017 with 16 IFUs mounted. IFUs were installed on the telescope gradually. All IFUs were completed with their installation in August 2021. Each IFU bundle consists of 448 1.5" diamter fibers. Upon completion, each HET-DEX exposure collects 34,944 fiber spectra. The survey was recently completed with all observations in August 2024. The spectral coverage is from 3500 to 5500 Å with the resolving power of $R \sim 800$.

The survey design, data reductions, and emissionline detection algorithms are detailed in Gebhardt et al. (2021). Each "shot" consists of three 6-minute dithered exposures to fill the space between fibers of individual IFU. This procedure yields a filling factor of 1/4.6 on the completion of all 78 IFUs. Sky subtraction is done with single amplifier (112 fibers). A HETDEX g-band reconstructed image (integrated over 4400 - 5200 Å) is generated for each shot. Astrometry and flux of the reconstructed images are calibrated to a collection of stars in the Sloan Digital Sky Survey (SDSS) fifteenth Data Release (DR15) (York et al. 2000; Abazajian et al. 2009), Gaia DR2 (Gaia Collaboration et al. 2018), Panoramic Survey Telescope and Rapid Response System (PanStarrs; Chambers et al. 2016; Flewelling et al. 2020), and United States Naval Observatory (Roeser et al. 2010) catalogs. All HETDEX flux calibrated spectra in this paper are not corrected for foreground Galactic extinction.

Image quality and its error is calculated as the mean Full Width at Half Maximum (FWHM) of the Point Spread Functions (PSFs) of bright stars in the frame (typically ~ 30 stars). The typical image quality is FWHM_virus \sim 1.8". At the project's nominal depth, the PSF-weighted line flux sensitivity reaches a 5σ limit of 3.5×10^{-17} ergs cm $^{-2}$ s $^{-1}$ at $\lambda\sim5000$ Å.

The first HETDEX Data Release (HDR1) contains observations through June 2019 and was commissioning so kept internal. HDR2 is through June 2020. The HDR2 source catalog (200,000 sources with 51,863 $z\sim2.5$ LAEs) is available in Mentuch Cooper et al. (2023). The HDR2 AGN catalog has 5,322 AGN (Liu et al. 2022a), hereafter Liu22. The third HETDEX Data Release (HDR3) is through August 2022. The first public data release (PDR1) based on HDR3 will contain ~300 million fiber spectra and 500,000 sources (Mentuch Cooper et al., in preparation 2025). Observations of HDR4 were completed in August 2023 with the full survey 72% completed. This paper describes the HETDEX HDR4 AGN catalog.

3. AGN DETECTION IDENTIFICATION

The most important sources that meet HETDEX's primary goal of measuring the cosmology at cosmic noon are the LAEs. The main source catalog is focused on the narrow emission line detections down to signal-to-noise ratio (SNR) levels of $\sim 4.5\sigma$. The AGN whose lines are usually broad should be identified independently from the main source catalog.

Liu22 presents details of the AGN identification process in Section 4 and summarizes it in a flowchart (Figure 5). Here, we briefly review this process. We start from the direct detection products of the HETDEX pipeline (Section 3.1), narrow down the parent sample with quality control (Section 3.2), run the AGN search algorithms (Section 3.3), and collect the AGN detec-

tion candidates. These candidates are then visually inspected (Section 3.4).

3.1. HETDEX SOURCE DETECTION

The HETDEX project focuses on the high completeness and the low false positive rate of detecting the LAEs. Continuum bright sources produce a high false positive rate of line detections because windows of continuums sometimes can be incorrectly fit with significant broad lines during the 3-dimensional element search of line emission signals. However, broad emission lines are rare in the LAE population. Therefore, it is more efficient to separate the continuum bright sources (Section 3.1.1) and the line emission detections (Section 3.1.2) for different scientific purposes.

3.1.1. The Continuum Catalog

We measure the counts in a 200 Å window in the blue (3700 - 3900 Å) and in the red (5100 - 5300 Å). A threshold is set to separate the continuum detections and the line emission detections. If either region of a fiber spectrum contains more than 50 counts per 2 Å pixel on average $(g \sim 22.5)$, the position of the fiber is marked as a continuum source and searched with a 15×15 grid raster of 0.1'' spatial bins to locate the position that has the lowest χ^2 from the PSF fit. A PSF-weighted extraction spectrum is then generated for the continuum source, and no further wavelength resolved element search is performed to this continuum source.

3.1.2. The Line Catalog

All non-Continuum fiber spectra are examined for line emission signals in the 3-dimensional space of the IFU datacubes. The initial search uses a 3×3 grid of 0.5'' in the spatial direction and 8 Å element search in the wavelength direction. The large bins in the initial search resolution, for each IFU, is 448 fibers per dither \times 3 dithers \times 500 wavelength elements per fiber \times 9 spatial elements per fiber ~ 6 million element search. As of HDR4, there are 345,874 IFU observations in total, corresponding to 2×10^{12} element analyses. We performed numerical simulations and determined that this initial grid search can effectively save computation time while guaranteeing the completeness to a one percent level compared to finer grids. Each resolution element is fit with a single Gaussian profile using the instrumental line width of 2 Å. Any Gaussian line candidates (SNR > 4, χ^2 < 3) are examined with a (5×5) grid of 0.15'' raster to identify the line center. Each line detection is assigned parameters from the best single Gaussian fit (wavelength, linewidth, etc) and a PSF-weighted extraction spectrum.

3.2. Parent Sample

AGN usually have strong emission lines, and a significant population of the AGN are continuum bright quasars. Therefore, we start from a combination of the 600,000 continuum detections (Section 3.1.1) and the 28 million line detections (Section 3.1.2). Before running through AGN detection algorithm, we made some initial constraints on the data. First, we require that a nominal throughput, assuming a 360 s exposure time, must be greater than 0.08. We then refine the catalog by removing known issues, such as bad amplifiers, hot pixels, and meteors. Finally, we remove some artifacts, mostly bleeding cosmic ray hits, using $\chi^2_{PSF} < 4$ from the 2D fit. After removal of suspicious detections with the three criteria, the 29 million raw catalog is reduced to 12 million detections (500,000 continuum detections and 11.5 million line detections).

3.3. AGN Identification Methods

We executed our two AGN search methods: the Line Pair method (LP, Section 3.3.1) and the single Broad Line search (sBL, Section 3.3.2), as detailed in Liu22.

3.3.1. The Line Pair Method

The line pair (LP) search basically identifies emission line pairs characteristic of AGN, especially when the highly ionized lines, such as C IV $\lambda1549$, are present (SNR > 5). This approach is applied for both the continuum catalog (Section 3.1.1) and the line catalog (Section 3.1.2). Considering the wavelength coverage of HETDEX (3500 - 5500 Å), the strongest AGN emission lines visible are O VI $\lambda1034$, Ly α $\lambda1215$, N V $\lambda1241$, C IV $\lambda1549$, C III] $\lambda1909$, Mg II] $\lambda2799$ from redshift of z=4.32 to z=0.25 (see Figure 1 in Liu22).

For each line detection, we assume the wavelength suggested by the HETDEX pipeline's single Gaussian fit to be one of the six strongest lines and check if there are signals matched to at least another line emission. The other emission line is not limited to be one of the six lines, e.g. He II $\lambda 1640$ can be used to confirm the C IV $\lambda 1549$ emission. If the full wavelength range of the line detection spectrum is detected with the strongest and the second strongest lines at $> 8\sigma$ and $> 5\sigma$, this object is selected as an AGN candidate with a redshift indicated by the line pair(s). Higher thresholds would result in missing real AGN, and lower thresholds would bring in too many false positives making it beyond our visual inspection ability (Section 3.4). We find that with the $> 8\sigma$ and $> 5\sigma$ thresholds no known AGN missed and the false positive rate is controlled at $\lesssim 50\%$ in our visual inspection experiments on a few small test samples. We will eventually push to lower thresholds to achieve higher completeness by allowing higher false positive rates in our final data release.

For a continuum detection, there is no line wavelength suggested by the HETDEX pipeline in addition to a PSF-weighted extraction spectrum. We fit a power law continuum, find the highest peak in the continuum subtracted spectrum, attempt to fit the peak as one of the six strong AGN lines, and see if any other emission line(s) match with at least another peak(s). If the spectrum of a continuum detection is detected with the two strongest emission lines at levels of $> 8\sigma$ and $> 5\sigma$, it is then identified as an AGN candidate. All AGN identified by the LP method are labeled with $\mathfrak{sflag}=2$ (Column 8 described in Section 7 and provided in Table 2).

3.3.2. The Single Broad Line Method

Because the wavelength coverage of HETDEX is only 2000 Å and the limited number of lines available in this wavelength range, many of the detections only have one line detected in their spectra. For example, at 0.96 < z < 1.26, the only line among the six strong lines visible is C III] $\lambda 1909$. Another possibility is that the second strongest line in our wavelength range is not significant enough to be identified ($< 5\sigma$) so the spectrum also only shows a single line (see Figure 3 in Liu22 for some examples). We fit multi-Gaussian profiles to these single lines. Our code allows two emission line components, one capturing the broad feature and the other for the narrow emission line, and at most four absorption components. If a line is detected with FWHM > 1200 km s⁻¹ at > 5σ , the source is a broadline AGN candidate. Again, the choice of 5σ is a result of the balance between the completeness and the false positive rate. When testing on several simulated test samples, we find that a 4.5σ threshold can marginally increase the completeness from 89% to 91%, while the false positive rate is dramatically increased from 50% to 90% compared to the 5σ threshold. 5σ is believed to be efficient in recovering real broad lines while reducing the amount of work in visual inspections.

Some of the single broad line (sBL) identified objects are only AGN candidates, especially the ones with intermediate broad lines FWHM $\sim 1200~\rm km~s^{-1}$; they can be AGN with intermediate massive black holes (IMBHs), or type 1.5 - 2 Seyferts whose narrow line components are as strong or stronger than their broad line components. They can also be star-bursting galaxies or galaxies undergoing other activities that can increase the gas velocity dispersion. These single intermediate broad lines (sIBLs) are labeled with agn_flag=0 (Column 7 described in Section 7 and provided in Table 2) so that they can be easily removed from statistics.

For any sBL identified AGN candidate (sflag=1, Column 8 described in Section 7 and provided in Table 2), an estimated redshift (flagged by zflag=0, Column 6 described in Section 7 and provided in Table 2) is provided based on the wavelength of the line detection and the line emission guess. The line is mainly identified as a specific emission according to their equivalent widths (EWs). Liu22 shows in Figure 14, Figure 18, and Table 2 that for the HETDEX AGN different line emissions have different EW distributions. Within the HETDEX wavelength range, the most likely broad emission lines are (Ly α λ 1215+N V λ 1241), C IV λ 1549, C III] λ 1909, Mg II] $\lambda 2799$, and O VI $\lambda 1034$ in a decreasing EW order. The (Ly α λ 1215+N V λ 1241) emission is usually easily distinguished from other lines because of the high EW, and the line profiles of two blended strong emissions. O VI $\lambda 1034$ usually differs from the other emissions in their noisy line shape features due to the heavy Ly α $\lambda 1215$ forest absorption lines. It is usually difficult to distinguish single broad C IV $\lambda 1549$, C III] $\lambda 1909$, and Mg II] $\lambda 2799$ simply based on their EWs. We check if the stronger lines expected in the wavelength range are present or not to narrow down the possible line solutions. For example, assuming a single broad line at 5000 Å as C IV λ 1549, the Ly α λ 1215 emission should be expected at 3921 Å. If no line emission detected at 3921 Å, the single broad line at 5000 Å is then rejected to be C IV $\lambda 1549$. We checked the reliability of our redshift estimates by cross matching the sBL identified AGN with SDSS DR16Q (Lyke et al. 2020). About 90% of our redshift estimates are correct.

3.3.3. Cross match with SDSS DR16Q

Besides the two major AGN identification methods, the LP method described in Section 3.3.1 and the sBL method detailed in Section 3.3.2, we further cross match our parent sample (Section 3.2) with SDSS QSOs using the SDSS's 3" fiber size as the matching radius. The HDR2 AGN catalog (Liu22) used SDSS DR14Q (Pâris et al. 2018). In this paper, the HDR4 AGN catalog is matched to SDSS DR16Q (Lyke et al. 2020).

A significant benefit of the cross matches is to confirm or correct the redshifts for AGN identified by the sBL method. If a guessed redshift is either confirmed or corrected by an SDSS quasar, the redshift flag is reset from zflag=0 to zflag=1 (Column 6 in Table 2).

Besides redshift confirmations, the cross match with SDSS quasars can also identify some missed AGN (see Figure 4 in Liu22 for one example). For quasars with spatially extended emission-line region whose PSF like continuum sources fall just outside our IFU edges, the edge fibers sometimes can catch their weak diffuse emis-

sion line signals. For these cases, their spatially resolved information is important; while the lines are too weak and/or noisy to be identified by the LP method or the sBL method. Cross matching with SDSS can help recover these AGN. Additionally, at higher redshifts (z>4.32), even O VI $\lambda1034$ is beyond our wavelength coverage. The cross match can pick up the continuum spectra bluer than O VI $\lambda1034$ for these high-z AGN (see the first spectrum in Figure 7 for one example). For broad line AGN at low redshifts $z\gtrsim0.1$, their broad H β and H α lines lie beyond our red wavelength limit, the cross match can also recover these AGN (see the last spectrum in Figure 7 for one example).

3.4. Visual Identification

Once the AGN detection candidates are identified from the parent sample as detailed in Section 3.3, visual inspections are made of each candidate. This step can remove artifacts, such as bleeding cosmic rays misidentified by the sBL search. Continuum features of stars or galaxies wrongly identified as broad lines by the sBL search can also be removed. There are some line pairs whose weaker lines are not significant enough to be detected by the LP search ($\sim 4\sigma$) and their redshift estimates are given by the remaining single broad line detections. During the visual inspections, their $\sim 3\sigma$ - 4σ emission lines can provide additional information leading to better redshift guesses. The visual inspections reduce the 130K AGN detection candidates into 63,348 visually confirmed AGN detections.

4. DUPLICATE REMOVAL

As an IFU survey, a spatially extended source can illuminate multiple fibers and produce multiple detections in the HETDEX survey. This frequently occurs for the low-redshift big [O II] galaxies. At $z \sim 2-3$, about 5\% of the HETDEX LAE sample are "Ly α $\lambda 1215$ blobs" which are significantly more extended than the single PSF model (Mentuch Cooper et al. in preparation). There are also many duplicates in the 63,827 AGN detections identified by the processes in Section 3.3 and Section 3.4. We apply friend-of-friend grouping (FoF²) to remove duplicates from the sample. The challenge is the choice of the linking length to make the unique AGN sample: A large one would group real AGN overdensities into a single AGN, while an insufficient linking length would leave the sample with many duplicates. During our visual inspections, many of the HETDEX AGN are found to be surrounded by diffuse ionized gas

whose associated emission lines are more significantly extended than the typical FWHM=1.8" PSF (e.g. Liu et al. 2022b). Figure 1 displays an extended AGN in our catalog. The PSF plus exponential fit ($r_{\rm ext}=47.59~{\rm kpc}$) can better reproduce the Ly α λ 1215 density map than the PSF model alone ($r_{\rm n}=10.88~{\rm kpc}$).

There is no universal linking length suitable for the full AGN catalog. We carried out a set of FoF experiments with different linking lengths ($\delta r = 3.0''$, 3.5'', 4.0'', 4.5'', 5.0'', 5.5'', 6.0'') to determine the optimal choice. Liu22 demonstrates in Figure 16 that the broadline AGN fraction is $\sim 90\%$ of the AGN in the luminosity and redshift range we probe. Considering this high fraction of broad lines and the complex line profiles in the Ly α λ 1215 regime, the 3-D FoF is performed with $\delta z = 0.1$ in the redshift space. We also carried out 2-D FoF experiments for comparison reasons. Figure 2 displays that the number of unique AGN decreases significantly as δr increases at $\delta r \lesssim 5''$, reaching roughly a constant value at n(uniq AGN) $\sim 16,000$ at $\delta r \gtrsim 5''$. We randomly examine the line flux maps of some newly added distinct AGN in the $(\delta r, \delta z) = (4.5'', \delta z)$ 0.1) set in addition to the $(\delta r, \delta z) = (5.0'', 0.1)$ set. The newly added distinct AGN in the $(\delta r, \delta z) = (4.5'',$ 0.1) set are just the extended emission of existing AGN in the $(\delta r, \delta z) = (5.0'', 0.1)$ set. This suggests that $\delta r = 4.5''$ is not sufficient to remove duplicates. To avoid using a too large δr and group real AGN pairs or groups into single ones, we decided to adopt $\delta r =$ 5". The 2-D FoF ($\delta r = 5.0$ ") yields the unique AGN number as n(uniq AGN) = 15,939, while the 3-D FoF $(\delta r, \delta z) = (5.0'', 0.1)$ gives n(uniq AGN) = 15,940. The one additional AGN in the 3-D FoF experiment is a real superposition of two separate AGN within 5''. Our final choice of FoF parameter set to group the 63,827 AGN detections into a 15,940 unique AGN catalog is $(\delta r, \delta z) = (5.0'', 0.1)$. Among the 15,940 unique AGN sample, 10,499 of them have confirmed redshifts.

The coordinate of each unique AGN is the emission-line flux weighted center of all member detections in the FoF grouping. The member detection that is closest to the FoF center of a given AGN is then the "best" detection and marked as detectid_best (Column 12 in Table 2). Figure 3 compares the separations between detectid_best (left) and their emission-line flux weighted FoF centers (Column 2 & 3 in Table 2) to those of all AGN detections to their FoF centers (right). The median separations of the 15,940 detectid_best to their FoF center is $\delta D = 0.12$ ", while the median separations of all AGN detections to their FoF center is $\delta D = 0.63$ ". There are many AGN with member detections larger than 3" from their FoF centers. agnid=407 (Figure 1)

https://github.com/HETDEX/hetdex_api/blob/master/ hetdex_tools/fof_kdtree.py

Figure 1. An example of an AGN (agnid=407) detected with extended diffuse ionized gas. a) The HSC r-band $30'' \times 30''$ image with the red Ly α $\lambda 1215$ narrow-band 2σ density contour. b) The HETDEX Ly α $\lambda 1215$ narrow-band image. c) The radial profile of the Ly α $\lambda 1215$ flux density map. Blue data points are surface brightness variations. The red curve is an (PSF + exponential) fit to the blue points giving a $r_{\rm ext} = 47.6$ kpc. The green dashed curve gives the PSF model using the image quality of this observation. The gray dashed horizontal line marks the standard deviation in the continuum subtracted background in the line flux map. d) The spectrum extracted at the labeled coordinate in the observed frame. The yellow shaded region highlights the ± 21 Å wavelength range making the Ly α $\lambda 1215$ density map. We refer the readers to Mentuch Cooper et al. in preparation for more detailed analyses on the extended diffuse ionized gas around LAEs.

Figure 2. The FoF experiments with linking lengths of $\delta r = 3.0''$, 3.5'', 4.0'', 4.5'', 5.0'', 5.5'', 6.0'' for the 63,827 AGN detections. The 2-D FoF tests are the red crosses. The 3-D FoF tests ($\delta z = 0.1$) are the blue data points.

even has a $> 5\sigma$ member detection 8.2" away from its FoF center. With the HETDEX resolving power (2 Å in the wavelength space, and 0.15" in the fiber space, Section 3.1), agnid=407 shows no evidence of pair(s) or group(s) in the Ly α λ 1215 flux density map and the 1-D spectrum.

There are 4,060 (39%) out of the 10,499 redshift-confirmed HETDEX HDR4 AGN with member detections (> 5σ) more extended than their relevant PSF models (FWHM_virus + 3 FWHM_virus_err)/2. Detailed comparisons between single PSF model fit and two components fit of the line flux maps can be found in Mentuch Cooper et al. in preparation. This high fraction of AGN with extended emission-line regions could be AGN experiencing strong outflows blowing to

the circum-galactic medium or even the inter-galactic medium. Alternatively, the extended emission-line regions could also be gaseous haloes lit up by the central AGN. Detailed 2-dimensional analyses on the line shifts and the line widths would help understand the physics behind this (Liu et al. in preparation).

5. COMPLETENESS AND CONTAMINATION

HETDEX HDR4 AGN catalog consists 15,940 AGN after grouping duplicates into unique objects (Section 4). Among them, 10,499 AGN (zflag=1, Column 6 in Table 2) have redshifts either confirmed by the LP method or the cross match with SDSS DR16Q. The remaining 5,441 AGN (zflag=0) are sBL identified AGN with guessed redshifts only (see Section 3.3.2) for details). 3,358 out of the 5,441 AGN are only AGN candidates with single "intermediate" broad lines (FWHM $\sim 1200 \text{ km s}^{-1}$) whose emission lines might be broadened by activities other than AGN, such as star bursts. They are flagged with agn_flag=0 (Column 7 in Table 2). The (5,441 - 3,358 = 2,083) single broad line AGN combined with the 10,499 zflag=1 redshiftconfirmed AGN yields the 12,582 "secure AGN" catalog (agn_flag=1).

Table 1 summarizes the survey area, the number of AGN, and the raw AGN density in each field in HDR4. The high AGN number density in the GOODS-N fields can either originate from real cosmic variance or from small number statistics. Even only counting the redshift secured AGN, the HETDEX AGN density is 166.9 deg⁻², which is significantly higher than that of the SDSS quasars (56 deg⁻²; Pâris et al. 2018). This highlights the effectiveness and the high spatial completeness in detecting optically faint AGN with the untargeted observational strategy of HETDEX.

Figure 3. Left: Distributions of the separations between the "best" detections (detectid_best) to their emission-line flux weighted FoF centers. Right: Distributions of the separations between all AGN detections to their emission-line flux weighted FoF centers.

Field Name	Field center	Area	N_{AGN}	n_{AGN}	N _{AGN,secure z}	n _{AGN,secure z}
	J2000, deg	deg^2		\deg^{-2}		$ m deg^{-2}$
DEX-spring	(201.7620, 52.2367)	36.313	9,733	268.0	6,288	173.2
DEX-fall	(23.0755, 0.3056)	20.655	4,819	233.3	3,411	165.1
NEP	(270.2904, 65.9958)	4.238	981	231.5	548	129.3
COSMOS	(150.1025, 2.2396)	1.289	294	228.1	179	138.9
SSA22	(334.5131, 0.3211)	0.362	83	229.3	59	163.0
GOODS-N	(189.2030, 62.2461)	0.052	30	546.9	14	269.2
Total	_	62.909	15,940	253.4	10,499	166.9

Note: DEX-spring and DEX-fall fields are HETDEX survey fields. COSMOS and GOODS-N fields are HETDEX science verification fields. The NEP field (Chávez Ortiz et al. 2023) and the SSA22 field are taken for our collaborators with their own scientific purposes.

Table 1. Summary of the survey areas of the HETDEX HDR4 AGN catalog

The HETDEX AGN identification is mostly regulated by the SNR of emission lines, as introduced in Section 3.1 and Section 3.3. The detection completeness as a function of line SNR is quantitatively introduced in Figure 6 & 7 of Liu22. Additionally, in order to calculate the HETDEX AGN luminosity function, we carefully modeled the sample completeness in Liu et al. (2022c) against all relevant parameters, including the line wavelengths, line fluxes, line widths, the relevant locations on IFUs, and redshifts for the HETDEX pipeline and the two AGN identification methods (Section 3.3.1 and Section 3.3.2). However, these parameters are not straightforward in comparing our completeness with other surveys. The broad-band continuum level (HETDEX qband magnitude) is then estimated for each detection by multiplying the 1-D HETDEX spectrum with the SDSS

g filter's throughput curve using the software Emission Line eXplorer³ (ELiXer; Davis et al. 2023).

Figure 4 presents the completeness estimation and the potential contamination of the HETDEX HDR4 AGN sample within each HETDEX g-band magnitude bin. We cross matched all 500 million HETDEX HDR4 fibers with the 638,022 SDSS DR16Q quasar sample (quasars flagged by redshift warnings removed) to evaluate the completeness of both the HETDEX pipeline (Section 3.1) and our AGN identification methods (Section 3.3). There are 5,872 SDSS quasars covered by HETDEX good fibers (hot fibers, fibers on the edge of the IFUs, and shots with low throughput excluded) within 1 arcsec. The weakness of using this cross-match sample to evaluate the completeness is that the sample size is limited at $g \gtrsim 22.5$.

³ https://github.com/HETDEX/elixer.

Figure 4. The completeness and contamination of the HETDEX HDR4 AGN sample in each HETDEX g-band magnitude bin. Completeness is estimated from the cross-matched sample between the SDSS DR16Q sample and all HETDEX HDR4 fibers. The black squares connected with a dashed line show the completeness of the parent sample of this work (Section 3.1 and Section 3.2). The blue circles connected by a solid line show the completeness of the AGN identified either by the LP method (Section 3.3.1) or by the sBL method (Section 3.3.2). The magenta triangles and the cyan stars show the completeness of the LP method (Section 3.3.1) and the sBL method (Section 3.3.2), respectively. The gray diamonds connected by a dotted line present the contamination rate from the unconfirmed redshifts (zflag=0, Column 6 in Table 2). The orange crosses connected by a dash-dotted line show the contamination rate from the unconfirmed AGN (agn_flag=0, Column 7 in Table 2).

The recovery fraction of the SDSS DR16Q quasars brighter than q = 22.5 is 93% for the HETDEX pipeline (black squares) and 80% for our AGN sample identified either by the LP method (Section 3.3.1) or by the sBL method (Section 3.3.2) (blue circles). Considering all 5,872 matched SDSS DR16Q quasars, these two fractions are 92% and 78%, respectively. The LP method (Section 3.3.1) requires the strongest emission line to be $> 8\sigma$. We would eventually push our current SNR thresholds to lower values in our final AGN data release so that the blue circles can match the black squares. Although the LP method suffers from the HET-DEX's short wavelength coverage (3500 - 5500 Å), it is the main contributor (65%) of the AGN sample. The sBL method is also very important (13%) in recovering AGN missed by the LP method. However, the sBL method also brings in AGN with unconfirmed redshifts

(zflag=0, Column 6 in Table 2) and even unconfirmed AGN (agn_flag=0, Column 7 in Table 2) into our sample as detailed in Section 3.3.2.

For AGN brighter than g=22.5, 9% of our AGN sample have unconfirmed redshifts, and 2% are unconfirmed AGN. When including fainter bins at g>22.5, the two fractions are increased to 28% and 15%. We note here that these unconfirmed redshifts are not necessarily wrong. They are simply estimated based on single broad line wavelengths. Similarly, the unconfirmed AGN are not necessarily non-AGN. They can be low-luminosity Seyferts. With our current data by hand, we don't have enough evidences to make further confirmations.

6. STATISTICS

Figure 5 shows the redshift distributions of the HET-DEX HDR4 AGN sample. The major six strong lines

Figure 5. The redshift distributions of the HETDEX HDR4 AGN catalog. The blue histogram is for the full 15,940 AGN set. The orange histogram excludes the single intermediate broad line AGN candidates (agn_flag=0, Column 7 in Table 2). The green histogram further excludes the AGN with estimated redshifts only (zflag=0, Column 6 in Table 2). The grey histogram is the scaled redshift distributions of the SDSS DR16Q sample to generally match the number of HETDEX AGN at $z \sim 1.5$.

(O VI λ 1034, Ly α λ 1215, N V λ 1241, C IV λ 1549, C III] $\lambda 1909$, Mg II] $\lambda 2799$) we used in our AGN search algorithm and the HETDEX wavelength range of 3500 -5500 Å suggest a redshift range of 0.25 < z < 4.32. The SDSS survey has a much broader wavelength range. By cross matching with SDSS DR16Q, a few AGN can be identified at higher (z > 4.32) and lower (z < 0.25) redshifts, while the majority of the HETDEX HDR4 AGN population is at $z \sim 2.1$. The blue histogram is clearly more populous at $z=2\sim 3.5$ than the secure AGN sub-sample (agn_flag=1), suggesting that many of the single "intermediate" broad-line AGN candidates could be non-AGN LAEs. SDSS quasars are more abundant than HETDEX AGN at $z \sim 1$; this result is because it is the redshift desert of single C III] $\lambda 1909$ in the HETDEX wavelength range.

Figure 6 presents the g-band magnitude distributions of HETDEX HDR4 AGN. The typical flux density limit of HETDEX's 6-min exposures is $\sim 5 \times 10^{-19} \ {\rm ergs \ s^{-1} \ cm^{-2} \ \AA^{-1}} \ (g \lesssim 25)$. HETDEX is better at detecting AGN fainter than $g \sim 22.5$ than SDSS. The second peak in the blue histogram at $g \sim 24$ is suspicious. This peak is dominated by the agn_flag=0 single intermediate broad line AGN candidates. It would be interesting to observe these objects in deep narrow-band images for potential emission lines at longer wavelengths

Figure 6. Similar format as Figure 5 but for the HETDEX g-band magnitudes. While g-band magnitudes are plotted as computed, the 5σ depth of HETDEX is roughly 25, marked by the shaded area.

in the future to determine whether they are non-AGN LAEs or low-luminosity Seyferts.

7. THE CATALOG

The HETDEX HDR4 AGN catalog will be made available on publication at the website⁴ and in the online Journal (Table 2). The FITS file (Wells et al. 1981) is constructed similar as the HDR2 release in Liu22 with six extensions. A simple Jupyter notebook at the public website describes how to use this FITS file in Python. The FITS extensions are as follows.

Extension 1 Table extension $(15,940 \text{ rows} \times 56 \text{ columns})$: Basic information, one row for one unique AGN, arranged in a descending order of redshifts. Column information is given in the header and summarized in Appendix A. We explain each column with more details as follows.

Column 1 Sequential ID number assigned for each AGN organized in a descending redshift order from agnid = 0 to 15,939.

Column 2-3 The right ascension and declination of the emission-line flux weighted FoF center of all member detections of a given AGN (J2000). If more than one line is present within the HETDEX wavelength range, only the strongest line is used as the weight. The FoF group-

⁴ http://web.corral.tacc.utexas.edu/hetdex/HETDEX/catalogs/agn_catalog_v2.0/

ing method to remove duplicates from the 63,827 AGN detection sample is detailed in Section 4.

Column 4-5 The best-fit redshift and its error of the 1-D spectrum of the "best" detection, i.e. detectid_best. Member detections can have slightly different redshifts due to gas kinematics.

Column 6 Redshift flag. Redshifts confirmed either by the LP method or matched SDSS quasars have zflag=1, while estimated redshifts from single broad lines are flagged with zflag=0.

Column 7 AGN flag. The single "intermediate" broadline AGN candidates have agn_flag=0; the remaining confirmed AGN have agn_flag=1.

Column 8 Source flag giving the information of a given AGN identified by which specific selection method described in Section 3.3. sflag= 1, 2, and 3 indicate the AGN is identified by the sBL method (Section 3.3.2), LP method (Section 3.3.1), and the cross match with SDSS DR16Q method (Section 3.3.3). The few sflag=0 AGN are identified by old versions of the AGN selection code.

Column 9 Field name in the HETDEX survey as indicated by Table 1.

Column 10 The number of shots with fiber coverage at (ra,dec). A given coordinate can be observed by more than one shot. For example, some of the COSMOS fields were observed more than ten times.

Column 11 Number of member detections related with a given AGN from the 63,827 AGN detection sample visually confirmed by Section 3.4.

Column 12 The member detection of a given AGN closest to its emission-line flux weighted FoF center as indicated by the coordinates recorded in Column 2 and 3.

Column 13-14 The right ascension and declination of detectid_best. The position can be slightly off from the FoF center as the spatial detection search resolution is 0.15" (Section 3.1).

Column 15 Offset between the coordinate of detectid_best (ra_best and dec_best in Column 13 and 14) and the FoF center (ra and dec in Column 2 and 3). Distributions of the offset (roff) are presented in the left panel of Figure 3.

Column 16-17 The HETDEX g-band magnitude and its 68% confidence interval calculated by multiplying the 1-D spectrum of detectid_best with the SDSS g filter's throughput curve using ELiXer.

Column 18 The identification of the fiber closest to detectid_best. It is a standard string with the format of yyyymmddsss_multi_bbb_ccc_ddd_aa_fff. The first eight letters give the date detectid_best is observed. The next three digits are the shot number on the date catches detectid_best. bbb, ccc, and ddd are all three digit numbers giving the spectrograph number, the IFU number, and the IFU slot number of detectid_best. There are four amplifiers for each IFU: LL, LU, RL, and RU. aa is a two letter code among the four indicating the amplifier for detectid_best. Each amplifier has 112 fibers. fff is the three digit number of the specific fiber on the amplifier contributes the most flux to the 1-D PSF weighted spectrum of detectid_best. The full string of fiberid can identify the raw data of a given AGN.

Column 19 The ID of the shot for detectid_best. This is an 11-digit number consistent with the first 11 digits of fiberid.

Column 20 The specific amplifier for detectid_best. This is a 20-letter string consistent with the 13-32 letters of fiberid.

Column 21 The throughput of shotid. This parameter is described in Gebhardt et al. (2021). Basically, it is defined as the nominal throughput treating each exposure as if it were 360 s long through a 50 m² clear aperture. Throughput varies at different wavelengths. The typical throughput at 4540 Å of our AGN sample is 0.15. In this paper, we require the throughput should be greater than 0.08 for an observation to be included in the catalog.

Column 22-23 Image quality and its error. Image quality is calculated as the mean FWHM of the Point Spread Functions (PSFs) of bright stars in the full frame (typically ~ 30 stars). Details can be found in Gebhardt et al. (2021) Section 6.15. The typical image quality is FWHM_virus $\sim 1.8''$.

Column 24 The aperture correction of detectid_best. Typical value of our AGN catalog is 0.92. A value of 1 means no correction.

Column 25-26 The best-fit observed line wavelength and its error from ELiXer's single Gaussian fit. For line detections (Section 3.1.2), ELiXer fits to the wavelength identified by the HETDEX line detection algorithm. For continuum detections (Section 3.1.1), ELiXer finds the most possible line to fit.

Column 27-46 The best-fit continuum subtracted rest-frame line fluxes, SNRs, FWHMs, and EWs of Ly α

 $\lambda 1215$, C IV $\lambda 1549$, C III] $\lambda 1909$, Mg II] $\lambda 2799$, and O VI $\lambda 1034$. Parameters of lines falling outside the wavelength range are set to a default value of -99.0.

Column 47-52 The best single Gaussian fit parameters from the HETDEX's pipeline (Gebhardt et al. 2021) in the observed frame. For detections in the continuum catalog, these parameters are set to 0.

Column 53 The χ^2 of fit to the 2-D spectrum. A high value (chi2fib_pipe > 4) usually indicates issues such as hot pixels, bleeding cosmic rays, etc.

Column 54-56 Match results with the SDSS DR16Q sample. The match radius is 3". AGN with no matches within 3" are set with default values of rsep_dr16q=999.0", z_dr16q=-999.0, and sdssid_dr16q="?".

Extension 2 Image extension (15,940 rows \times 1036 columns): 1-D spectra for the detectid_{best} of each AGN (no extinction correction applied). Rows are arranged in the same order as Extension 1. The wavelength array starts from 3470 Å and contains 1036 elements with a stepsize of 2.0 Å. The flux densities are in units of 10^{-17} erg cm⁻² s⁻¹ Å⁻¹. The wavelength solution and the flux density units are recorded in the extension header.

Extension 3 Image extension (15,940 rows \times 1036 columns): The error array for Extension 2, with the same wavelength solution and flux units.

Extension 4 Table extension $(17,552 \text{ rows} \times 4)$ columns): Repeat information for each AGN. Some AGN were observed multiple times. In this table, each unique observation is listed with their shotid. Column 1 is the agnid, Column 2 gives the number of repeat observations of agnid, and Column 3 gives the shotid of the observation. An AGN observed multiple times will have multiple entries in this table with the same agnid and nshots, but different shotid. There are 14,306 AGN observed only once with no repeats, 1,125 AGN observed twice, and 240 AGN observed more than twice. Note: 15.671 AGN can be successfully extracted with spectra at their FoF grouping center (ra,dec) in Extension 1. 269 AGN are lack of their extracted spectra because their flux weighted FoF center falling on bad amplifiers (low throughput or other issues).

Extension 5 Image extension (17,552 rows × 1036 columns): 1-D PSF weighted extracted spectra at the FoF center, repeat observations included, no extinction correction applied. Rows are arranged in the same order as Extension 4. The wavelength solution and flux units

are the same as Extension 2, and can be found in the header.

Extension 6 Image extension $(17,552 \text{ rows} \times 1036 \text{ columns})$: Error array for Extension 5.

8. SUMMARY

The HETDEX HDR4 AGN catalog has 15,940 AGN. A total 10,499 have redshifts either confirmed by line pairs or matched SDSS quasars, while the rest are single broad-line AGN candidates provided with redshift estimates. The catalog contains observations from January 2017 through August 2023. The effective survey area is 62.9 deg², giving a raw AGN density of 253.4 deg⁻². The redshifts range from 0.1 to 4.6, and peak at $z \sim 2.1$. The g-band magnitudes of the faint AGN can reach the HETDEX continuum detection limit at $g \sim 25$ mag. Approximately 39% of the 10,499 redshift-confirmed AGN sample have extended emission-line regions with $> 5\sigma$ signals detected at distances significantly larger than the image quality > (FWHM_virus + 3 FWHM_virus_err)/2.

HETDEX is led by the University of Texas at Austin McDonald Observatory and Department of Astronomy with participation from the Ludwig-Maximilians-Universität München, Max-Planck-Institut für Extraterrestrische Physik (MPE), Leibniz-Institut für Astrophysik Potsdam (AIP), Texas A&M University, The Pennsylvania State University, Institut für Astrophysik Göttingen, The University of Oxford, Max-Planck-Institut für Astrophysik (MPA), The University of Tokyo, and Missouri University of Science and Technology. In addition to Institutional support, HETDEX is funded by the National Science Foundation (grant AST-0926815), the State of Texas, the US Air Force (AFRL FA9451-04-2-0355), and generous support from private individuals and foundations.

The Hobby-Eberly Telescope (HET) is a joint project of the University of Texas at Austin, the Pennsylvania State University, Ludwig-Maximilians-Universität München, and Georg-August-Universität Göttingen. The HET is named in honor of its principal benefactors, William P. Hobby and Robert E. Eberly.

The authors acknowledge the Texas Advanced Computing Center (TACC, http://www.tacc.utexas.edu) at The University of Texas at Austin for providing high performance computing, visualization, and storage resources that have contributed to the research results reported within this paper.

APPENDIX

A. CATALOG FORMAT AND COLUMN INFORMATION

The HETDEX HDR4 AGN catalog is made available in the online Journal in FITS format, and is described in Table 2. Other extensions to the FITS file are described in Section 7.

Table 2. Columns of Extension 1 in the FITS file.

Column	Name	$_{ m dtype}$	Unit	Description
1	agnid	int32	-	Sequencial number for each unique AGN
2	ra	float32	\deg	RA of the AGN (center of flux weighted FoF, J2000)
3	dec	float32	\deg	DEC of the AGN (center of flux weighted FoF, J2000
4	\mathbf{z}	float32	-	Redshift
5	z_err	float32	-	Redshift error
6	zflag	int32	-	zflag=0/1: 1 confirmed z; 0 estimated z
7	agn_flag	int32	-	agn_flag=0/1: 1 confirmed AGN; 0 AGN candidate
8	sflag	int32	-	Method flag: sBL=1,2em=2,sdss=3,else=0
9	field	bytes10	-	Field name in the HETDEX survey
10	nshot	int32	-	Number of the observed shots of (ra,dec)
11	nmem	int32	-	Number of member detectids
12	$detectid_best$	int64	-	Detectid closest to the FoF center
13	ra_best	float32	deg	RA of detectid_best
14	dec_best	float32	deg	DEC of detectid_best
15	roff	float32	arcsec	Offset between ra_best,dec_best with fof center
16	mag_g_wide	float32	mag	HETDEX g measured at (ra_best, dec_best)
17	mag_g_wide_err	float32	mag	Error of mag_g_wide
18	fiberid	bytes38	-	ID of the fiber that is closest to detectid_best
19	shotid	int64	-	ID of the shot for detectid_best
20	multiframe	bytes20	-	IFU for detectid_best
21	throughput	float32	-	Throughput of shotid
22	$fwhm_virus$	float32	arcsec	Image Quality (FWHM) of shotid
23	$fwhm_virus_err$	float32	arcsec	Error of fwhm_virus
24	apcor	float32	=	Aperture correction of detectid_best
25	wobs_elixer	float32	Angstrom	Observed line wavelength fit by ELIXER
26	wobs_err_elixer	float32	Angstrom	Error of wobs_elixer
27	flux_LyA	float32	$1e-17 \text{ ergs s}^{-1} \text{ cm}^{-2}$	Rest-frame flux of the LyA emission
28	snr_LyA	float32	=	S/N of LyA
29	fwhm_LyA	float32	${\rm km~s^{-1}}$	Rest-frame FWHM of the LyA emission
30	ew_LyA	float32	Angstrom	Rest-frame EW of the LyA emission
31	flux_CIV	float32	$1e-17 \text{ ergs s}^{-1} \text{ cm}^{-2}$	Rest-frame flux of the CIV emission
32	$\operatorname{snr}_{\operatorname{-}}\operatorname{CIV}$	float32	-	S/N of CIV
33	$fwhm_CIV$	float32	${\rm km~s^{-1}}$	Rest-frame FWHM of the CIV emission
34	ew_CIV	float32	Angstrom	Rest-frame EW of the CIV emission
35	$flux_CIII$	float32	$1e-17 \text{ ergs s}^{-1} \text{ cm}^{-2}$	Rest-frame flux of the CIII emission
36	snr_CIII	float32	-	S/N of CIII
37	$fwhm_CIII$	float32	${\rm km~s}^{-1}$	Rest-frame FWHM of the CIII emission
38	ew_CIII	float32	Angstrom	Rest-frame EW of the CIII emission
39	flux_MgII	float32	$1e-17 \text{ ergs s}^{-1} \text{ cm}^{-2}$	Rest-frame flux of the MgII emission
40	snr_MgII	float32	<u>-</u>	S/N of MgII

41	$fwhm_MgII$	float32	${\rm km~s^{-1}}$	Rest-frame FWHM of the MgII emission
42	ew_MgII	float32	Angstrom	Rest-frame EW of the MgII emission
43	flux_OVI	float32	$1e-17 \text{ ergs s}^{-1} \text{ cm}^{-2}$	Rest-frame flux of the OVI emission
44	$\operatorname{snr}_{\operatorname{-}}\!\operatorname{OVI}$	float32	-	S/N of OVI
45	$fwhm_OVI$	float32	$\mathrm{km}\ \mathrm{s}^{-1}$	Rest-frame FWHM of the OVI emission
46	ewOVI	float32	Angstrom	Rest-frame EW of the OVI emission
47	$wave_pipe$	float32	Angstrom	Observed line wavelength from the HETDEX pipeline
48	$flux_pipe$	float32	$1e-17 \text{ ergs s}^{-1} \text{ cm}^{-2}$	Observed line flux from the HETDEX pipeline
49	$continuum_pipe$	float32	$1e-17 \text{ ergs s}^{-1} \text{ cm}^{-2} \text{ Å}^{-1}$	Observed continuum from the HETDEX pipeline
50	$linewidth_pipe$	float32	Angstrom	Observed sigma from the pipeline's single Gaussian fit
51	$\mathrm{sn_pipe}$	float32	-	S/N from the pipeline's single Gaussian fit
52	${\rm chi2_pipe}$	float32	-	chi2 from the pipeline's single Gaussian fit
53	$chi2fib_pipe$	float32	-	chi2 of fit to 2d spec for each fiber
54	$rsep_dr16q$	float64	arcsec	Separation between the matched SDSS DR16Q AGN
55	z_dr16q	float32	-	Redshift of the matched SDSS DR16Q AGN
56	$sdssid_dr16q$	bytes18	-	SDSS name of the matched SDSS DR16Q AGN
