We study the nuclear compositions and neutrino reaction rates in the central region of the corecollapse supernova, assuming the existence of dineutrons  $\binom{2n}{n}$  and tetraneutrons  $\binom{4n}{n}$ . At 100 ms after core bounce,  $^{2}n$  and  $^{4}n$  are more abundant than deuterons within radii of approximately 100 km and 50 km, respectively. Compared to the model ignoring the existence of  ${}^{2}n$  and  ${}^{4}n$ , the mass fraction of neutrons up to a radius of 100 km reduces. Hence, the neutrino absorption and antineutrino emission rates decrease by approximately 40%–50%. Conversely, those of protons, deuterons, and <sup>4</sup>He increase, leading to the increase in the neutrino emission and antineutrino absorption rates by approximately eight times within a radius of 100 km.

#### I. INTRODUCTION

Core-collapse supernovae are phenomena that occur when a massive star with mass  $\gtrsim 10 M_{\odot}$  dies. Several simulations have shown that the shock wave generated in core bounce is delayed and halted by energy loss due to iron decomposition reactions and neutrino emissions. Multidimensional effects such as convection improve the efficiency of this neutrino heating mechanism; moreover, the explosion has been reproduced by these effects in multidimensional simulations [\[1\]](#page-4-0).

After core bounce and shock propagation, the central region within the shock radius is a hot and dense environment with an excess of neutrons. Light elements such as deuterons and <sup>4</sup>He are abundant in the central region at subsaturation densities [\[2\]](#page-4-1). In almost all simulations, detailed reactions between light elements and neutrinos are not considered; however, the weak interactions may affect neutrino emissions and the shock revival [\[3](#page-4-2)[–5\]](#page-5-0).

Meanwhile, the existence of multineutron states is under debate  $[6, 7]$  $[6, 7]$  $[6, 7]$ . Dineutrons  $({}^2n)$  were theoretically predicted in neutron halo  $[8]$ , and some experiments involving neutron-rich nuclei have supported their existence [\[9,](#page-5-4) [10\]](#page-5-5). The dineutron is known to be unbound, and its binding energy is believed to be approximately –100 keV in free space, which is consistent with a negative neutronneutron scattering length [\[11,](#page-5-6) [12\]](#page-5-7). Furthermore, tetraneutrons  $\binom{4n}{}$  have been indirectly observed as both a possible resonant state and a weakly bound state [\[13–](#page-5-8) [16\]](#page-5-9).

The impact of multineutrons on astrophysics has been a topic of discussion; for example, the role of  $2n$  in nucleosynthesis during the early universe [\[17,](#page-5-10) [18\]](#page-5-11) and the potential influence of  ${}^{4}n$  on the structure of neutron stars [\[19\]](#page-5-12). Additionally, Panov et al. [\[20\]](#page-5-13) investigated the role of  $2n$  and  $4n$  in high-temperature and subsatura-

tion density environments such as supernova matter and found that  $2n$  is present near the centeral region nearly as much as other light elements such as deuterons. However, the calculation is based on a spherically symmetric supernova simulation, and their impacts on neutrino reactions are not discussed.

In this paper, we focus on the roles of  $2n$  and  $4n$  in the supernova. Using the results of the supernova simulation with the axial symmetry approximation  $[21]$  to characterize the thermodynamic environment, and assuming the existence of  $2n$  and  $4n$ , we calculate the nuclear compositions at 100 ms after core bounce. We apply the nuclear statistical equilibrium approximation to determine the nuclear compositions, which works well for describing the central region of core-collapse supernovae. Subsequently, we use our model to calculate the neutrino reaction with the supernova matter, which may impact on the supernova dynamics [\[22–](#page-5-15)[24\]](#page-5-16). We will discuss in detail the roles of the multineutron states in neutrino reactions.

This paper is organized as follows. Section II describes the models used to calculate the nuclear compositions and neutrino reaction rates. Section III presents the results and Section IV gives a summary and discussion of the study.

### II. MODEL

We use the natural unit with  $\hbar = 1, c = 1$  and calculate the nuclear compositions of the supernova matter. The mass density  $\rho_B$ , electron ratio  $Y_e$ , and temperature T are obtained from the recent supernova simulation through axial symmetry approximation [\[21\]](#page-5-14). Because the temperature is higher than 0.4 MeV, we assume that the nucleons and nuclei are in nuclear statistical equilibrium (NSE), in which the chemical potential of a nucleus with neutron number  $N$  and proton number  $Z$  is given by

$$
\mu_{N,Z} = N\mu_N + Z\mu_Z \tag{1}
$$

Moreover, we assume that the nucleons and nuclei behave as the ideal Boltzmann gases, and their number densities  $n_{N,Z}$  are calculated as

$$
n_{N,Z} = \kappa g_{N,Z} \left(\frac{M_{N,Z} k_B T}{2\pi}\right)^{3/2} \exp\left(\frac{\mu_{N,Z} - M_{N,Z}}{k_B T}\right)
$$
(2)

where  $g_{N,Z}$  is internal degrees of freedom and  $\kappa$  is the factor of the excluded volume effect:  $\kappa = 1$  for nucleons and  $\kappa = 1 - n_B/n_0$  for nuclei with the baryon number density  $n_B$  and nuclear saturation density  $n_0$  [\[2\]](#page-4-1).

The mass of nucleus  $M_{N,Z} = Nm_N + Zm_p - B_{N,Z}$  is calculated in terms of the binding energy  $B_{N,Z}$  obtained from experiments done on the Earth; 3556 nuclei consid-ered [\[25\]](#page-5-17). As for  ${}^{2}n$  and  ${}^{4}n$ , we follow previous works and adopt  $B_{2n} = -0.066 \text{ MeV}$  [\[20\]](#page-5-13) and 0.42 MeV [\[16\]](#page-5-9) as the binding energies of  ${}^{2}n$  and  ${}^{4}n$ , respectively. To determine the nuclear compositions, we solve the following two equations for nucleons and nuclei

<span id="page-1-0"></span>
$$
\sum_{N,Z} n_{N,Z}(N+Z) = n_B,\tag{3}
$$

<span id="page-1-1"></span>
$$
\sum_{N,Z} n_{N,Z} Z = Y_e n_B. \tag{4}
$$

Equations [\(3\)](#page-1-0) and [\(4\)](#page-1-1) express the local baryon number conservation and the local charge conservation, respectively.

We now proceed to calculate the neutrino scattering processes with the supernova matter mediated by the weak interaction. While both charged and neutral current interactions contribute to neutrino emissivity [\[23\]](#page-5-18), we focus solely on the charged current interaction, for simplicity, aiming to clarify the role of  ${}^{2}n$  under the supernova environment. The weak Hamiltonian for the charged current interaction is expressed in terms of the hadron current  $J_{\lambda}$  and the lepton current  $L_{\lambda}$ ;

$$
H_W = \frac{G_F V_{ud}}{\sqrt{2}} \int d^3x [J_\lambda L^\lambda + \text{h.c.}],\tag{5}
$$

$$
J_{\lambda} = \bar{\psi}_n \gamma_{\lambda} (1 - a \gamma^5) \psi_p, \qquad (6)
$$

$$
L^{\lambda} = \bar{\psi}_{\nu_e} \gamma^{\lambda} (1 - \gamma^5) \psi_e, \qquad (7)
$$

where  $G_F = 1.1803 \times 10^{-5} \text{ GeV}^{-2}$  and  $V_{ud} =$ 0.9740 are the weak coupling constant and the Cabbibo–Kobayashi–Maskawa matrix element, respectively [\[23\]](#page-5-18),  $\psi$  is the fermion field operator, the subscript denotes the type of particles, and  $a = 1.26$  is the nucleon axial-vector coupling constant.

(i) $\nu_e + n \rightarrow e^- + p$ (vi) $e^- + p \rightarrow \nu_e + n$	
(ii) $\nu_e + d \rightarrow e^- + p + p$ (vii) $e^- + d \rightarrow \nu_e + n + n$	
(iii) $\nu_e + {}^2n \longrightarrow e^- + n + p$ (viii) $e^+ + n \longrightarrow \bar{\nu_e} + p$	
(iv) $\bar{\nu}_e + p \longrightarrow e^+ + n$ (ix) $e^+ + d \longrightarrow \bar{\nu}_e + p + p$	
(v) $\bar{\nu_e} + d \rightarrow e^+ + n + n$ (x) $e^+ + {}^2n \rightarrow \bar{\nu_e} + p + n$	

<span id="page-1-2"></span>TABLE I. Weak interactions.

In Table [I,](#page-1-2) we list the weak interactions considered in this study. These involve possible bound  $(d)$  and quasibound  $(2n)$  states in the initial state, while the final states are described exclusively by free particles. We neglect d and  $2n$  in the final state, as well as the contribution from the final state interaction and the pion exchange current, for simplicity. Since the nucleon mass is larger than lepton energies, nucleons and nuclei represented by b are treated as static in order to calculate the weak transition amplitudes [\[26\]](#page-5-19), and nucleon energies are replaced with their chemical potentials  $\mu_b$  determined from NSE calculation. For  $d$  and  $2n$ , their energies should be calculated by solving the two-body bound state equation. Under our static approximation, however, their energies are assumed to be replaced by their chemical potentials, shifted by their binding energies as  $\mu_b - B_{N,Z}$ . On the other hand, the chemical potentials of the electron and neutrino are obtained from the supernova simulation [\[21\]](#page-5-14). The degeneracy of the lepton l is taken into account with the Fermi–Dirac distribution  $f^l$ . We then calculate the neutrino reaction rates as

<span id="page-1-3"></span>
$$
Q = G_F^2 (1 + 3a^2) n_i^b \int \frac{d^3 p_f^l}{(2\pi)^3} \int \frac{d^3 p_i^l}{(2\pi)^3} \epsilon_\nu f_i^l (1 - f_f^l) \times 2\pi \delta(E_f^l + \sum_f \mu_f^b - E_i^l - \mu_i^b + B_{N,Z}),
$$
\n(8)

where i and f represent the initial and final states,  $p<sup>l</sup>$  and  $E^l$  are the momentum and energy of leptons,  $\epsilon_{\nu} = E_f^l$  or  $E_i^l$ . We note that the Pauli-blocking for the final state lepton is incorporated in Eq. [\(8\)](#page-1-3).

## III. RESULTS

We first show the distributions of the density, temperature, and electron ratio obtained by the supernova simulation through the axial symmetry approximation at 100 ms and 200 ms after core bounce [\[21\]](#page-5-14) in Figs. [1,](#page-2-0) [2,](#page-2-1) and [3,](#page-2-2) respectively. The central region exhibits higher temperature and density, and neutron-rich compared to the outer regions.

Using the thermodynamical inputs  $\rho_B$ , T and  $Y_e$ , we calculate the mass fractions  $X_{N,Z} = n_{N,Z}(N +$  $Z)/n_B$  of all nuclei including  $\frac{2n}{n}$  and  $\frac{n}{2}n$ . We show a two-dimensional map of the mass fractions of  $2n$  and

<span id="page-2-0"></span>FIG. 1. Mass density distributions at 100 ms and 200 ms after core bounce on the left and right, respectively. The radius is shown up to 500 km, with scale intervals of 100 km.

<span id="page-2-1"></span>FIG. 2. Temperature distributions at 100 ms and 200 ms after core bounce on the left and right, respectively.

<span id="page-2-2"></span>FIG. 3. Electron ratio distributions at 100 ms and 200 ms after core bounce on the left and right, respectively.

<span id="page-2-3"></span>FIG. 4. Mass fraction of the dineutron (left) to the deuteron (right) at 100 ms after core bounce.

<span id="page-2-4"></span>FIG. 5. Mass fraction of the dineutron (left) to the deuteron (right) at 200 ms after core bounce.

deuterons at 100 ms and 200 ms in Figs. [4](#page-2-3) and [5,](#page-2-4) respectively. Notably,  $X_{2n}$  becomes larger than  $X_d$  inside the shock radius, although  $X_d$  has considered to be the largest around proto-neutron stars [\[2\]](#page-4-1). In the following, we focus on the mass fractions of the 180◦ angle at 100 ms, which is illustrated in Fig. [6.](#page-3-0) In this case,  $X_{4n}$  is large within a radius of approximately 50 km.

Moreover, we add the results for the nuclear composition excluding  $2n$  and  $4n$  in Fig. [6](#page-3-0) by dotted curves. A significant difference is found within a radius of 100 km. The mass fraction of neutrons decreases due to populations of  $2n$  and  $4n$ . Interestingly, the number of the protons, deuterons, and <sup>4</sup>He is found to increase if we include  $^{2}n$  and  $^{4}n$ .

The isotopes of hydrogen and helium are shown in Figs. [7](#page-3-1) and [8,](#page-3-2) respectively. The nuclei of  ${}^{3}$ He and  ${}^{5}$ He increase in some regions, whereas neutron-rich nuclei such as  $H<sup>5</sup>$  tend to decrease. The decrease of neutrons results in the decrease of the chemical potential of the neutrons. Consequently, the number of neutron-rich nuclei

<span id="page-3-0"></span>FIG. 6. Nuclear composition on the 180 $^{\circ}$  angle at 100 ms after core bounce. Neutron (blue), proton (magenta), deuteron (red), <sup>4</sup>He (gold),<sup>2</sup>n (green), and <sup>4</sup>n (black) are displayed. The solid line shows the nuclear composition when the presence of  $2n$  and  $4n$  is considered, and the dotted line shows one when they are not.

<span id="page-3-1"></span>FIG. 7. The isotopes of hydrogen within the region up to 200 km.  ${}^{3}H(blue)$ ,  ${}^{4}H(\text{red})$ ,  ${}^{5}H(\text{green})$ ,  ${}^{6}H(\text{purple})$ , and  $\rm{H(black)}$  are displayed.

decreases, leading to an increase in the number of protons, deuterons, and <sup>4</sup>He through the total proton conservation of Eq. [4.](#page-1-1)

For completeness, we calculated the nuclear composition for different values of the binding energy of  $^2n$ , and the results are presented in Fig. [9.](#page-3-3) As shown in previous studies  $[20]$ , the binding energy of  ${}^{2}n$  affects its mass fraction; the maximum mass fraction of  ${}^{2}n$  with  $B_{2n} = 1.0 \text{ MeV}$  is approximately double that of the model with  $B_{2n} = -3.0$  MeV.

We finally calculated the neutrino and antineutrino reaction rates of the model with  $B_{2n} = -0.066$  MeV within a radius of 100 km, where the impact of  $2n$  on the nu-

<span id="page-3-2"></span>FIG. 8. The isotopes of helium within the region up to 200 km.  ${}^{3}$ He(blue),  ${}^{5}$ He(red),  ${}^{6}$ He(green),  ${}^{7}$ He(purple), and <sup>8</sup>He(black) are displayed.

<span id="page-3-3"></span>FIG. 9. The nuclear compositions for different values of the binding energy of  $^2n$ . The solid, dashed, and dotted lines represent the nuclear compositions at −0.066 MeV, −3.0 MeV, and 1.0 MeV, respectively. The colors in the graph have the same meaning as in Fig. [6.](#page-3-0)

clear compositions is significant. We show in the Fig. [10](#page-4-3) the results for the electron-type neutrino absorption rates (i)-(iii) and antineutrino emission rates (viii)- $(x)$ , which are reactions involving neutrons, deuterons, and  $2n$ . We also calculated the ratio of the reaction rates in the presence of  $2n$  and  $4n$  to those without them. The neutrino absorption and antineutrino emission rates decrease by approximately 40%–50% due to the decrease in neutrons. In Fig. [11](#page-4-4) we show the results for the neutrino emission rates (vi) and (vii), and antineutrino absorption rates (iv) and (v), which are reactions involving protons and deuterons. Since the number of protons and deuterons increases, the neutrino emission and antineutrino absorption rates are considered to have increased

<span id="page-4-3"></span>FIG. 10. Neutrino reaction rates involving the neutrino absorption (red) and antineutrino emission (gold) rates of neutrons, deuterons, and  $^{2}n$ .

<span id="page-4-4"></span>FIG. 11. Neutrino reaction rates involving neutrino emission (blue) and antineutrino absorption (green) rates of protons and deuterons.

by approximately eight times. The change in the nuclear composition has a significant effect on the electron-type neutrino reactions. The presence of  $^2n$  and  $^4n$  suppresses the reaction in which neutrons are converted to protons. Conversely, it promotes the reactions in the conversion process from protons to neutrons. This means that the existence of  $\frac{2n}{n}$  and  $\frac{4n}{n}$  may accelerate the neutronization of the proto-neutron star and shorten its neutrino cooling time.

# IV. SUMMARY AND DISCUSSION

We have calculated the nuclear compositions and the neutrino and antineutrino reaction rates at 100 ms after core bounce using the results of a two-dimensional simulation [\[21\]](#page-5-14), considering the existence of  ${}^{2}n$  and  ${}^{4}n$ . Compared to the deuteron, which is reported to be abundant in a previous study [\[2\]](#page-4-1), the mass fractions of  $2n$  and  $4n$  are larger up to a radius of approximately 100 km and 50 km, respectively. Within a radius of about 100 km, the change in nuclear composition derived from  $2n$  and  $\frac{4}{n}$  is large, where the neutrons decrease and the protons, deuterons, and <sup>4</sup>He increase. The chemical potential of the neutrons decreases, and consequently, the number of neutron-rich nuclei such as <sup>5</sup>H decreases, leading to an increase in the number of the protons, deuterons, and  $^{4}$ He.

We have also calculated neutrino and antineutrino reaction rates by the nucleons, deuterons, and  ${}^{2}n$ . The neutrino absorption and antineutrino emission rates decrease by approximately 40%−50%, whereas the neutrino emission and antineutrino absorption rates increase by approximately eight times. These results confirm that the presence of  $\overline{a_n}$  and  $\overline{a_n}$  facilitates the neutronization near the central region. The early neutronization and contraction of the proto-neutron star may increase neutrino emissions and contribute to the supernova explosion or the early birth of neutron stars.

However, this study leaves room for further improvement. First, we adopted the experimental values from the Earth for the binding energy of nuclei; however, those in high-temperature and high-density environments are unknown. The change to a bound state in the environment within the supernova should be clarified and reflected in the calculations. Additionally, the binding energies of  $2n$  and  $4n$  have not been determined experimentally. Second, we assumed that the nucleons and nuclei are Boltzmann gases; however, the significant change in the nuclear compositions is near the central region of the proto-neutron star, which is near the subsaturation density. Since the effect of the nuclear forces cannot be ignored, the dependence on the equation of state should be investigated. Finally, the present calculation of neutrino reaction rate does not completely consider the quasibound states in the two-nucleon system or the energy dependence of the baryons. The application of these improvements may change the results by a few factors.

# V. ACKNOWLEDGMENTS

We thank K. Mameda and K. Sumiyoshi for productive discussions, H. Nagakura for providing the simulation data, and T. Uemura for providing the nuclear statistical equilibrium code. S.F. is supported by Grantin-Aid for Scientific Research (19K14723 and 24K00632).
