**Abstract:** In this article, we introduce LASER (Locally Adaptive Smoothing Estimator for Regression), a computationally efficient locally adaptive nonparametric regression method that performs variable bandwidth local polynomial regression. We prove that it adapts (near-)optimally to the local Hölder exponent of the underlying regression function *simultaneously* at all points in its domain. Furthermore, we show that there is a single ideal choice of a global tuning parameter under which the above mentioned local adaptivity holds. Despite the vast literature on nonparametric regression, instances of practicable methods with provable guarantees of such a strong notion of local adaptivity are rare. The proposed method achieves excellent performance across a broad range of numerical experiments in comparison to popular alternative locally adaptive methods.

**Keywords and phrases:** Nonparametric regression, local adaptivity, local polynomial regression, variable bandwidth selection.

# 1. Introduction

# 1.1. Nonparametric regression: general background

Nonparametric regression is a classical and fundamental problem in Statistics; see [21, 47, 43] for an introduction to the subject. The basic problem is to estimate the conditional expectation function  $f(x) = \mathbb{E}(Y|X=x)$  from data points  $\{x_i, y_i\}_{i=1}^n$ . In nonparametric regression the goal is to be able to estimate f under weak assumptions, such as f belongs to some infinite dimensional function class like all Lipschitz / Hölder Smooth functions. In

<sup>\*</sup>Author names are sorted alphabetically.

this paper, we focus on univariate nonparametric regression. For simplicity of exposition, we will focus on the simplest possible setting where the design points  $\{x_i\}_{i=1}^n$  are fixed to be on a grid in [0, 1], i.e.,

$$x_1 < x_2 \dots < x_n$$

where  $x_i = \frac{i}{n}$ . In this case, denoting  $\theta_i^* = f(\frac{i}{n}) + \epsilon_i$  we have the usual signal plus noise model

$$y_i = \theta_i^* + \epsilon_i. \tag{1.1}$$

We also make the standard assumption that  $\epsilon_i$ 's are independent mean zero sub-Gaussian variables with sub-Gaussian norm bounded by  $\sigma > 0$ , i.e.,

$$\sup_{i \in [n]} \mathbb{E}\left[\exp(\frac{\epsilon_i^2}{\sigma^2})\right] \leqslant 2.$$
(1.2)

Under this standard model, the task is to estimate the unknown function/signal  $f/\theta^*$  upon observing the data vector y.

There is a rich collection of methods in the nonparametric regression toolbox. Some methods estimate the function at a given point in the domain by selecting a neighborhood of the point and then the fitted value is essentially a function of the data within this neighborhood. Examples include K-nearest neighbors [8], Local Polynomial Regression [15] and Kernel Smoothing [29, 46] among others. Other methods produce the fitted function as a solution of an optimization problem over a space of functions. Typically, the optimization problem is framed as a regularized least squares problem over an appropriate class of functions. Smoothing Splines [9, 19, 44], RKHS [39], Wavelet Thresholding [11], Trend Filtering [42], Regression Trees [3], Neural Networks [1] etc. all fall under this class of methods.

#### 1.2. Meaning of local adaptivity

In many real problems, the true regression function f may not be uniformly smooth, and its degree of smoothness may vary in different parts of the domain. It should be easier to estimate a function where it is smooth and harder where it is rough. In this article, we revisit and reinvestigate the phenomena of *local adaptivity*. Intuitively, we can say that a nonparametric regression method is locally adaptive if it estimates the function at each location in the domain "as good as possible" depending on the local degree of smoothness. Since there does not seem to be a standardized definition of local adaptivity in the literature; the above intuitive meaning needs to be well formulated.

For an illustration on a somewhat extreme example, let us consider the Doppler function from [11] as a test function:

$$f_{\text{Doppler}}(x) = \sqrt{x(1-x)} \sin\left(\frac{2.1\pi}{x+0.5}\right)$$

The Doppler function provides a well-established benchmark test for locally adaptive nonparametric regression methods, see [41, 12], [31]. This function is very smooth near 1

Fig 1 – Locally polynomial (of degree 2) regression fits (in red) are shown for 4 different bandwidths when the underlying function (in black) is the  $f_{\text{Doppler}}$  function (rescaled to have signal-to-noise ratio = 1) and noisy data n = 2048 is simulated with errors i.i.d N(0, 0.5).

and starts to oscillate faster as we go near 0. Its smoothness (say the second derivative) varies a lot over the domain  $x \in [0, 1]$ . To illustrate the problem, we fit one of the most intuitive and classic nonparametric methods, local (quadratic) polynomial regression with a *fixed* bandwidth. In Figure 1, we see that at larger bandwidths, the low frequency part is estimated very well but the high frequency part is completely missed; as we decrease the bandwidth, the high frequency part starts to be captured, but the low frequency part is overfit. There does not seem to be a *single good* choice of the bandwidth which estimates both the smooth and the rough parts as good as it is possible.

In this sense, local polynomial regression (with a fixed bandwidth) is a quintessential example of a non-locally adaptive method. Clearly, the way to make this locally adaptive is to choose the "right" bandwidth at every location. In this work we propose a relatively intuitive and clean idea to solve this problem.

## 1.3. Existing locally adaptive methods

As we saw in Figure 1, not all nonparametric regression methods in the current toolbox are locally adaptive. In fact, a large class of methods, e.g., Local Polynomial Regression, Kernel Smoothing, Smoothing Splines, RKHS etc. which are linear smoothers are considered to be not locally adaptive. Linear smoothers are estimators which are linear functions of the data, produce fitted values  $\hat{\theta} = (\hat{\theta}_1, \dots, \hat{\theta}_n)$  of the form  $\hat{\theta} = S^{(\lambda)}y$  for some smoothing matrix  $S^{(\lambda)} \in \mathbb{R}^{n \times n}$  depending on the design points and a tuning parameter  $\lambda$ . It is understood that there is a precise minimax sense in which linear smoothers are not locally adaptive. There are inhomogenously smooth function classes, such as the class of bounded variation functions, where linear smoothers provably cannot attain the minimax rate in MSE, see [13, 36, 37]. Thus, one insight we can gain from such results is that a locally adaptive nonparametric method is perhaps *necessarily* a nonlinear smoother.

Nonlinear methods which are regarded as locally adaptive in the literature can be broadly categorized into two groups as before:

- Local methods such as Kernel Smoothing/polynomial regression with data dependent variable bandwidths. There is a long history of such methods in the literature. One line of work originates from the seminal Lepski's method [28, 26]. This is a procedure for selecting a local bandwidth in kernel smoothing. Roughly speaking, at each point x in the domain, it chooses the largest bandwidth (from a discrete set of possible values) such that the kernel estimate at x is within a carefully defined error tolerance to estimates at smaller bandwidths. Since its introduction, many papers have studied and generalized Lepski's method; see the survey [27] and references therein. There is also a large body of work on variable bandwidth local polynomial regression; some notable works include [16, 17, 18, 34, 35, 25].
- Global methods of the form l<sub>1</sub> or l<sub>0</sub> penalized least squares. Locally Adaptive Regression Splines [24, 31], Trend Filtering [40, 23, 41], Wavelet Smoothing [30, 22], Jump Penalized Least Squares [2], Dyadic CART [10, 7] all fall under this approach. All these methods owe their local adaptivity to the inherent localization/sparsity properties of the fits enforced by l<sub>1</sub> or l<sub>0</sub> penalty on the derivative. It appears that Trend Filtering is now the most popular locally adaptive method; its advantages over a previously leading tool, Wavelet Thresholding, is documented in [41].

#### 1.4. Some problems with existing locally adaptive methods

The local methods which are variants of Lepski's method can theoretically be shown to adapt to local smoothness which is what we desire; however, we are not aware of an efficient and operational implementation of Lepski's method. These methods appear to be regarded as more of a theoretical device rather than a ready to use practical method; see, e.g., the discussion in [38, page 6, Section 1.3]. On the other hand, the existing variable bandwidth local polynomial regression methods [16, 17, 18, 34, 35, 25] seem to lack the type of theoretical guarantees we formulate and prove in this paper.

Global methods, like the Trend Filtering and Wavelet Thresholding, appear to be far more ubiquitously used for locally adaptive estimation. However, it seems that, as we will now argue, there are still a couple of deficiencies that Trend Filtering, Wavelet Thresholding and in general any nonlinear global method suffers from.

• Lack of understanding of pointwise errors. In order to certify local adaptivity of

nonlinear global methods such as Trend Filtering and Wavelet Smoothing, the main theoretical characteristic that is typically used in the current literature seems to be minimax rate optimality in mean squared error (MSE) over a spatially heterogenous function class. For example, Trend Filtering (with ideal tuning) is shown to be minimax rate optimal over the class of functions with bounded variation [41] unlike any linear smoother. The MSE is a global notion of error averaging up the squared estimation errors at every location. However, using global error bounds to justify local adaptivity seems slightly unsatisfying. A method that does well "on average" over the entire domain may be very suboptimal for some particular set of points in the domain. Ideally, local/pointwise estimation error bounds which reveal the dependence of the estimation error on some notion of local smoothness of f would perhaps be a better way of explaining, understanding and interpreting local adaptivity of a nonparametric regression estimator.

• Choice of ideal tuning parameter varies with smoothness. A nonparametric regression method is not a single method, rather it is a family of methods, indexed by one or more tuning parameters. As shown in Fig 1, one typically needs to set the tuning parameter differently for estimating the smooth and the rough parts optimally, e.g., this is the case for any linear smoother to the best of our knowledge. *Even Trend Filtering*, which is regarded as more locally adaptive than linear smoothers, appears to suffer from this issue. The existing MSE bounds [41, 20, 32, 48] for the (r-1)-th order Trend Filtering suggest that one needs to set the tuning parameter  $\lambda = \tilde{O}(n^{1/(2r+1)})$ , where  $\tilde{O}(\cdot)$  is  $O(\cdot)$  with a logarithmic factor, to attain the so called slow rate  $\tilde{O}(n^{-2r/(2r+1)})$  for general r-th order bounded variation functions; on the other hand for functions which are exactly piecewise polynomial of degree r - 1, to attain the so called *fast rate* one needs to set  $\lambda = O(n^{1/2})$ . To give a simple example, consider the Check function on [0, 1]

$$f_{\text{Check}}(x) = (x - 0.5)\mathbb{1}\{x \ge 0.5\}.$$

It is constant on [0, 0.5] and linear on [0, 0.5]. Existing results suggest that the ideal tuning parameter for Fused Lasso, which is Trend Filtering of order 0, in the region [0, 0.5] should scale like  $O(\sqrt{n})$  and in the region [0.5, 1] should scale like  $O(n^{1/3})$ ; e.g. see Theorem 3.5 in [5]. So, it appears that for Fused Lasso, there is no single choice of a tuning parameter which can attain the optimal rate for both regions [0, 0.5] and [0.5, 1]. Note that cross validation *does not help* here as finally it selects only one tuning parameter to be applied to the whole domain. The same problem plagues Trend Filtering of all orders as a similar counter example can be constructed for any degree  $r \ge 0$ . Here we show a numerical experiment (with the given  $f_{Check}$ function) which suggests that our proposed method is able to alleviate this problem suffered by Trend Filtering, see Figure 2.

Fig 2 – We take the underlying function (in black) to be the Check function (rescaled to have signal to noise ratio 1), sample size n = 2048, simulate errors i.i.d N(0, 0.5). We did 100 Monte Carlo replications. The left plot shows the boxplots of the corresponding root mean squared errors (RMSE) of the proposed method and (5-fold cross validated) Trend Filtering (of order 0) and the right plot shows fits for one of these 100 realizations. It appears that the Trend Filtering fit is more wiggly in the linear part.

### 1.5. Formulating our study

In light of the discussion in the previous subsection it seems natural to formulate and set the following two requirements as benchmarks for the local adaptivity of a given method.

- Estimation error at any point should adapt to some reasonable notion of local smoothness of the regression function at that point, *simultaneously* over all or most points in the domain.
- The tuning parameter is global, i.e., there is an ideal choice of a single tuning parameter which facilitates adapting to the local smoothness levels; simultaneously over all or most points in the domain.

Surprisingly, in spite of the classical nature of this problem, there seem to be very few, if any, existing nonparametric methods which have been *provably* shown to attain both the criterion above.

To verify our first criterion for local adaptivity, it is not enough to just bound the MSE of a method. We need to be able to bound the (local) estimation errors  $\hat{f}(x) - f(x)$  at each point  $x \in [0, 1]$ . For 0-th order Trend Filtering or Fused Lasso, some recent works [48, 5] have established pointwise error bounds. However, for more general global locally adaptive

methods like Trend Filtering of higher orders or Wavelet Smoothing, showing such local estimation error bounds appears to be hard. This is because there is no simple formula for the fitted value at any given point as these are estimators which are solutions to a global optimization problem.

This motivates us to revisit local methods which enjoy explicit formulas for the fitted values and hence are more tractable to bound local estimation errors. At the same time, unlike versions of Lepski's method, we are mindful of maintaining a relatively simple and intuitive description of our estimator which would be easy to implement with a single global choice of the tuning parameter.

In this article, we set the goal of developing a version of local polynomial regression, where we choose the bandwidth at each location adaptively and in a fully data driven way. We also wish to accompany the proposed methodology with rigorous theoretical analysis, proving that our proposed method attains both the above mentioned criteria for local adaptivity, as well as efficient algorithms for computation.

# 1.6. Our main contributions

- We propose a variable bandwidth local polynomial regression estimator which provably adapts to the local Hölder smoothness coefficient.
- We arrive at our bandwidth selection mechanism being inspired by the splitting criterion used in regression trees.
- Our estimator has only one global tuning parameter  $\lambda$  which when set to be  $\lambda = C\sigma\sqrt{\log n}$  for a small constant C appears to set all the bandwidths near optimally.
- Our analysis furnishes simple and relatively short proof of the adaptive bias variance control.
- We suggest computationally efficient versions of our method and show comparisons with several alternative locally adaptive methods such as Trend Filtering and Wavelet Thresholding. It appears that our method is competitive and performs significantly better than these existing methods for many types of signals. This leads us to believe that the proposed method is a viable and useful addition to the toolbox of locally adaptive nonparametric regression methods. We have developed an accompanying **R** package named laser, which comes with a ready-to-use reference implementation of LASER.

# 1.7. Outline

In Section 2, we introduce LASER and discuss its properties culminating with the associated risk bounds in Theorem 2.2. Section 3 gives a pseudo code for of LASER as well as a computationally faster variant with comparable performance and provide a detailed analysis of their computational complexities. In §3.2, we compare LASER with several popular alternative nonparametric methods via numerical experiments. We elaborate further on

the comparison between our method and other existing variable bandwidth methods in Section 4. Finally in Section 5 we give the proof of our main result, i.e., Theorem 2.2.

#### 1.8. Notation and conventions

We use [n] to denote the set of positive integers  $\{1, 2, ..., n\}$  and  $[\![a, b]\!]$  to denote the (integer) interval  $\{a, a + 1, ..., b\}$  for any  $a, b \in \mathbb{Z}$ . The (real) interval  $\{x \in \mathbb{R} : a \leq x \leq b\}$ , where  $a, b \in \mathbb{R}$ , is denoted using the standard notation [a, b]. We use, in general, the bold font  $\mathbf{I}$  (with or without subscripts) to indicate a real interval, like [0, 1], and I to denote an integer interval, like [n] or a subset thereof. In the sequel, whenever we speak of a sub-interval of I (respectively  $\mathbf{I}$ ), where I is an integer (respectively a real) interval, it is implicitly understood to be an integer (respectively a real) interval. For a real interval  $\mathbf{I}$ , we denote its length by  $|\mathbf{I}|$  whereas for a subset I of [n], we use |I| to denote its cardinality, i.e., the number of elements in I. Their particular usage would always be clear from the context.

For any subset I of [n] and  $\theta = (\theta_i)_{i \in [n]} \in \mathbb{R}^n$ , we let  $\theta_I = (\theta_i)_{i \in I} \in \mathbb{R}^I$  denote its restriction to I. The space  $\mathbb{R}^I$  can be canonically identified with  $\mathbb{R}^{|I|}$  by mapping the *j*-th smallest element in I to the *j*-th coordinate of vectors in  $\mathbb{R}^{|I|}$ .

In this article, we work extensively with discrete polynomial vectors. To this end, given any non-negative integer r and a subset I of [n], we let  $S_I^{(r)}$  denote the linear subspace of discrete polynomial vectors of degree r on the interval I, i.e.,

$$S_I^{(r)} = \left\{ \theta \in \mathbb{R}^I : \theta_i = \sum_{0 \le k \le r} a_k (\frac{i}{n})^k \text{ for all } i \in I \text{ and } (a_k)_{0 \le k \le r} \in \mathbb{R}^{r+1} \right\}.$$
(1.3)

We denote by  $\Pi_{I}^{(r)}$  the orthogonal projection onto the subspace  $S_{I}^{(r)}$ . Identifying  $\mathbb{R}^{I}$  with  $\mathbb{R}^{|I|}$  as in the previous paragraph,  $\Pi_{I}^{(r)}$  corresponds to a matrix of order  $|I| \times |I|$ . We will make this identification several times in the sequel without being explicit.

We say that a sequence of events  $(E_n)_{n\geq 1}$ , indexed by n and possibly depending on degree r as a parameter, occurs with (polynomially) high probability (abbreviated as w.h.p.) if  $\mathbb{P}[E_n] \geq 1 - \max(C(r), n^{-2})$  for all n. The constant 2 is of course arbitrary as we can choose any large constant by altering the values of some constants in our algorithm (see Theorem 2.2 below).

Throughout the article, we use  $c, C, c', C', \ldots$  to denote finite, positive constants that may change from one instance to the next. Numbered constants are defined the first time they appear and remain fixed thereafter. All constants are assumed to be absolute and any dependence on other parameters, like the degree r etc. will be made explicit in parentheses. We prefix the subsections with § while referring to them.

## 2. Description of LASER and risk bounds

In this section, we introduce LASER formally, detailing the development of the estimator as a local bandwidth selector in a step-by-step manner. In  $\S2.2$  we discuss the connection

with Regression Trees and how it motivates LASER. An informal explanation for the local adaptivity of our method is given in §2.3 aided by an illustration on a very simple yet interesting signal. Finally in §2.4, we state risk bounds for LASER when the underlying signal is a realization of a locally Hölder regular function.

#### 2.1. Formal description of the method

We will perform local polynomial regression of some fixed degree r with a data driven bandwidth. To achieve local adaptivity w.r.t. the regularity of the underlying signal around each point, the main issue is how to select the bandwidth adaptively across different locations. We now describe a way of setting the bandwidth at any given point. Let us recall from the introduction the fixed (equispaced) design model

$$y_i = \theta_i^* + \epsilon_i = f(\frac{i}{n}) + \epsilon_i, \ 1 \le i \le n,$$
(2.1)

where  $f : [0, 1] \mapsto \mathbb{R}$  is the underlying regression function and  $\epsilon_i$ 's are independent mean zero sub-Gaussian variables (see (1.1)-(1.2)) with sub-Gaussian norm bounded by  $\sigma > 0$ .

Let us recall the orthogonal projections  $\Pi_I^{(r)}$  onto spaces of polynomial vectors of degree r from around (1.3). Now for any  $I \subset [n]$  and a partition of I into sets  $I_1$  and  $I_2 = I \setminus I_1$  and any vector  $\theta \in \mathbb{R}^n$ , let us define

$$Q^{(r)}(\theta; I_1, I) = \|\theta_I - \Pi_I^{(r)} \theta_I\|^2 - \|\theta_{I_1} - \Pi_{I_1}^{(r)} \theta_{I_1}\|^2 - \|\theta_{I_2} - \Pi_{I_2}^{(r)} \theta_{I_2}\|^2 = \|\Pi_{I_1}^{(r)} \theta_{I_1}\|^2 + \|\Pi_{I_2}^{(r)} \theta_{I_2}\|^2 - \|\Pi_I^{(r)} \theta_I\|^2 = \|\Pi_{I_1, I_2}^{(r)} \theta_I\|^2$$
(2.2)

where  $\|\eta\| \stackrel{\text{def.}}{=} (\sum_{j \in J} \eta_j^2)^{\frac{1}{2}}$  denotes the usual  $\ell_2$ -norm of any  $\eta \in \mathbb{R}^J$   $(J \subset [n])$  and  $\Pi_{I_1,I_2}^{(r)}$  is the orthogonal projection onto the subspace  $S_I^{(r)\perp} \cap (S_{I_1}^{(r)} \oplus S_{I_2}^{(r)})$  (note in view of (1.3) that  $S_I^{(r)}$  is a subspace of  $S_{I_1}^{(r)} \oplus S_{I_2}^{(r)}$ ). Consequently,  $Q^{(r)}$  (for every fixed I and  $I_1$ ) is a positive semi-definite quadratic form on  $\mathbb{R}^n$ . We will be interested in the case where I and  $I_1$  are sub-intervals of [n].

Next we introduce what we call a *local discrepancy measure*. For any  $\theta \in \mathbb{R}^n$ , let us introduce the associated *(r-th order) local discrepancy measure* on sub-intervals of [n] as follows.

$$T_{\theta}^{(r)}(I) \stackrel{\text{def.}}{=} \max_{I_1, I_2} \sqrt{Q^{(r)}(\theta; I_1, I)}$$

$$(2.3)$$

where  $\{I_1, I_2\}$  range over all partitions of I into an interval  $I_1$  and its complement. This definition is legitimate as  $Q^{(r)}$  is positive semi-definite. Intuitively, one can think of  $T_{\theta}^{(r)}(I)$  as a measure of deviation of  $\theta$  from the subspace of degree r polynomial vectors on the interval I. If  $\theta$  is exactly a polynomial of degree r on I, then  $T_{\theta}^{(r)}(I) = 0$ .

We now come to the precise description of our estimator. Given any location  $i_0 \in [n]$ and a *bandwidth*  $h \in \mathbb{N}$ , let us consider the *truncated* symmetric interval

$$\llbracket i_0 \pm h \rrbracket = \llbracket i_0 \pm h \rrbracket_n \stackrel{\text{def.}}{=} \llbracket (i_0 - h) \lor 1, (i_0 + h) \land n \rrbracket (\subset [n]).$$
(2.4)

Our idea is to choose  $I = \llbracket i_0 \pm h \rrbracket$  as a potential interval for estimating  $\theta_{i_0}^*$  if the local discrepancy measure  $T_y^{(r)}(I)$  is small. Just checking that  $T_y^{(r)}(I)$  is small is of course not enough; for instance the singleton interval  $\{i_0\}$  will have  $T_y^{(r)}(\{i_0\}) = 0$ . Naturally, we are led to choosing the largest symmetric interval I around  $i_0$  for which  $T_y^{(r)}(I)$  is still small. To this end, let us define a threshold  $\lambda \in (0, \infty)$  which would be the *tuning parameter* in our method. For any such threshold  $\lambda$ , we define the set of "good" bandwidths as

$$\mathcal{G}^{(r)}(\lambda, y) = \{ h \in [\![0, n-1]\!] : T_y^{(r)}([\![i_0 \pm h]\!]) \le \lambda \}.$$
(2.5)

We now propose our optimal local bandwidth as follows.

$$\widehat{h}_{i_0} = \widehat{h}_{i_0}^{(r)}(\lambda, y) \stackrel{\text{def.}}{=} \max \mathcal{G}^{(r)}(\lambda, y).$$
(2.6)

With this choice of optimal bandwidth, our proposed estimator for  $f(\frac{i_0}{n}) = \theta_{i_0}^*$  (of degree r) takes the following form:

$$\widehat{f}(\frac{i_0}{n}) = \widehat{f}_{\mathsf{LASER}(r,\lambda)}(\frac{i_0}{n}) = \left(\prod_{[i_0 \pm \widehat{h}_{i_0}]}^{(r)} y_{[i_0 \pm \widehat{h}_{i_0}]}\right)_{i_0}.$$
(2.7)

# 2.2. Connection to Regression Trees

Our estimator is naturally motivated by the splitting criterion used in Regression Trees. In this section, we explain this connection. Note that trees are in one to one correspondence with partitions of [n] in the univariate setting. One can define the *Optimal Regression Tree* (ORT) estimator, described in [6] as a solution to the following penalized least squares problem:

$$\widehat{\theta}_{\text{ORT},\lambda}^{(r)} = \operatorname*{arg\,min}_{\theta \in \mathbb{R}^n} \left( \|y - \theta\|^2 + \lambda k^{(r)}(\theta) \right),$$

where  $k^{(r)}(\theta)$  denotes the smallest positive integer k such that if we take a partition of [n]into k intervals  $I_1, \ldots, I_k$  then the restricted vector  $\theta_{I_j}$  is a degree r (discrete) polynomial vector on  $I_j$  for all  $1 \leq j \leq k$ . The version with r = 0 is also called jump penalized least squares or the Potts functional minimizer; see [2]. The final tree produced is a random partition  $\mathcal{P}^{(r)}$  and the final fit is obtained by performing least squares degree r polynomial regression on each interval of the partition  $\mathcal{P}^{(r)}$ .

We now make a key observation. If we split a resulting interval I of the final 'tree'  $\mathcal{P}^{(r)}$  further into *any* two intervals; one does not decrease the optimization criterion. This turns out to be equivalent to saying that the decrease in residual sum of squares is less than a threshold (the tuning parameter)  $\lambda$ . Let us call this property (P\*) which the interval I satisfies.

The residual sum of squares splitting criterion when splitting I into two contiguous intervals  $I_1, I_2$  is precisely  $Q^{(r)}(y; I_1, I)$  defined in (2.2). In view of property (P\*), we see that I satisfies

$$\max_{I_1,I_2} Q^{(r)}(y;I_1,I) \leqslant \lambda,$$

where  $I_1, I_2$  ranges over all splits of I into two contiguous intervals. The above display naturally leads us to define the local discrepancy measure  $T_y^{(r)}(I)$  as in (2.3). The only difference is instead of maximizing over all splits, we insist on  $I_1$  being any subinterval of I and  $I_2 = I \cap I_1^c$  not necessarily an interval. We found that this modification simplifies our proof substantially.

Our idea to produce locally adaptive fits is to now execute the following principle. For any given point, choose the largest interval containing this point which satisfies property  $(P^*)$  and estimate by the mean (or higher order regression) within this interval. In effect, motivated by the splitting criterion for Regression Trees, we are proposing a principled way to perform adaptive bandwidth selection in local polynomial regression.

#### 2.3. Local adaptivity of LASER in a toy example

Intuitively, it is perhaps clear that our bandwidth (2.6) at a given location  $i_0$  is larger when  $\theta^*$  is 'smoother' around  $i_0$ . This smoothness is measured by the local discrepancy statistic  $T_I^{(r)}(y)$  for various intervals I centered at  $i_0$ . The following quantity turns out to play the role of an 'effective noise' in our problem.

NOISE 
$$\stackrel{\text{def.}}{=} \max_{I} T_{\epsilon}^{(r)}(I)$$

Using concentration inequalities involving sub-Gaussian variables it can be shown that, this effective noise does not exceed  $C\sigma\sqrt{\log n}$  w.h.p. (see Lemma 5.1 in Section 5). Combining this with the seminorm property of  $\sqrt{Q^{(r)}}$ , one gets a valuable information on the selected bandwidth  $\hat{h}_{i_0}$  in view of our selection rule in (2.5)–(2.6), namely

$$T_{\theta^*}^{(r)}(\llbracket i_0 \pm \hat{h}_{i_0} \rrbracket) \approx \sigma \sqrt{\log n}$$
(2.8)

w.h.p. simultaneously for all  $i_0 \in [n]$  as long as the tuning parameter  $\lambda$  kills the effective noise, as in, e.g.,

$$\lambda = 2$$
 NOISE  $= C\sigma \sqrt{\log n}$ .

Here ' $\approx$ ' in (2.8) means that the ratio of both sides stay bounded away from 0 and  $\infty$ . We refer to (2.8) as the *Bandwidth Selection Equation* and this feature as the *noise removal guarantee* in the future. See Lemma 5.2 for a precise formulation.

In effect, (2.8) says that if  $\lambda = C\sigma\sqrt{\log n}$  is chosen so that it exceeds the effective noise level, then LASER selects the bandwidths resembling the following oracle. The oracle can see the signal  $\theta^*$  itself. For every location  $i_0$ , the oracle starts with the smallest bandwidth h = 0 and continues to increase h. At each step, the oracle calculates the local discrepancy measure  $T_{\theta^*}^{(r)}(\llbracket i_0 \pm h \rrbracket)$  and stops the first time it goes above  $C\sigma\sqrt{\log n}$  to output the selected bandwidth at  $i_0$ . What is very crucial is that the stopping threshold is universal in the sense that it does not depend on the location  $i_0$  nor the underlying signal  $\theta^*$ . We illustrate the importance of this observation with a simple yet illuminative example. To this end let us again consider the function  $f_{check}(x) = (x - \frac{1}{2})1\{x \ge \frac{1}{2}\}$  from §1.4 (see Figure 2). The signal version, i.e., the corresponding  $\theta$  is  $\theta_i^* = \frac{i-1}{2}1\{i \ge n/2\}$ .

Let us now examine local averaging which is local polynomial regression of degree 0, i.e.,

$$\widehat{\theta}_{i_0}(h) = \overline{y}_{[\![i_0 \pm h]\!]}$$

where h > 0 is some bandwidth. For any h > 0, one can compute explicitly the bias and variance of  $\hat{\theta}_{i_0}(h)$  as a function of h. One can then check that the ideal bandwidths for any point in [0,0.5) and any point in [0.5,1] are cn and  $cn^{2/3}$  respectively. The ideal squared error rates turn out to be at most  $Cn^{-1}$  and  $Cn^{-2/3}$  respectively. So, even in this simple example, one needs to set different bandwidths in different locations to get the best possible rates of convergence.

Let us now check if the oracle selects the right bandwidths in this example. Take a point in [0.5, 1] such as  $x = \frac{3}{4}$ , i.e.,  $i_0 = \frac{3n}{4}$ . Consider intervals of the form  $I(h) = [[i_0 \pm h]]$ . We need to find h which solves the Bandwidth Selection Equation (2.8) (with h in place of  $\hat{h}_{i_0}$ ). In the case of local averaging with r = 0, the splitting criterion Q admits of a simplified expression as follows:

$$Q^{(0)}(\theta^*; I_1, I) = \frac{|I_1||I_2|}{|I|} \left(\overline{\theta}_{I_1}^* - \overline{\theta}_{I_2}^*\right)^2$$

where  $I_2 = I \setminus I_1$ .

It turns out in this case, that the local discrepancy  $T_{\theta^*}^{(0)}(I(h))$  is maximized when  $I_1$  and  $I_2$  are roughly of size h/2. Clearly, for such a pair  $(I_1, I_2)$ , one has

$$\frac{|I_1||I_2|}{|I|} \approx ch \text{ and } \left(\overline{\theta}_{I_1}^* - \overline{\theta}_{I_2}^*\right) \approx c\frac{h}{n}.$$

This implies that

$$T_{\theta^*}^{(r)}(\llbracket i_0 \pm h \rrbracket) \approx c \frac{h^3}{n^2}$$

Thus, in order to solve (2.8) we need  $h \approx n^{2/3}$  which is exactly the right bandwidth size for this  $i_0$ .

Now, let us consider a point in (0, 0.5) such as  $i_0 = \frac{3n}{8}$ . It is clear that if  $h \leq \frac{n}{8}$  then  $T_{\theta^*}^{(r)}([i_0 \pm h]) = 0$ , hence the selected bandwidth is not less than  $\frac{n}{8}$ . This means that  $h \approx n$  which is exactly the right bandwidth size for this  $i_0$ .

To summarize, we find that solving the same Bandwidth Selection Equation (2.8) gives the correct bandwidth for locations *both* in the left and right half of the domain. This illustration suggests that an h satisfying (2.8) is potentially the right bandwidth to select even for general degrees  $r \ge 0$ . It turns out that this intuition is correct and LASER precisely implements the above bandwidth selection rule. The underlying reason why this bandwidth selection rule works is due to the *self-adaptive* growth rate of the local

discrepancy measure  $T^{(r)}(\cdot)$  (see, e.g., Lemma 5.4) of which we have seen some indication in the case of r = 0.

Our proof in Section 5 gives a unified analysis for all degrees  $r \ge 0$ . Since there does not seem to be a 'simple' expression for the splitting criterion  $Q^{(r)}$  for higher degrees r > 0, the general case turns out to be more subtle. Our proof in Section 5 reveals that the calibrated bandwidth obtained by LASER, as a solution to the Bandwidth Selection Equation (2.8), leads to an automatic and correct balancing of the local bias and variance terms yielding the desired property of local adaptivity.

# 2.4. Pointwise risk bounds for LASER

For theoretical risk bounds and the accompanying in-depth mathematical analysis of LASER, we choose to work with (locally) Hölder regular functions which have a long history in nonparametric regression, see, e.g., [28], [14] and [26]. Let us formally introduce this class of functions with a slightly non- standard notation for our convenience.

**Definition 2.1** (Hölder space). Given any (open) sub-interval  $\mathbf{I}$  of [0, 1],  $\alpha \in [0, 1]$  and  $r \ge 0$  an integer, we define the Hölder space  $C^{r,\alpha}(\mathbf{I})$  as the class of functions  $f : [0, 1] \mapsto \mathbb{R}$  which are *r*-times continuously differentiable on  $\mathbf{I}$  and furthermore the *r*-th order derivative  $f^{(r)}$  is Hölder continuous with exponent  $\alpha$ , i.e.,

$$|f|_{\mathbf{I};r,\alpha} \stackrel{\text{def.}}{=} \sup_{x,y \in \mathbf{I}, x \neq y} \frac{|f^{(r)}(x) - f^{(r)}(y)|}{|x - y|^{\alpha}} < \infty.$$
(2.9)

We call  $|f|_{\mathbf{I};r,\alpha}$  the  $(r, \alpha)$ -Hölder coefficient (or norm) of f on  $\mathbf{I}$ . Notice that if (2.9) holds for some  $\alpha > 1$ , then  $|f|_{\mathbf{I};r,\alpha}$  is necessarily 0, i.e.,  $f^{(r)}(\cdot)$  is constant and consequently fis a polynomial of degree r on  $\mathbf{I}$ . For the sake of continuity, we denote the space of such functions by  $C^{r,\infty}(f)$  and set  $|f|_{\mathbf{I};r,\infty} = 0$ .

Our main result (see Theorem 2.2 below) in this paper shows that LASER indeed attains the two criteria for local adaptivity set in §1.5. In the sequel, for any  $x \in [0, 1]$  and s > 0, we let

$$[x \pm s] \stackrel{\text{def.}}{=} [(x - s) \lor 0, (x + s) \land 1] (\subset [0, 1])$$

(cf. (2.4)).

**Theorem 2.2** (Local Adaptivity Result). Fix a degree  $r \in \mathbb{N}$  and let  $f : [0,1] \mapsto \mathbb{R}$ . There exist constants  $C_1$  and  $C_2 = C_2(r)$  such that the following holds with high probability for  $\lambda = C_1 \sigma \sqrt{\log n}$ . Simultaneously for all quadruplets  $(i_0, s_0, r_0, \alpha_0)$  where  $i_0 \in [n]$ ,  $s_0 > 0$ ,  $r_0 \in [0, r]$  an integer and  $\alpha_0 \in [0, 1] \cup \{\infty\}$  such that  $f \in C^{r_0, \alpha_0}([\frac{i_0}{n} \pm s_0])$ , one has, with  $\alpha = \alpha_0 + r_0$ ,

$$\hat{f}(\frac{i_0}{n}) - f(\frac{i_0}{n})| \leq C_2 \left( \sigma^{\frac{2\alpha}{2\alpha+1}} \left| f \right|_{[\frac{i_0}{n} \pm s_0]; r_0, \alpha_0}^{\frac{1}{2\alpha+1}} \left( \frac{\log n}{n} \right)^{\frac{\alpha}{2\alpha+1}} + \sigma \left( \frac{\log n}{ns_0} \right)^{\frac{1}{2}} \right),$$
(2.10)

where  $\hat{f}(\frac{i_0}{n}) = \hat{f}_{LASER(r,\lambda)}(\frac{i_0}{n})$  is from (2.7) and we interpret  $0^0 = 0$ .

Let us now discuss some aspects of the above theorem.

- Our bound achieves near optimal sample complexity. For instance, if  $f \in C^{r_0,\alpha_0}([0,1])$  is globally Hölder continuous and we ignore the dependence on the Hölder coefficient of f or the noise strength  $\sigma$ , then the risk bound in (2.10) reads as  $C(r)(\frac{\log n}{n})^{\frac{\alpha}{2\alpha+1}}$  which is known to be the minimax optimal rate up to logarithmic factors (see, e.g., [14]).
- We are mainly interested in the cases where the Hölder exponents are different at different points  $i_0$  in the domain, i.e.,  $r_0$ ,  $\alpha_0$  can depend on  $i_0$ . One can think of  $s_0$  as typically O(1) in any reasonable example. The main point we emphasize here is that our bound at different points  $i_0$  adapts optimally to  $r_0$ ,  $\alpha_0$  simultaneously under the same choice of  $\lambda$ . The first term gives the optimal rate up to logarithmic factors and the second term gives a parametric rate and hence is a lower order term.
- The degree r of the estimator is chosen by the user. Once chosen, LASER adapts to any local Hölder degree  $r_0 \leq r$ .
- The logarithmic factor is known to be necessary if one wants to adapt to all levels of Hölder exponent  $\alpha_0 \in [0, 1]$ . It appears that the logarithmic factor  $(\log n)^{\frac{\alpha_0 + r_0}{2(\alpha_0 + r_0) + 1}}$  that we incur in (2.10) is the best possible (see [28]).
- The case  $\alpha_0 = \infty$  is particularly interesting. Let us recall from Definition 2.1 that f is locally a polynomial of degree (at most) r in this case so that  $|f|_{\left[\frac{i_0}{n}\pm s_0;r,\infty\right]}=0$ . Consequently, we recover the parametric rate from (2.10).
- Although we are unaware of any result on the optimal dependence of the risk in terms of the Hölder coefficient  $|f|_{\left[\frac{i_0}{n}\pm s_0;r_0,\alpha\right]}$ , it is clear that our bound gets better for smoother functions with smaller Hölder coefficients.

# 3. Algorithm and simulations

In this section we first discuss the computational aspects of LASER. After that, we provide a comparative study of our method vis-à-vis other popular methods in the literature backed by simulation studies.

# 3.1. Pseudo-code of LASER

We now present a pseudo code for LASER. For ease of understanding, we have broken down the full algorithm into three subroutines. Algorithm 1, named ComputeDiscrepancy, outputs for an interval I, the discrepancy criterion (2.2). Algorithm 2, called BandwidthSelector, uses ComputeDiscrepancy to compute local bandwidths á la (2.6) at co-ordinates of interest given the tuning parameter  $\lambda$ . Algorithm 3 calls BandwidthSelector at each co-ordinate to obtain a local bandwidth and performs a local polynomial regression to output the final estimate at that co-ordinate. We note that the degree of polynomial regression r is an input parameter, which can be specified by the user.

# Algorithm 1 ComputeDiscrepancy: Compute the discrepancy criterion

**Input:** Interval *I*; vector  $\theta$ ; degree parameter *r*, tuning parameter  $\lambda$ .

**Output:** Discrepancy criterion over *I*.

1: for all sub-intervals  $I_1 \subset I$  do

- 2: Compute  $Q^{(r)}(y, I_1, I)$ .
- 3: end for
- 4: Return  $\max_{I_1} Q^{(r)}(y, I_1, I)$ .

#### Algorithm 2 BandwidthSelector: Select local bandwidth at a specified co-ordinate

**Input:** Requested co-ordinate  $i_0$ ; data y; degree parameter r, tuning parameter  $\lambda$ . **Output:**  $\hat{h}_{i_0}$ , local bandwidth.

1: Criterion  $\leftarrow 0$ . 2:  $h \leftarrow -1$ . 3: while Criterion  $\leq \lambda$  do 4:  $h \leftarrow h + 1$ 5: Criterion  $\leftarrow$  ComputeDiscrepancy( $\llbracket i_0 \pm h \rrbracket, y, X, \lambda, r$ ). 6: end while 7: Return h - 1.

# Algorithm 3 LASER: Locally Adaptive Smoothing Estimator for Regression

Input: Data y; degree parameter r, tuning parameter  $\lambda$ . Output:  $\hat{\theta}$ . 1: for  $i_0 = 1, ..., n$  do 2:  $\hat{h}_{i_0} \leftarrow \text{BandwidthSelector}(i_0; y, X, r, \lambda)$ . 3: Obtain  $\hat{\theta}_{i_0}$  by fitting a degree-r polynomial to  $y_{[\![i_0 \pm \hat{h}_{i_0}]\!]}$  using least squares. 4: end for 5: Return  $\hat{\theta}$ .

# 3.1.1. Computational complexity and a fast dyadic variant

First consider the complexity of ComputeDiscrepancy.

- Each computation of  $Q^{(r)}(y, I_1, I)$  in ComputeDiscrepancy involves a least squares fit with O(|I|) observations and r + 1 variables. Thus each such computation incurs an O(|I|) cost, where the hidden constant is dependent on r. Here and in the sequel, we hide such dependence on r under the O-notation.
- There are  $O(|I|^2)$  choices for the sub-intervals  $I_1 \subset I$ .

Thus the full complexity of ComputeDiscrepancy is  $O(|I|^3)$ . If one searches over intervals with endpoints and lengths on a dyadic scale, then the complexity of the second step reduces to  $O((\log |I|)^2)$  and hence that of ComputeDiscrepancy to  $O(|I|(\log |I|)^2)$ .

It follows that the worst case complexity of a single run of BandwidthSelector is  $\sum_{h \leq n} O(h^3) = O(n^4)$ . If, on the other hand, we search over h on a dyadic scale as well and also use the dyadic version of ComputeDiscrepancy, then the complexity of BandwidthSelector becomes  $O(n(\log n)^3)$ . It follows that the complexity of the full-blown variant of LASER is  $O(n^5)$  whereas that of its dyadic variant is  $O(n^2(\log n)^3)$ . In our reference implementation, we use these dyadic variants of ComputeDiscrepancy and BandwidthSelector. Our numerical experiments show that this dyadic variant has comparable performance to the full-blown version. In fact, although our theoretical risk bounds in Theorem 2.2 are stated and proved for the full version of our method, our proof in Section 5, subject to minor modifications, yields similar bounds for this dyadic variant. Moreover, LASER naturally lends itself to a hierarchy of implementations with progressively coarser search spaces but *lesser* computational tax, and an inspection of our proof reveals that the statistical performance of such variants degrade by *at most* logarithmic factors.

#### 3.2. Numerical experiments

We compare LASER with three popular nonparametric regression methods, namely Trend Filtering (TF), Wavelet Thresholding (WT) and Cubic Smoothing Splines (CSS) on the four test functions described in [11]. We have used the genlasso, wavethresh (with so-called *universal tuning*) and npreg R packages to compute cross validated versions of TF, WT and CSS, respectively. For LASER, we have developed an eponymous R package laser, available at https://gitlab.com/soumendu041/laser.

Fig 3 – We take the underlying function to be the Blocks function from [11] (rescaled to have a signal-to-noise ratio (SNR) of 4), sample size n = 2048, simulate errors i.i.d N(0, 0.5). We did 100 Monte Carlo replications. The left plot shows the boxplots of the corresponding root mean squared errors (RMSE) of the four methods and the right plot shows fits for one of these 100 realizations. For LASER, r = 0, for Trend Filtering, r = 0. Both are tuned via 5-fold CV.

Figures 3, 4, 5 and 6 show the results of four experiments, one for each of the functions Blocks, Bumps, HeaviSine, Doppler from [11]. The experimental set-up of each

Fig 4 – We take the underlying function to be the Bumps function from [11] (rescaled to have an SNR of 4), sample size n = 2048, simulate errors i.i.d N(0, 0.5). We did 100 Monte Carlo replications. The left plot shows the boxplots of the corresponding root mean squared errors (RMSE) of the four methods and the right plot shows fits for one of these 100 realizations. For LASER, r = 2, for Trend Filtering, r = 2. Both tuned via 5-fold CV.

of these experiments, is as follows. For  $f \in \{\text{Blocks}, \text{Bumps}, \text{HeaviSine}, \text{Doppler}\}$ , we set  $\vartheta_f = (f(\frac{i}{n}))_{1 \leq i \leq n}$ . The observations are generated as

$$y = \theta_f + \sigma \epsilon,$$

where  $\sigma > 0$ ,  $\epsilon \sim N_n(0, \text{Id})$  and

$$\theta_f := \mathrm{SNR} \cdot \sigma \cdot \frac{\vartheta_f}{\mathrm{sd}(\vartheta_f)}.$$

Here  $\operatorname{sd}(x) := \frac{1}{n} \sum_{i=1}^{n} x_i^2 - (\frac{1}{n} \sum_{i=1}^{n} x_i)^2$  denotes the numerical standard deviation of a vector  $x \in \mathbb{R}^n$ . The factor SNR captures the signal-to-noise ratio of the problem in the sense that

$$SNR = \frac{\mathrm{sd}(\theta_f)}{\sigma}$$

We have used 5-fold cross-validation (CV) to tune  $\lambda$  for LASER. We have also used 5-fold CV to tune the penalty parameter in TF.

In all but one of these experiments, LASER substantially outperforms the other three methods. For instance, we see that LASER captures more than six cycles (from the right) of the Doppler function accurately in the realization shown in Figure 6. CSS also seems to do so, but it significantly overfits in the first cycle. TF, on the other hand, overfits much less in the first cycle but captures only about three cycles. Another noteworthy case

Fig 5 – We take the underlying function to be the HeaviSine function from [11](rescaled to have an SNR of 4), sample size n = 2048, simulate errors i.i.d N(0, 0.5). We did 100 Monte Carlo replications. The left plot shows the boxplots of the corresponding root mean squared errors (RMSE) of the four methods and the right plot shows fits for one of these 100 realizations. For LASER, r = 2, for Trend Filtering, r = 2. Both tuned via 5-fold CV.

is that of the Bumps function (see Figure 4), where TF (2-nd order) does not appear to capture the interesting peaks. LASER (with degree 2) does an excellent job in capturing most of these features while overfitting to a much lesser extent compared to both WT and CSS. For the HeaviSine function (see Figure 5), both LASER and CSS capture the discontinuity near x = 0.7, with LASER again overfitting to a lesser degree. (The other two methods both fail to capture this.) Finally, for the piecewise constant Blocks function, 0-th order TF and LASER with r = 0 both significantly outperform the other two methods (see Figure 3), with TF showing a slight edge over LASER in terms of RMSE.

Our numerical experiments suggest that the proposed method carries a lot of promise and can be a practically useful addition to the current nonparametric regression toolbox. The accompanying R package laser comes with a ready-to-use reference implementation of the dyadic version of LASER.

## 4. Discussions

In this section we discuss some aspects of our work in this article.

Comparison with other locally adaptive methods. Our method is operationally different from existing variable bandwidth methods. For example, to obtain their data driven bandwidths, the works in [16, 17, 34, 35] minimize the local mean squared error, plugging in estimates of unknown population quantities. The theoretical guarantees, however, do not seem to provide simultaneous adaptive estimation errors of the kind we

Fig 6 – We take the underlying function to be the **Doppler** function from [11] (rescaled to have an SNR of 4), sample size n = 2048, simulate errors i.i.d N(0, 0.5). We did 100 Monte Carlo replications. The left plot shows the boxplots of the corresponding root mean squared errors (RMSE) of the four methods and the right plot shows fits for one of these 100 realizations. For LASER, r = 2, for Trend Filtering, r = 2. Both tuned via 5-fold CV.

provide in Theorem 2.2.

Our method is closer in spirit to the celebrated Lepski's method [28, 26]. More specifically, both our estimator and Lepski's pick the largest symmetric interval satisfying some criterion as the ideal bandwidth. However, the exact criterion that we employ is different.

**Beyond equispaced design.** Our estimator can naturally be defined at points other than the design points  $\{x_i\}_{i=1}^n$  and moreover the design points need not be equispaced. For instance, at a point x one can consider symmetric intervals around x and sub intervals just as before. The estimate will only be a function of the data points  $y_i$  for which the corresponding design points  $x_i$  fall within these intervals.

#### 5. Proof of the main result

In this section we give the proof of Theorem 2.2 which requires some preparation. Let us recall the quadratic form  $Q^{(r)}(\theta; I_1, I)$  from (2.2) where  $I_1 \subset I \subset [n]$  (not necessarily intervals). Also recall the definition of the local discrepancy measure  $T_{\theta}^{(r)}(I)$  (of degree r) from (2.3). Our first result in this section shows that  $T_{\epsilon}^{(r)}(I)$  is small uniformly over Iw.h.p. where  $\epsilon = (\epsilon_i)_{i \in [n]} \in \mathbb{R}^n$  is the vector of noise from (2.1).

Lemma 5.1. We have,

$$\max_{I} T_{\epsilon}^{(r)}(I) \leqslant C \sigma \sqrt{\log n} \ w.h.p.$$

where I ranges over all sub-intervals of [n] and  $\epsilon$  is as in (2.1).

*Proof.* Consider a sub-interval I of [n] and a partition of I into  $I_1$  and  $I_2$  where  $I_1$  is an interval. From definition (2.2), we have

$$Q^{(r)}(\theta; I_1, I) = \|\Pi_{I_1, I_2}^{(r)} \theta_I\|^2$$
(5.1)

where  $\Pi_{I_1,I_2}^{(r)}$  is the orthogonal projection onto the subspace  $S_I^{(r)\perp} \cap (S_{I_1}^{(r)} \oplus S_{I_2}^{(r)})$ . Assuming that  $\epsilon$  is a vector of independent centered sub-Gaussian random variables with sub-Gaussian norm bounded by  $\sigma$  (see (1.2)), we obtain as a consequence of the Hanson-Wright inequality (cf. Theorem 2.1 in [33]) that

$$\sqrt{Q^{(r)}(\epsilon; I_1, I) - \|\Pi_{I_1, I_2}^{(r)}\|_{\mathrm{Fr}}} = \|\Pi_{I_1, I_2}^{(r)}\epsilon\| - \sigma\|\Pi_{I_1, I_2}^{(r)}\|_{\mathrm{Fr}} \text{ is sub-Gaussian}$$
(5.2)

with sub-Gaussian norm bounded by  $C\sigma^2 \|\Pi_{I_1,I_2}^{(r)}\|$  where, for any operator on  $\mathbb{R}^I$  or equivalently a  $|I| \times |I|$  matrix X (see below (1.3) to recall our convention),  $\|X\|$  denotes the  $(\ell_2$ -)operator norm whereas

$$\|X\|_{\mathrm{Fr}} \stackrel{\mathrm{def.}}{=} \sqrt{\mathrm{Tr}(X^{\top}X)}$$

is the Frobenius (or the Hilbert-Schmidt) norm.

Since  $\Pi_{I_1,I_2}^{(r)}$  is an orthogonal projection, we have

$$\|\Pi_{I_1, I_2}^{(r)}\| \leqslant 1. \tag{5.3}$$

Also,

$$\|\Pi_{I_1,I_2}^{(r)}\|_{\rm Fr}^2 = {\rm Tr}(\Pi_{I_1,I_2}^{(r)}) = r+1$$
(5.4)

where in the final step we used the property that the trace of a projection (idempotent) matrix is equal to its rank.

Now using standard facts about the maxima of sub-Gaussian random variables (see, e.g., [45, Exercise 2.12]) and observing that there are at most  $n^4$  many pairs of intervals  $(I, I_1)$  under consideration below, we obtain from the preceding discussions that

$$\max_{I} T_{\epsilon}^{(r)}(I) \stackrel{(2.3)}{=} \max_{I} \max_{\substack{I_{1},I_{2}\\I_{1}\cup I_{2}=I}} \sqrt{Q^{(r)}(\epsilon;I_{1},I)} \stackrel{(5.1)}{=} \max_{I} \max_{I_{1},I_{2}} \|\Pi_{I_{1},I_{2}}^{(r)}\epsilon\|$$

$$\leq \max_{I} \max_{I_{1},I_{2}} \|\Pi_{I_{1},I_{2}}^{(r)}\|_{\mathrm{Fr}} + \max_{I} \max_{I_{1},I_{2}} \left( \|\Pi_{I_{1},I_{2}}^{(r)}\epsilon\|_{\mathrm{Fr}} - \|\Pi_{I_{1},I_{2}}^{(r)}\|_{\mathrm{Fr}} \right)$$

$$\stackrel{(5.2),(5.3)}{\leq} C\sigma(\sqrt{r}+1) + C\sigma\sqrt{\log n}.$$

Now we can give a precise formulation of the noise removal property of our estimator as suggested by (2.8). Let us recall the signal plus noise decomposition

$$y_i = \theta_i^* + \epsilon_i = f(\frac{i}{n}) + \epsilon_i, \ 1 \le i \le n,$$

from (2.1) in §2.1 where  $f : [0, 1] \mapsto \mathbb{R}$ .

**Lemma 5.2.** There exists an absolute constant  $C_3 \in (0, \infty)$  such that for any  $\lambda \in (0, \infty)$ , we have

$$T_{\theta^*}^{(r)}(\llbracket i_0 \pm \hat{h}_{i_0} \rrbracket) \leqslant \lambda + C_3 \sigma \sqrt{\log n}$$
(5.5)

w.h.p. simultaneously for all  $i_0 \in [n]$  where  $\hat{h}_{i_0} = \hat{h}_{i_0}^{(r)}(\lambda, y)$  is from (2.6). Furthermore, unless  $\llbracket i_0 \pm \hat{h}_{i_0} \rrbracket = [n]$ , we also have

$$T_{\theta^*}^{(r)}(\llbracket i_0 \pm (\hat{h}_{i_0} + 1) \rrbracket) \ge \lambda - C_3 \sigma \sqrt{\log n}$$
(5.6)

w.h.p. simultaneously for all  $i_0 \in [n]$ .

*Remark* 5.3. The source of randomness on the left-hand side of both (5.5) and (5.6) is the bandwidth  $\hat{h}_{i_0}$ .

*Proof.*  $\sqrt{Q^{(r)}(\theta; I_1, I)}$  is a seminorm on  $\mathbb{R}^n$  due to (5.1). Since  $y = \theta^* + \epsilon$ , we then obtain from the triangle inequality,

$$\sqrt{Q^{(r)}(y;I_1,I)} - \sqrt{Q^{(r)}(\epsilon;I_1,I)} \leq \sqrt{Q^{(r)}(\theta^*;I_1,I)} \leq \sqrt{Q^{(r)}(y;I_1,I)} + \sqrt{Q^{(r)}(\epsilon;I_1,I)}.$$

Since  $\sqrt{Q^{(r)}(\epsilon; I_1, I)} \leq T_{\epsilon}^{(r)}(I)$  by definition, we obtain

$$\sqrt{Q^{(r)}(y;I_1,I)} - T^{(r)}_{\epsilon}(I) \leqslant \sqrt{Q^{(r)}(\theta^*;I_1,I)} \leqslant \sqrt{Q^{(r)}(y;I_1,I)} + T^{(r)}_{\epsilon}(I).$$

Now taking maximum over all pairs  $(I_1, I_2)$  that form a partition of a sub-interval I of [n] with  $I_1$  an interval, we get

$$T_y^{(r)}(I) - T_{\epsilon}^{(r)}(I) \leq T_{\theta^*}^{(r)}(I) \leq T_y^{(r)}(I) + T_{\epsilon}^{(r)}(I).$$

Plugging the bound on the maximum of  $T^{(r)}(\epsilon, I)$  from Lemma 5.1 into this display, we obtain

$$T_y^{(r)}(I) - C\sigma\sqrt{\log n} \leqslant T_{\theta^*}^{(r)}(I) \leqslant T_y^{(r)}(I) + C\sigma\sqrt{\log n}$$

w.h.p. simultaneously for all sub-intervals I of [n]. We can now conclude (5.5) and (5.6) from this in view of the definition of  $\hat{h}_{i_0}$  in (2.6) (and (2.5)).

Our next result together with (5.6) above would be used later to derive a lower bound on the optimal bandwidth  $\hat{h}_{i_0}$ .

**Lemma 5.4.** Let **I** be a sub-interval of [0, 1] such that  $f \in C^{r_0, \alpha}(\mathbf{I})$  for some  $r_0 \in [0, r]$  an integer and  $\alpha \in [0, 1] \cup \{\infty\}$ . Then we have,

$$T_{\theta^*}^{(r)}\left(\llbracket n\mathbf{I} \rrbracket\right) \leqslant \frac{|f|_{\mathbf{I};r_0,\alpha}}{r_0!} \sqrt{n|\mathbf{I}|+1} \cdot |\mathbf{I}|^{r_0+\alpha}$$
(5.7)

(recall (2.9) for  $|f|_{\mathbf{I};r_0,\alpha}$ ) where  $[\![n\mathbf{I}]\!] \stackrel{\text{def.}}{=} n\mathbf{I} \cap \{1, 2, \ldots\} (\subset [n])$  and we always interpret  $0^{r_0+\alpha} = 0$ .

*Proof.* Since  $\Pi_I^{(r)}$  is the orthogonal projector onto the subspace  $S_I^{(r)}$  spanned by all polynomial vectors in  $\mathbb{R}^I$  with degree r (here  $I \subset [n]$ ), it follows that

$$\left(\mathrm{Id} - \Pi_{I}^{(r)}\right)\theta_{I} = \left(\mathrm{Id} - \Pi_{I}^{(r)}\right)\theta_{I}^{\prime}$$
(5.8)

for any  $\theta' \in \mathbb{R}^n$  satisfying  $(\theta - \theta')_I \in S_I^{(r)}$  where Id is the identity operator on  $\mathbb{R}^I$ . Consequently, in view of the definition of  $Q^{(r)}(\theta; I_1, I)$  in (2.2) (the first expression in particular), we have

$$Q^{(r)}(\theta; I_1, I) = Q^{(r)}(\theta'; I_1, I)$$
(5.9)

for any such  $\theta$  and  $\theta'$ . Now since

$$\Pi_{\llbracket n\mathbf{I} \rrbracket}^{(r)} \theta_{\llbracket n\mathbf{I} \rrbracket}^* \in S_{\llbracket n\mathbf{I} \rrbracket}^{(r)},$$

there is a polynomial  $p : [0,1] \mapsto \mathbb{R}$  of degree r satisfying  $(\Pi_{\llbracket n\mathbf{I} \rrbracket}^{(r_0)} \theta_{\llbracket n\mathbf{I} \rrbracket}^*)_i = p(\frac{i}{n})$  for all  $i \in \llbracket n\mathbf{I} \rrbracket$  so that, with  $\overline{\theta}^* \stackrel{\text{def.}}{=} ((f-p)(\frac{i}{n}))_{i \in [n]} \in \mathbb{R}^n$ ,

$$\Pi_{\llbracket n\mathbf{I}\rrbracket}^{(r)}\bar{\theta}_{\llbracket n\mathbf{I}\rrbracket}^* = 0.$$

Also, we have  $|f - p|_{\mathbf{I};r_{0},\alpha} = |f|_{\mathbf{I};r_{0},\alpha}$  owing to its definition in (2.9) as p is a degree r polynomial and  $r_{0} \leq r$ . Therefore, in view of (5.9), (5.7) amounts to the same statement with  $\theta^{*}$  replaced by  $\overline{\theta}^{*}$ . In other words, we can assume without any loss of generality that

$$\Pi_{\llbracket \mathbf{n}\mathbf{I} \rrbracket}^{(r)} \boldsymbol{\theta}_{\llbracket \mathbf{n}\mathbf{I} \rrbracket}^* = 0.$$
(5.10)

Now by (5.1), we can write

$$Q^{(r)}(\theta^*, I_1, \llbracket n\mathbf{I} \rrbracket) = \|\Pi_{I_1, I_2}^{(r)} \theta^*_{\llbracket n\mathbf{I} \rrbracket}\|^2 \leqslant \|\Pi_{I_1, I_2}^{(r)}\|^2 \|\theta^*_{\llbracket n\mathbf{I} \rrbracket}\|^2 \leqslant \|\theta^*_{\llbracket n\mathbf{I} \rrbracket}\|^2$$
(5.11)

for any interval  $I_1 \subset \llbracket n\mathbf{I} \rrbracket$  where, in the final step, we used that  $\lVert \Pi_{I_1,I_2}^{(r)} \rVert \leq 1$  as it is an orthogonal projection. Now, letting  $\llbracket n\mathbf{I} \rrbracket = \llbracket a, b \rrbracket$  where  $a, b \in [n]$ , consider the vector  $\operatorname{Tayl}_{\llbracket n\mathbf{I} \rrbracket}^{(r_0)}(f) \in S_{\llbracket n\mathbf{I} \rrbracket}^{(r)}(\supset S_{\llbracket n\mathbf{I} \rrbracket}^{(r_0)})$  defined as

$$(\operatorname{Tayl}_{\llbracket n\mathbf{I} \rrbracket}^{(r_0)}(f))_i = \sum_{0 \leqslant k \leqslant r_0} \frac{f^{(k)}(\frac{a}{n})}{k!} \frac{(i-a)^k}{n^k} \text{ for all } i \in I.$$
(5.12)

Since  $f \in C^{r_0,\alpha}(\mathbf{I})$ , it follows from Taylor's theorem that

$$\|\theta_{\llbracket n\mathbf{I}\rrbracket}^* - \operatorname{Tayl}_{\llbracket n\mathbf{I}\rrbracket}^{(r_0)}(f)\|_{\infty} \leq \frac{|f|_{\mathbf{I};r_0,\alpha}}{r_0!} |\mathbf{I}|^{r_0+\alpha}$$
(5.13)

where  $\|\eta\|_{\infty} \stackrel{\text{def.}}{=} \max_{j \in J} |\eta_j|$  denotes the  $\ell_{\infty}$ -norm for any  $\eta \in \mathbb{R}^J$   $(J \subset [n])$  and hence

$$\begin{aligned} \|\boldsymbol{\theta}_{\llbracket n\mathbf{I} \rrbracket}^{*}\| \stackrel{(5.10)}{=} \|\boldsymbol{\theta}_{\llbracket n\mathbf{I} \rrbracket}^{*} - \Pi_{\llbracket n\mathbf{I} \rrbracket}^{(r_{0})} \boldsymbol{\theta}_{\llbracket n\mathbf{I} \rrbracket}^{*}\| &\leq \|\boldsymbol{\theta}_{\llbracket n\mathbf{I} \rrbracket}^{*} - \operatorname{Tayl}_{\llbracket n\mathbf{I} \rrbracket}^{(r_{0})}(f)\| \\ &\leq \|\boldsymbol{\theta}_{\llbracket n\mathbf{I} \rrbracket}^{*} - \operatorname{Tayl}_{\llbracket n\mathbf{I} \rrbracket}^{(r_{0})}(f)\|_{\infty} \sqrt{n|\mathbf{I}| + 1} &\leq \frac{|f|_{\mathbf{I};r_{0},\alpha}}{r!} |\mathbf{I}|^{r_{0}+\alpha} \sqrt{n|\mathbf{I}| + 1}. \end{aligned}$$

Plugging this into (5.11) and taking maximum over all partitions  $\{I_1, I_2\}$  of  $[\![n\mathbf{I}]\!]$  with  $I_1$  an interval, we can deduce (5.7) in view of the definition of  $T_{\theta}^{(r)}([\![n\mathbf{I}]\!])$  in (2.3).

The following result is a technical lemma capturing the regularity of the space of polynomials  $S_I^{(r)}$ .

**Lemma 5.5.** For any (non-empty) sub-interval I of [n] and  $\eta \in S_I^{(r)}$  (recall (1.3)), we have

$$\|\eta\|_{\infty} \leqslant C(r) \frac{\|\eta\|}{\sqrt{|I|}}.$$
(5.14)

Furthermore, letting  $\|\Pi_{I}^{(r)}\|_{\infty} \stackrel{\text{def.}}{=} \sup_{\theta \neq 0} \frac{\|\Pi_{I}^{(r)}\theta\|_{\infty}}{\|\theta\|_{\infty}}$  denote the operator norm of  $\Pi_{I}^{(r)}$  w.r.t. to the  $\ell_{\infty}$ -norm on  $\mathbb{R}^{I}$ , we have

$$|\Pi_I^{(r)}\|_{\infty} \leqslant C(r). \tag{5.15}$$

*Proof.* Since I is an interval, we can use Lemma A.8 and A.9 in [4] to deduce the existence of an orthonormal basis (ONB)  $\{\tilde{\eta}^{(k)}\}_{0 \leq k \leq r}$  for  $S_I^{(r)}$  such that

$$\max_{0 \le k \le r \land (|I|-1)} \|\widetilde{\eta}^{(k)}\|_{\infty} \le \frac{C(r)}{\sqrt{|I|}}.$$
(5.16)

Now writing for any  $\eta \in S_I^{(r)}$ ,

$$\eta = \sum_{0 \le k \le r \land (|I|-1)} a_k \, \widetilde{\eta}^{(k)}$$

with  $a_k \in \mathbb{R}$ , whence

$$\|\eta\|_{2} = \Big(\sum_{0 \le k \le r \land (|I|-1)} a_{k}^{2}\Big)^{\frac{1}{2}} \text{ and } \|\eta\|_{\infty} \le \max_{0 \le k \le r \land (|I|-1)} \|\widetilde{\eta}^{(k)}\|_{\infty} \Big(\sum_{0 \le k \le r \land (|I|-1)} |a_{k}|\Big).$$

By the Cauchy-Schwarz inequality,

$$\sum_{0 \le k \le r \land (|I|-1)} |a_k| \le \sqrt{r} \left(\sum_{0 \le k \le r \land (|I|-1)} a_k^2\right)^{\frac{1}{2}} = \|\eta\|_2$$

Combined with (5.16), the last two displays yield (5.14).

Identifying  $\Pi_I^{(r)}$  with the corresponding matrix, we have the following standard expression for  $\|\Pi_I^{(r)}\|_{\infty}$ .

$$\|\Pi_{I}^{(r)}\|_{\infty} = \max_{i \in I} \sum_{j \in I} |(\Pi_{I}^{(r)})_{i,j}|.$$

Since  $\Pi_I^{(r)}$  is an orthogonal projection, it is idempotent and symmetric (as a matrix) and hence

$$\sum_{j \in I} ((\Pi_I^{(r)})_{i,j})^2 = (\Pi_I^{(r)})_{i,i}$$

for each  $i \in I$ . Consequently by the Cauchy-Schwarz inequality,

$$\|\Pi_{I}^{(r)}\|_{\infty} = \max_{i \in I} \sum_{j \in I} |(\Pi_{I}^{(r)})_{i,j}| \leq \sqrt{|I|} \sqrt{\max_{i \in I} \sum_{j \in I} ((\Pi_{I}^{(r)})_{i,j})^{2}} = \sqrt{|I|} \sqrt{\max_{i \in I} (\Pi_{I}^{(r)})_{i,i}}.$$
 (5.17)

As I is an interval, we can use Proposition A.7 from [4] to conclude that

$$\max_{i \in I} (\Pi_I^{(r)})_{i,i} \leqslant \frac{C(r)}{|I|}.$$

Plugging this into the right-hand side of (5.17), we obtain (5.15).

Using Lemma 5.5 and the ideas in the proof of Lemma 5.4, we derive two bounds bearing on the goodness of approximation of  $\theta_I$  by  $\Pi_I^{(r)}$  which are the subjects of our next two results.

Lemma 5.6. Under the same set-up as in Lemma 5.4, we have

$$\left\| \left( \mathrm{Id} - \Pi_{\llbracket n\mathbf{I} \rrbracket}^{(r)} \right) \theta_{\llbracket n\mathbf{I} \rrbracket}^* \right\|_{\infty} \leqslant C(r) |f|_{\mathbf{I};r_0,\alpha} |\mathbf{I}|^{r_0+\alpha}.$$
(5.18)

*Proof.* Since  $\operatorname{Tayl}_{\llbracket n\mathbf{I} \rrbracket}^{(r_0)}(f) \in S_{\llbracket n\mathbf{I} \rrbracket}^{(r)}(\supset S_{\llbracket n\mathbf{I} \rrbracket}^{(r_0)})$  (see (5.12)) and  $\Pi_{\llbracket n\mathbf{I} \rrbracket}^{(r)}$  is the orthogonal projector onto  $S_{\llbracket n\mathbf{I} \rrbracket}^{(r)}$ , we have

$$\left(\mathrm{Id} - \Pi_{\llbracket n\mathbf{I} \rrbracket}^{(r)}\right)\theta_{\llbracket n\mathbf{I} \rrbracket}^* = \left(\mathrm{Id} - \Pi_{\llbracket n\mathbf{I} \rrbracket}^{(r)}\right)\left(\theta_{\llbracket n\mathbf{I} \rrbracket}^* - \mathrm{Tayl}_{\llbracket n\mathbf{I} \rrbracket}^{(r_0)}(f)\right).$$

Therefore,

$$\begin{aligned} \left\| \left( \mathrm{Id} - \Pi_{\llbracket n\mathbf{I} \rrbracket}^{(r)} \right) \theta_{\llbracket n\mathbf{I} \rrbracket}^{*} \right\|_{\infty} &= \left\| \left( \mathrm{Id} - \Pi_{\llbracket n\mathbf{I} \rrbracket}^{(r)} \right) \left( \theta_{\llbracket n\mathbf{I} \rrbracket}^{*} - \mathrm{Tayl}_{\llbracket n\mathbf{I} \rrbracket}^{(r_{0})}(f) \right) \right\|_{\infty} \\ &\leq \left\| \left( \mathrm{Id} - \Pi_{\llbracket n\mathbf{I} \rrbracket}^{(r)} \right) \right\|_{\infty} \left\| \left( \theta_{\llbracket n\mathbf{I} \rrbracket}^{*} - \mathrm{Tayl}_{\llbracket n\mathbf{I} \rrbracket}^{(r_{0})}(f) \right) \right\|_{\infty} \\ &\stackrel{(5.15)+(5.13)}{\leq} C(r) \left| f \right|_{\mathbf{I};r_{0},\alpha} |\mathbf{I}|^{r_{0}+\alpha}. \end{aligned}$$

**Lemma 5.7.** Let I be a sub-interval of [n] and  $\lambda \ge 0$ . Then for any interval  $I_1 \subset I$  and  $\theta \in \mathbb{R}^n$ , we have

$$\|(\Pi_{I}^{(r)}\theta_{I})_{I_{1}} - \Pi_{I_{1}}^{(r)}\theta_{I_{1}}\|_{\infty} \leq C(r) \frac{T_{\theta}^{(r)}(I)}{\sqrt{|I_{1}|}}.$$
(5.19)

*Proof.* Using the same invariance argument as in the proof of Lemma 5.4, in particular the display (5.8), we can assume without any loss of generality that

$$\Pi_I^{(r)} \theta_I = 0. \tag{5.20}$$

But in that case we can write

$$\|(\Pi_{I}^{(r)}\theta_{I})_{I_{1}} - \Pi_{I_{1}}^{(r)}\theta_{I_{1}}\|_{\infty} = \|\Pi_{I_{1}}^{(r)}\theta_{I_{1}}\|_{\infty}.$$
(5.21)

Also,

$$\|\Pi_{I_1}^{(r)}\theta_{I_1}\|^2 \stackrel{(2.2)+(5.20)}{\leqslant} Q^{(r)}(\theta; I_1, I) \stackrel{(2.3)}{\leqslant} (T_{\theta}^{(r)}(I))^2.$$
(5.22)

imsart-generic ver. 2014/02/20 file: laser\_arxiv\_v1.tex date: December 30, 2024

Since  $\Pi_{I_1}^{(r)} \theta_{I_1} \in S_{I_1}^{(r)}$ , it follows from (5.14) in Lemma 5.5 that

$$\|\Pi_{I_1}^{(r)}\theta_{I_1}\|_{\infty} \leqslant C(r) \frac{\|\Pi_{I_1}^{(r)}\theta_{I_1}\|}{\sqrt{|I_1|}}.$$

Combined with (5.21) and (5.22), this yields (5.19).

We can now finish the

*Proof of Theorem 2.2.* We start with a bias variance type decomposition.

$$\widehat{f}(\frac{i_{0}}{n}) - \theta_{i_{0}}^{*} \stackrel{(2.7)}{=} \left( \Pi_{\llbracket i_{0} \pm \hat{h}_{i_{0}} \rrbracket}^{(r)} y_{\llbracket i_{0} \pm \hat{h}_{i_{0}} \rrbracket} \right)_{i_{0}}^{} - \theta_{i_{0}}^{*} \\
\stackrel{(2.1)}{=} \left( \left( \Pi_{\llbracket i_{0} \pm \hat{h}_{i_{0}} \rrbracket}^{(r)} \theta_{\llbracket i_{0} \pm \hat{h}_{i_{0}} \rrbracket}^{*} \right)_{i_{0}}^{} - \theta_{i_{0}}^{*} \right) + \left( \Pi_{\llbracket i_{0} \pm \hat{h}_{i_{0}} \rrbracket}^{(r)} \epsilon_{\llbracket i_{0} \pm \hat{h}_{i_{0}} \rrbracket} \right)_{i_{0}}^{} = B_{i_{0}}^{} + N_{i_{0}}^{}.$$
(5.23)

We start with the second, i.e., the variance/noise term  $N_{i_0}$ . We have the following bound from [4, Proposition 3.4] which is applicable in this case since  $[\![i_0 \pm \hat{h}_{i_0}]\!]$  as an interval.

$$\sup_{i_0} \sqrt{\left| \left[ \begin{bmatrix} i_0 \pm \hat{h}_{i_0} \end{bmatrix} \right| \left| \mathbf{N}_{i_0} \right| \leqslant C(r) \sigma \sqrt{\log n} \quad \text{w.h.p.}$$
(5.24)

If  $\llbracket i_0 \pm \hat{h}_{i_0} \rrbracket = \llbracket n \rrbracket$  or if  $\llbracket i_0 \pm (\hat{h}_{i_0} + 1) \rrbracket \oplus \llbracket n \mathbf{I}_0 \rrbracket$  where  $\mathbf{I}_0 = \llbracket \frac{i_0}{n} \pm s_0 \rrbracket$  (see below (2.10)), then the above implies

$$|\mathcal{N}_{i_0}| \leqslant C(r)\sigma \sqrt{\frac{\log n}{ns_0}}.$$
(5.25)

Otherwise by (5.6) in Lemma 5.2, we have

$$T_{\theta^*}^{(r)}(\llbracket i_0 \pm (\hat{h}_{i_0} + 1) \rrbracket) \ge \lambda - C_3 \sigma \sqrt{\log n}$$

w.h.p. simultaneously for all  $i_0 \in [n]$ . Also since  $\llbracket i_0 \pm (\hat{h}_{i_0} + 1) \rrbracket \subset \llbracket n\mathbf{I}_0 \rrbracket$  in this case, Lemma 5.4 yields us that if  $f \in C^{r_0,\alpha_0}(\mathbf{I}_0)$ , then

$$T_{\theta^*}^{(r)}(\llbracket i_0 \pm (\hat{h}_{i_0} + 1) \rrbracket) \leqslant \frac{|f|_{\mathbf{I}_0; r_0, \alpha_0}}{n^{r_0 + \alpha_0}} \left| \llbracket i_0 \pm (\hat{h}_{i_0} + 1) \rrbracket \right|^{r_0 + \alpha_0 + \frac{1}{2}}.$$

Together the last two displays imply, when

$$\lambda = 2C_3 \sigma \sqrt{\log n},\tag{5.26}$$

that

$$\left| \left[ \left[ i_0 \pm (\hat{h}_{i_0} + 1) \right] \right] \right| \ge c \left( \sigma \sqrt{\log n} \right)^{\frac{1}{r_0 + \alpha_0 + \frac{1}{2}}} |f|_{\mathbf{I}_0; r_0, \alpha_0}^{\frac{1}{r_0 + \alpha_0 + \frac{1}{2}}} n^{\frac{r_0 + \alpha_0}{r_0 + \alpha_0 + \frac{1}{2}}} \text{ w.h.p.}$$
(5.27)

simultaneously for all quadruplets  $(i_0, s_0, r_0, \alpha_0)$  satisfying  $f \in C^{r_0, \alpha_0}(\mathbf{I}_0)$ ,  $\llbracket i_0 \pm (\hat{h}_{i_0} + 1) \rrbracket \subset \llbracket n\mathbf{I}_0 \rrbracket$  and  $\llbracket i_0 \pm \hat{h}_{i_0} \rrbracket \neq [n]$ . Plugging this into (5.24) and combining with (5.25), we obtain

$$N_{i_0} | \leq C(r) \left( \sigma^{\frac{2\alpha}{2\alpha+1}} |f|_{\mathbf{I}_0; r_0, \alpha_0}^{\frac{1}{2\alpha+1}} \left( \log n \right)^{\frac{\alpha}{2\alpha+1}} n^{-\frac{\alpha}{2\alpha+1}} + \sigma \sqrt{\log n} \left( ns_0 \right)^{-\frac{1}{2}} \right)$$
(5.28)

imsart-generic ver. 2014/02/20 file: laser\_arxiv\_v1.tex date: December 30, 2024

w.h.p. simultaneously for all quadruplets  $(i_0, s_0, r_0, \alpha_0)$  satisfying  $f \in C^{r_0, \alpha_0}(\mathbf{I}_0)$  where  $\alpha = \alpha_0 + r_0$ .

As to the bias term  $B_{i_0}$ , we can further decompose it as follows. For any interval  $I_1 \subset [i_0 \pm \hat{h}_{i_0}]$  such that  $i_0 \in I_1$ ,

$$B_{i_{0}} = \left(\Pi_{[[i_{0}\pm\hat{h}_{i_{0}}]]}^{(r)}\theta_{[[i_{0}\pm\hat{h}_{i_{0}}]]}^{*}\right)_{i_{0}} - \theta_{i_{0}}^{*}$$
  
=  $\left(\Pi_{[[i_{0}\pm\hat{h}_{i_{0}}]]}^{(r)}\theta_{[[i_{0}\pm\hat{h}_{i_{0}}]]}^{*}\right)_{i_{0}} - \left(\Pi_{I_{1}}^{(r)}\theta_{I_{1}}^{*}\right)_{i_{0}} + \left(\Pi_{I_{1}}^{(r)}\theta_{I_{1}}^{*}\right)_{i_{0}} - \theta_{i_{0}}^{*}.$ 

Therefore, we obtain

$$\begin{aligned}
\mathbf{B}_{i_{0}} &\| \leq \| \Pi_{[i_{0} \pm \hat{h}_{i_{0}}]}^{(r)} \theta_{[i_{0} \pm \hat{h}_{i_{0}}]}^{*} - \Pi_{I_{1}}^{(r)} \theta_{I_{1}}^{*} \|_{\infty} + \| (\mathrm{Id} - \Pi_{I_{1}}^{(r)}) \theta_{I_{1}}^{*} \|_{\infty} \\
\overset{(5.19)}{\leq} C(r) \frac{T_{\theta^{*}}^{(r)} (\llbracket i_{0} \pm \hat{h}_{i_{0}} \rrbracket)}{\sqrt{|I_{1}|}} + \| (\mathrm{Id} - \Pi_{I_{1}}^{(r)}) \theta_{I_{1}}^{*} \|_{\infty} \\
\overset{(5.5), (5.26)}{\leq} \frac{C(r) \sigma \sqrt{\log n}}{\sqrt{|I_{1}|}} + \| (\mathrm{Id} - \Pi_{I_{1}}^{(r)}) \theta_{I_{1}}^{*} \|_{\infty} \\
\overset{(5.18)}{\leq} \frac{C(r) \sigma \sqrt{\log n}}{\sqrt{|I_{1}|}} + C(r) \| f \|_{\mathbf{I}_{0}; r, \alpha} \left( \frac{|I_{1}| - 1}{n} \right)^{r_{0} + \alpha_{0}},
\end{aligned}$$
(5.29)

where for the final step we also need  $I_1 \subset [nI_0]$ . Now setting  $I_1 = [i_0 \pm \tilde{s}_1]$  where

$$\widetilde{s}_{1} = c(r) \left(\sigma \sqrt{\log n}\right)^{\frac{1}{r_{0} + \alpha_{0} + \frac{1}{2}}} |f|_{\mathbf{I}_{0}; r_{0}, \alpha_{0}}^{-\frac{1}{r_{0} + \alpha_{0} + \frac{1}{2}}} n^{\frac{r_{0} + \alpha_{0}}{r_{0} + \alpha_{0} + \frac{1}{2}}} \wedge ns_{0}$$

we see in view of (5.27) that we can make  $I_1 \subset [\![i_0 \pm \hat{h}_{i_0}]\!] \cap [\![n\mathbf{I}_0]\!]$  by suitably choosing c(r). Therefore, we can plug the value of  $|I_1|$  corresponding to this choice into the last line of (5.29) to obtain, with  $\alpha = \alpha_0 + r_0$ ,

$$|\mathbf{B}_{i_0}| \leq C(r) \left(\sigma^{\frac{2\alpha}{2\alpha+1}} |f|_{\mathbf{I}_0; r_0, \alpha_0}^{\frac{1}{2\alpha+1}} \left(\log n\right)^{\frac{\alpha}{2\alpha+1}} n^{-\frac{\alpha}{2\alpha+1}} + \sigma \sqrt{\log n} \left(ns_0\right)^{-\frac{1}{2}}\right)$$

w.h.p. simultaneously for all triplets  $(i_0, s_0, r_0, \alpha_0)$  satisfying  $f \in C^{r_0,\alpha_0}(\mathbf{I}_0)$ . Adding this bound to the one on  $|\mathcal{N}_{i_0}|$  given by (5.28) and subsequently plugging it to the right-hand side of (5.23), we deduce (2.10).
