## Abstract

This study aims to develop a deep learning model for predicting the binding affinity of ligands targeting the Peroxisome Proliferator-Activated Receptor (PPAR) family, using 2D molecular descriptors. A dataset of 3,764 small molecules with known binding affinities, sourced from the ChEMBL database, was preprocessed by eliminating duplicates and incomplete data. Molecular docking simulations using AutoDock Vina were performed to predict binding affinities for the PPAR receptor family. 2D molecular descriptors were computed from the SMILES notation of each ligand, capturing essential structural and physicochemical features. These descriptors, along with the predicted binding affinities, were used to train a deep learning model to predict binding affinity as a regression task. The model was evaluated using metrics such as Mean Squared Error (MSE), Mean Absolute Error (MAE), and R-squared ( $R^2$ ). Results indicated strong performance with an  $R^2$  value of 0.861 for the training set and 0.655 for the test set, suggesting good model generalization. The model shows promise for predicting ligand-receptor interactions and can be applied in drug discovery efforts targeting PPAR-related diseases.

**Keywords:** PPAR, deep learning, binding affinity, molecular docking, 2D descriptors, AutoDock Vina, machine learning

## Introduction

Diabetes mellitus has emerged as a significant global health concern, with its prevalence escalating alarmingly across both developed and developing nations. The International Diabetes Federation reported that approximately 537 million adults were living with diabetes in 2021, a figure projected to rise substantially in the coming years [1]. This chronic condition is characterized by elevated blood glucose levels due to insulin resistance and inadequate insulin production, leading to severe complications such as cardiovascular diseases, renal failure, and increased mortality rates [2][3]. The economic burden of diabetes is also profound, with healthcare costs associated with the disease reaching an estimated \$245 billion in the United States alone in 2012 [4][5]. The increasing incidence of diabetes necessitates the development of effective antidiabetic therapies to mitigate its health and economic impacts.

Peroxisome proliferator-activated receptors (PPARs) play a crucial role in glucose metabolism and insulin sensitivity, making them a promising target for therapeutic interventions in type 2 diabetes (T2D). PPARs, which include three isoforms—PPAR- $\alpha$ , PPAR- $\beta/\delta$ , and PPAR- $\gamma$ —are nuclear receptors that regulate gene expression involved in lipid and glucose metabolism [6]. Agonists of PPAR- $\gamma$ , such as thiazolidinediones, have been clinically utilized to improve insulin sensitivity and manage hyperglycemia associated with T2D [7]. Additionally, PPAR- $\delta$  has been implicated in enhancing glucose homeostasis through pathways involving adiponectin and sodium-glucose transporters, highlighting the multifaceted roles of PPARs in metabolic regulation [8][9]. The therapeutic potential of PPARs extends beyond glucose metabolism, as they also influence inflammatory processes and energy balance, which are critical in the pathophysiology of diabetes [10][11].

Despite the promising role of PPARs in diabetes management, the drug discovery process for antidiabetic compounds faces significant challenges. The complexity of PPAR-ligand interactions presents a substantial hurdle, as the efficacy of PPAR agonists can be influenced by their selective activation of different receptor isoforms, leading to varied metabolic outcomes [12][6]. Furthermore, the costs associated with experimental methods for drug development are considerable, often limiting the exploration of novel therapeutic agents [4][13]. The intricate nature of diabetes pathophysiology, combined with the economic constraints of drug development, underscores the need for innovative strategies to enhance the discovery and efficacy of antidiabetic therapies.

The integration of artificial intelligence (AI) in predicting binding affinity represents a transformative shift in drug discovery, offering a cost-effective alternative to traditional experimental methods. Traditional approaches to determining binding affinity often involve extensive laboratory work, which can be time-consuming and resource-intensive. In contrast, AI models leverage vast datasets and computational power to predict how well a drug candidate will bind to its target, significantly reducing the time and costs associated with drug development Singh [14][15]. By employing machine learning algorithms, researchers can

analyze complex interactions between proteins and ligands, leading to more efficient identification of promising drug candidates [16][17].

Success stories abound in the application of AI models for molecular docking, dynamics, and quantitative structure-activity relationship (QSAR) analyses. For instance, recent advancements in deep learning have enabled the development of scoring functions that improve the accuracy of binding affinity predictions in protein-ligand interactions [18][19]. These models have demonstrated their potential in various studies, such as the identification of the flavonoid Troxerutin as a candidate TRPV1 antagonist, showcasing the capability of AI to streamline the drug discovery process [20]. Furthermore, AI-driven molecular generation techniques have been employed to create novel compounds with desirable properties, enhancing the efficiency of lead optimization [21][22]. The ability of AI to predict binding affinities accurately has been validated through numerous studies, underscoring its role in optimizing lead compounds and advancing drug discovery efforts [23][24].

Accurate binding affinity prediction is paramount for optimizing lead compounds in drug discovery. The binding affinity of a ligand to its target protein is a critical determinant of its efficacy and safety profile. Models that can reliably predict these affinities enable researchers to prioritize compounds for further development, thus enhancing the likelihood of clinical success [25][26]. Moreover, the ability to predict how modifications to a compound affect its binding affinity allows for iterative design processes that can lead to the identification of more potent and selective drug candidates [27][28]. As AI continues to evolve, its integration into drug discovery processes will likely lead to more rapid advancements in therapeutic development, ultimately improving patient outcomes.

The application of artificial intelligence (AI) in predicting binding affinity for peroxisome proliferator-activated receptors (PPAR)-ligand systems presents several limitations that hinder the effectiveness of current models. One significant challenge is the limited size of datasets available for training these models. The performance of AI algorithms heavily relies on the quantity and quality of data; however, the datasets specific to PPAR-ligand interactions are often small and may not encompass the diversity of chemical structures and biological contexts necessary for robust model training Libouban [29][30]. This scarcity can lead to overfitting, where models perform well on training data but fail to generalize to unseen compounds, thereby limiting their predictive power [31].

Another critical limitation is the feature selection process used in these AI models. Many existing models primarily focus on a narrow range of features, such as molecular descriptors or 3D structural information, which may not capture the complexity of PPAR-ligand interactions adequately [32]. For instance, while some models utilize advanced techniques like deep learning to analyze structural data, they often overlook essential biochemical properties that influence binding affinity, such as solubility, permeability, and metabolic stability [32]. This lack of comprehensive feature representation can result in inaccurate predictions and hinder the optimization of lead compounds targeting PPARs.

Moreover, the generalizability of AI models is a significant concern, particularly for antidiabetic compounds targeting PPARs. Many current models have been developed with a focus on specific protein-ligand pairs or classes of compounds, which may not translate effectively to other PPAR-ligand systems [31]. The absence of comprehensive models specifically designed for antidiabetic compounds targeting PPARs further exacerbates this issue. Most existing methodologies do not account for the unique pharmacological profiles and mechanisms of action associated with PPAR agonists and antagonists, limiting their applicability in drug discovery for diabetes [33]. This gap underscores the need for dedicated AI frameworks that can integrate diverse datasets and accurately model the interactions specific to PPAR-ligand systems.

The primary objective of this research is to develop and validate an AI-based model for accurately predicting the binding affinity of antidiabetic compounds targeting PPARs (Peroxisome Proliferator-Activated Receptors). The model aims to leverage advanced molecular descriptors, cutting-edge machine learning architectures, and robust datasets to improve prediction accuracy and generalizability. By integrating computational chemistry insights with AI techniques, this research seeks to provide a reliable tool for screening and optimizing potential drug candidates.

This research holds significant potential to revolutionize antidiabetic drug discovery by streamlining and enhancing the development process. By providing a robust computational framework, it accelerates the identification of promising lead compounds, thereby reducing the time required to advance potential therapeutics through the early stages of drug development. Moreover, the reliance on *in silico* predictions minimizes the need for costly experimental methods, such as labor-intensive *in vitro* and *in vivo* assays, making the process more economically feasible.

Beyond cost and efficiency, this research also advances the integration of AI technologies into precision medicine, enabling the design of tailored therapeutic approaches. This targeted strategy enhances the management of diabetes, addressing the unique needs of individual patients more effectively. By overcoming the limitations of traditional drug discovery methodologies, this work paves the way for innovative and affordable solutions, aligning with the broader vision of leveraging AI to transform healthcare and improve treatment outcomes for diabetes patients.

## **Methods**

### **Computational Infrastructure**

To ensure efficient and accurate execution of this study, a combination of high-performance hardware and state-of-the-art software tools was utilized for data preparation, molecular docking simulations, and deep learning model development.

### **Hardware Configuration**

The majority of computational tasks, excluding molecular docking simulations, were executed on a Hewlett-Packard HP Z840 workstation. This system, equipped with a 40-core Intel® Xeon® E5-2650 v3 processor, 32.0 GiB of RAM, and an NVIDIA GeForce RTX™ 3070 GPU, provided the processing power required for demanding tasks such as descriptor generation and neural network training. Its 3.0 TB storage capacity ensured efficient data handling and storage throughout the project. These specifications were instrumental in managing large datasets and performing computationally intensive operations.

Molecular docking simulations, which required exceptional computational precision, were conducted on the Fugaku Supercomputer. This cutting-edge facility offered unparalleled performance, ensuring highly accurate ligand-receptor binding affinity calculations and enabling the study to achieve precise docking results.

### *Software Environment*

The computational setup for this study was based on the Ubuntu 24.10 (64-bit) operating system, supported by the Linux kernel version 6.11.0-9-generic. The GNOME 47 desktop environment with the Wayland windowing system provided a stable and efficient user interface. This configuration was chosen to ensure compatibility and optimal performance with the required scientific software tools.

### *Key Computational Tools*

Python 3.11 served as the central programming platform, supplemented by specialized libraries to streamline specific tasks. RDKit (Version 2024.09.1) was used for cheminformatics operations, including molecular fingerprint generation and SMILES processing. Open Babel (Version 3.1.1) facilitated molecular file conversions to ensure interoperability. TensorFlow (Version 2.13) was employed for developing and training deep learning models, while Scikit-learn (Version 1.4.1) supported preprocessing and performance evaluation. Pandas (Version 2.2.0) enabled efficient data manipulation.

Molecular docking simulations were carried out using AutoDock Vina (Version 1.2.5) on the Fugaku Supercomputer, which allowed precise prediction of binding affinities. Data visualization was performed with Matplotlib (Version 3.8.1) and Seaborn (Version 0.13.0), which provided detailed and aesthetically pleasing graphical representations of results.

## **Macromolecule and Inhibitor Identification**

Protein targets were retrieved from the ChEMBL database using the keyword "PPAR," corresponding to the Peroxisome Proliferator-Activated Receptor family. This search identified key isoforms, including PPAR $\alpha$ , PPAR $\gamma$ , and PPAR $\delta$ , which play crucial roles in regulating lipid and glucose metabolism, making them significant targets for antidiabetic therapies.

Small molecule inhibitors were subsequently extracted by filtering for compounds with IC<sub>50</sub> values, ensuring that the dataset included bioactivity data necessary for accurate modeling. Compounds lacking IC<sub>50</sub> data or showing insufficient potency (IC<sub>50</sub> above a defined

threshold) were excluded to focus on the most promising inhibitors. The Python scripts used to perform these queries and extractions are provided in Appendices 1 and 2.

### Data Preparation and Cleaning

A meticulous data-cleaning process was employed to enhance the quality and reliability of the dataset. Duplicate entries, identified by identical molecule\_chembl\_id values, were consolidated by retaining the record with the lowest IC50 value, which indicates higher potency. Rows containing missing or invalid IC50 values, such as NaN or zero, were removed to prevent inaccuracies in downstream analyses. Additionally, columns irrelevant to the computational workflows, such as pref\_name and search\_term, were eliminated to streamline the dataset.

These steps produced a high-quality dataset, optimized for molecular descriptor generation, docking simulations, and machine learning model development. Detailed descriptions of the data-cleaning procedures are included in Appendix 3.

This systematic approach, combining advanced data processing techniques and robust computational tools, ensured the reliability and precision of the study's outcomes.

### Binding Affinity Prediction Using AutoDock Vina

Binding affinities were predicted using AutoDock Vina, a widely adopted molecular docking tool designed to model the interactions between ligands and receptors. This involved careful preparation of both the macromolecule (receptor) and the small molecules (ligands) to ensure accurate and biologically relevant simulations.

#### **Receptor Preparation**

The 3D structure of the PPAR $\gamma$  protein (PDB ID: 7VWG) was used as the receptor in this study. Prior to docking, the protein structure was refined to ensure its stability and functional integrity. Water molecules, ions, and other non-essential elements were removed to prevent interference with ligand binding. The binding site was identified and defined using a grid box centered at coordinates X = -23.234, Y = -18.882, Z = 9.755, with dimensions X = 20, Y = 20, and Z = 20. This configuration ensured that the docking simulations were focused on the receptor's active site, capturing biologically meaningful interactions.

To validate the binding site, a re-docking procedure was conducted with the co-crystallized ligand from PDB ID 7VWG. This step verified the accuracy of the docking protocol, ensuring reliable predictions for subsequent simulations.

#### **Docking Simulation Setup**

AutoDock Vina was configured to achieve high accuracy in predicting ligand-receptor interactions. The grid spacing was set to 0.375 to provide a fine resolution for the search space. The exhaustiveness parameter was adjusted to 32 to thoroughly explore potential binding

conformations, balancing precision and computational efficiency. To optimize performance, the simulations were executed using 32 CPU threads.

The Vina scoring function was employed to estimate binding affinities, ranking ligands based on their predicted interaction strength with the PPAR $\gamma$  receptor. This systematic approach ensured reliable predictions, forming the basis for evaluating the potential of candidate antidiabetic compounds.

This comprehensive docking procedure, combining precise receptor preparation, grid definition, and advanced computational settings, provided a robust framework for estimating ligand binding affinities in the study.

### **Docking Results and Pose Validation**

The most favorable docking pose targeting the PPAR receptor yielded a binding affinity of -10.09 kcal/mol. The results demonstrated a high level of agreement between the docked ligand pose and the native conformation, affirming the reliability of the docking procedure. Figure 1 illustrates the superimposition of the docked ligand (orange carbon) and its native conformation (blue carbon) within the PPAR binding site, highlighting their overlap and alignment.

*Figure 1. Superimposition of the docked native ligand (orange carbon) and its original conformation (blue carbon) within the PPAR receptor's active site.*

### **Molecular Descriptor Calculation**

To numerically represent the chemical and structural features of the ligands, 2D molecular descriptors were calculated using the RDKit library. These descriptors encompassed topological, geometric, and electronic properties, enabling comprehensive molecular characterization.

Selected descriptors were tailored to capture the relevant molecular attributes associated with ligand-receptor interactions. Each molecule's descriptor values were formatted as feature vectors, forming the input dataset for subsequent model training. Details of descriptor generation and the corresponding Python code are outlined in Appendix 5.

### **Deep Learning Model Construction for PPAR Binding Affinity Prediction**

A deep learning model was developed to predict the binding affinities of small molecules targeting PPAR. Using 2D molecular descriptors as input features, the model provided a robust framework for capturing the complex relationships between molecular properties and binding strength.

#### **Data Preparation**

The descriptors served as input features (X), while binding affinities (y) were used as the target variable. For training and validation, the dataset was split into 80% for training and 20% for testing. Binding affinity values were scaled to enhance numerical stability during training.

## Model Architecture

The predictive model was developed as a feedforward neural network designed to accommodate the descriptor feature vectors as input. The network architecture consisted of three hidden layers, each responsible for capturing the complex, non-linear interactions between the molecular descriptors. The first hidden layer contained 128 neurons, followed by a second and third hidden layer with 64 neurons each. To introduce non-linearity and enhance the model's ability to learn intricate patterns, the ReLU activation function was applied to all hidden layers. The network's output layer consisted of a single neuron, which provided the predicted binding affinity values, making the model suitable for regression tasks. This architecture was carefully chosen to ensure that the model could effectively predict the binding affinities of the ligands targeting the Peroxisome Proliferator-Activated Receptor (PPAR) family based on their molecular descriptors.

## Training and Evaluation

The model was trained using the Adam optimizer with the mean squared error (MSE) loss function over five epochs and a batch size of 32. Validation data comprising 20% of the training set was used to monitor performance during training.

Model evaluation involved calculating metrics such as Mean Squared Error (MSE), Mean Absolute Error (MAE), and R-squared ( $R^2$ ) values. These metrics quantified prediction accuracy, error magnitude, and variance explained by the model for both training and testing subsets. A complete implementation of the workflow, including Python scripts, is provided in Appendix 6.

## Results

The search for macromolecular targets using the term "PPAR" identified proteins associated with the Peroxisome Proliferator-Activated Receptor (PPAR) family. Each target was categorized by its respective ChEMBL ID (target\_chembl\_id) and the associated preferred name (pref\_name), representing individual receptors within the PPAR family.

**Table 1.** Macromolecular targets associated with the PPAR family identified through the "PPAR" keyword search.

target_chembl_id	pref_name
CHEMBL3559683	Peroxisome proliferator-activated receptor

CHEMBL239	Peroxisome proliferator-activated receptor alpha
CHEMBL3979	Peroxisome proliferator-activated receptor delta

CHEMBL20969 76	Peroxisome proliferator-activated receptor gamma/Nuclear receptor corepressor 2

### Identifying Small Molecules as PPAR Modulators

The subsequent phase focused on identifying small molecule modulators targeting the PPAR receptor family. This involved querying the ChEMBL database using the target\_chembl\_id identifiers retrieved from the macromolecule search. The dataset was curated to include only compounds with available IC<sub>50</sub> values, ensuring the inclusion of bioactivity data relevant for evaluating modulator potency.

A total of 15,161 small molecules were identified as potential modulators of the PPAR receptor family. The IC<sub>50</sub> values, recorded in the standard\_value column, served as the key metric for determining compound efficacy, with lower IC<sub>50</sub> values signifying stronger modulatory activity. These values are expressed in nanomolar (nM) units.

A representative subset of the dataset is provided in **Table 2**, showcasing select modulators along with their IC50 values and supplementary details. The `pref_name` column highlights the specific PPAR receptor targeted by each compound, with a particular focus on Peroxisome Proliferator-Activated Receptor Gamma (PPAR- $\gamma$ ). Additionally, the `canonical_smiles` column contains the SMILES notation of each compound's molecular structure, enabling further computational analyses such as molecular docking and the extraction of features for machine learning-based predictions.

**Table 2.** A sample of small molecule modulators targeting the PPAR receptor family, including IC50 values and SMILES representations.

------------------	---	-----	--

The dataset, comprising 3,764 small molecules with associated IC50 values, was prepared for subsequent steps, including data preprocessing, molecular docking simulations, and the construction of machine learning models for binding affinity prediction. Detailed Python implementation for this process is provided in Appendix 2.

### Data Preprocessing

The dataset from Step 2, initially containing 3,764 small molecules, underwent a comprehensive cleaning process to ensure its suitability for further analysis. Duplicate entries with identical molecule\_chembl\_id were identified and removed. From the duplicates, only the entries with the lowest standard\_value, indicating the most potent inhibitors, were retained to preserve the relevance and accuracy of the dataset.

Additionally, entries with missing or invalid values in the standard\_value column, such as NaN or 0, were discarded. These incomplete or erroneous data points could not contribute meaningful insights for binding affinity predictions, and their exclusion improved the overall quality of the dataset.

Columns not required for molecular docking or machine learning tasks, such as pref\_name and search\_term, were also removed to streamline the dataset for the computational workflows.

After these cleaning steps, the dataset was refined to 2,191 unique small molecules, formatted and prepared for molecular docking and the creation of predictive deep learning models. The Python code used for this data cleaning process is provided in Appendix 3.

### Binding Affinity Prediction Using AutoDock Vina

The binding affinities of the 3,764 small molecules, cleaned in Step 3, were predicted using molecular docking with AutoDock Vina. The process began with preparing each ligand from the cleaned dataset, using its canonical SMILES string. These SMILES strings were converted into the PDBQT format required for docking simulations in AutoDock Vina. This conversion was performed using RDKit and Open Babel, with the corresponding Python code provided in Appendix 4.

Following ligand preparation, molecular docking simulations were carried out using AutoDock Vina. Each ligand was docked with a receptor protein representing the PPAR target. The output from these simulations provided binding affinity predictions, which were extracted from the "REMARK VINA RESULT" section of the output file, indicating the optimal docking score.

The predicted binding affinities, measured in kcal/mol, reflect the strength of the interaction between each ligand and its respective receptor. These results were compiled into a new dataset and saved in CSV format for subsequent analysis. The dataset includes key columns such as `molecule_chembl_id` (unique identifier for each ligand), `canonical_smiles` (SMILES string for the ligand's structure), `standard_value` (IC50 value in nM), and `binding_affinity` (the predicted binding affinity in kcal/mol from the docking simulations).

An example of the docking results is shown in Table 3, where several small molecules are listed along with their IC50 values and predicted binding affinities. The receptor used in the docking simulations was a PPAR protein model in PDBQT format, and the final docking results were stored in the output file `ppar_docking.csv`.

**Table 3.** Example of docking results, showing small molecules, IC50 values, and predicted binding affinities.

## 2D Descriptor Calculation

In this step, 2D molecular descriptors were calculated for each small molecule in the dataset, including the ligands and their binding affinities obtained from the docking simulations in Step 4. These 2D descriptors offer a numerical representation of the molecular structure, capturing various structural and physicochemical properties, making them ideal for input into machine learning models.

The calculation process began by deriving the 2D descriptors for each ligand. These descriptors were based on the SMILES notation of each molecule, which was processed to obtain values representing various molecular features, such as molecular weight, lipophilicity, and polarity. A variety of 2D descriptors were computed, covering topological, geometric, and physicochemical properties of the molecules.

After computing the 2D descriptors, a new column, titled *2d\_descriptors*, was added to the dataset. This column contained the calculated descriptor values for each ligand. The updated dataset now included molecular identifiers, SMILES strings, IC50 values, docking binding affinities, and the newly computed 2D descriptors, all of which are crucial for subsequent machine learning analyses.

The final dataset, containing the 2D descriptors, was saved in the file *cleaned\_ppar\_docking\_with\_2d\_descriptors.csv*. In this dataset, the *2d\_descriptors* column represents a numerical vector of the calculated descriptors for each ligand, reflecting various molecular properties and structural features.

This dataset is now ready to be used as input for machine learning models, including deep learning and regression models, to predict the binding affinities of the ligands based on their structural and physicochemical characteristics.

## Model Training and Evaluation

In this study, a deep learning model was developed to predict the binding affinity of ligands targeting the PPAR receptor family, based on their 2D descriptors. The model's performance was assessed using several key metrics, including Mean Squared Error (MSE), Mean Absolute Error (MAE), and R-squared ( $R^2$ ) values, for both the training and test datasets.

To focus on potent inhibitors, the dataset was filtered to include only ligands with binding affinity values  $\leq -5$  kcal/mol. The

molecular structures of these ligands were represented by their 2D descriptors, derived from the SMILES notation of each molecule. These descriptors capture important molecular properties and structural features relevant to predicting binding affinity.

Before training, the binding affinity values were normalized using the StandardScaler to improve model convergence. The dataset was then divided into training and test sets, with 80% of the data allocated for training and 20% reserved for testing.

A deep learning model was built using the TensorFlow Keras library, designed to predict the binding affinity values of ligands as a regression task. The model architecture began with an input layer designed to accept 2D descriptor values, representing the ligands' structural features. This was followed by three fully connected hidden layers, containing 128, 64, and 64 neurons, respectively, with the ReLU activation function applied to introduce nonlinearity and enhance the model's learning capacity. The output layer consisted of a single neuron, responsible for predicting the binding affinity value.

The model was compiled using the Adam optimizer and the Mean Squared Error (MSE) loss function, which is suitable for regression tasks. Training was conducted over 50 epochs with a batch size of 32, and 20% of the dataset was reserved for validation to monitor the model's performance and prevent overfitting.

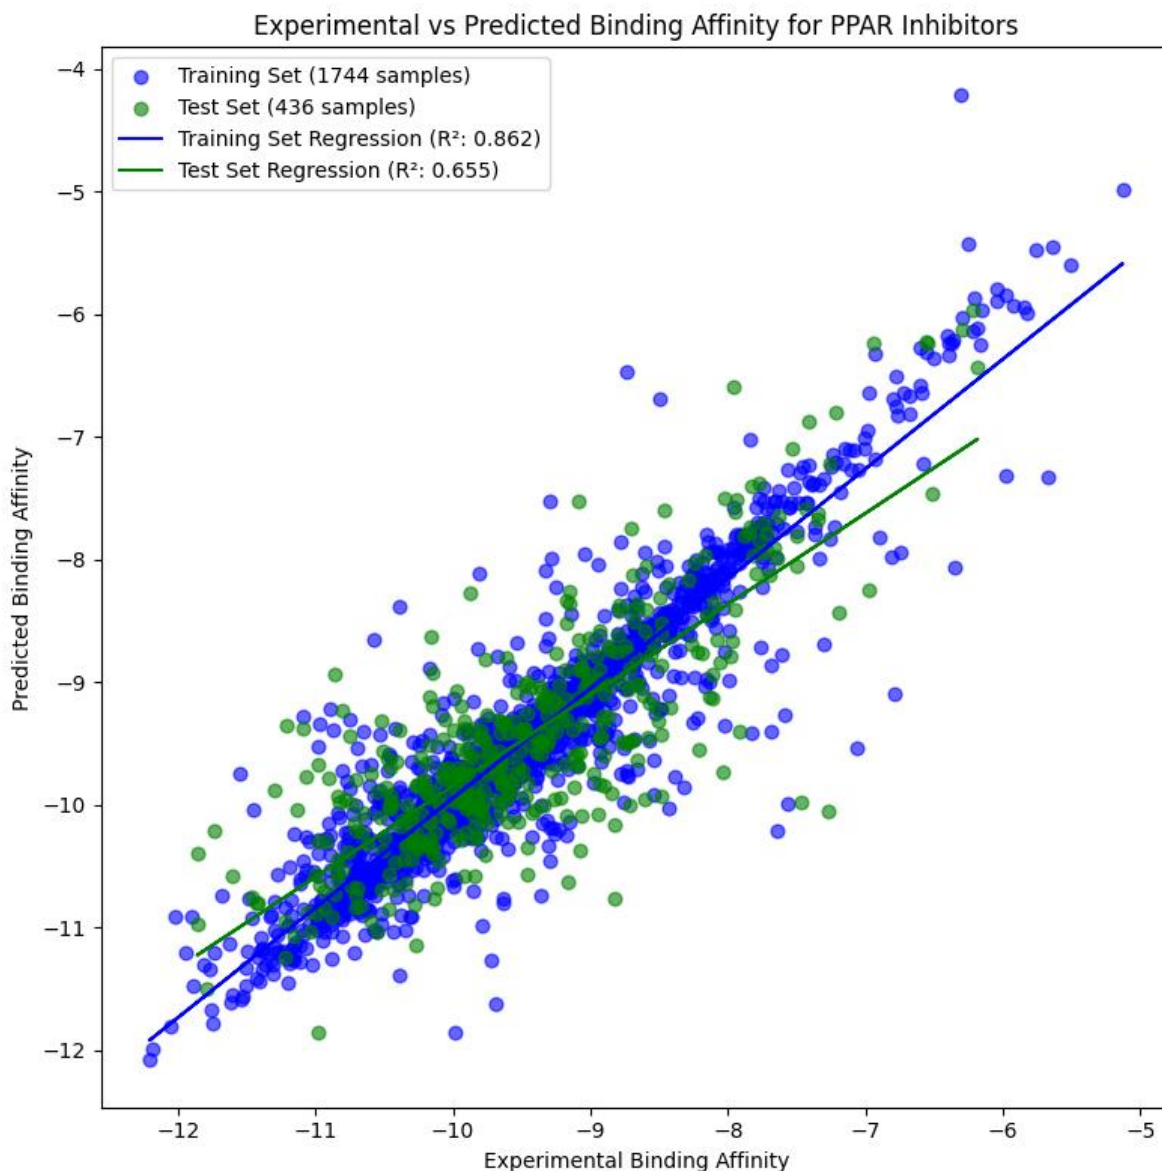

The model's performance evaluation showed its effectiveness in predicting binding affinities. The Mean Squared Error (MSE) was 0.361, while the Mean Absolute Error (MAE) was 0.436. The R-squared value for the training set was 0.862, indicating a strong fit, while the test set showed a value of 0.655, demonstrating good generalization. These results highlight the model's ability to capture the underlying patterns in the data.

For a visual assessment of the model's performance, a scatter plot comparing the true binding affinity values with the predicted binding affinities was generated. The plot included regression lines for both the training and test sets, further illustrating the model's ability to predict binding affinities accurately.

After training, the model was saved in the H5 format (*ppar\_binding\_affinity\_model.h5*) for future use, including potential deployment in further studies or clinical applications.

A comparison plot of experimental binding affinity versus predicted binding affinity for the PPAR inhibitors was also generated and saved as *binding\_affinity\_comparison\_plot.png* (Figure 2). The plot demonstrates a strong correlation between the true and predicted values, especially for the training set, emphasizing the model's effectiveness in predicting ligand binding affinity.

Figure 2. Experimental vs. Predicted Binding Affinity for PPAR Inhibitors.

## Discussion

This study aimed to develop a deep learning model to predict the binding affinity of ligands targeting the PPAR receptor family, based on 2D molecular descriptors derived from SMILES notation. Ligand data were sourced from the ChEMBL database, providing a reliable and comprehensive foundation for the analysis. The dataset included compounds with known binding affinities, ensuring that the study concentrated on experimentally validated inhibitors. This selection allowed for confident downstream analyses, ensuring the data were relevant for predicting ligand-receptor interactions.

## Strengths of the Dataset

The ChEMBL database is a widely trusted resource, known for its comprehensive and high-quality bioactivity data, making it an excellent source for ligand information. The compounds

chosen for this study had strong experimental validation, providing confidence in their interactions with the PPAR receptor. This feature of the dataset enhanced the credibility of our predictions, ensuring that the results were grounded in reliable bioactivity data.

### **Challenges and Data Cleaning**

While the ChEMBL dataset provided a solid foundation, significant preprocessing was required due to missing or invalid data for some ligands, such as missing binding affinities. These discrepancies in the dataset necessitated extensive cleaning. Duplicate entries were removed, and invalid or incomplete data points were excluded. Following this process, the dataset was reduced from 15,161 to 9,947 ligands with valid IC50 values, ensuring that the data maintained its integrity and suitability for model training.

Though this cleaning step reduced the sample size, it was essential to prioritize the inclusion of only high-quality, reliable data to avoid introducing bias or inaccuracies into the model. Despite the reduction, this approach enhanced the quality of the training dataset, ensuring more accurate and trustworthy results.

### **2D Descriptors as Molecular Representations**

In this study, 2D molecular descriptors were employed to represent the ligands' molecular structures. Unlike more complex representations such as 3D molecular structures or fingerprints, 2D descriptors offer a simplified yet effective means to capture key molecular features such as atom types, bond types, and functional groups. These descriptors are widely used in cheminformatics, facilitating molecular similarity searches and feature extraction for machine learning models.

The conversion of SMILES representations into 2D descriptors allowed the generation of a compact and informative set of features for model training. Although 2D descriptors are efficient in capturing structural information, they may not account for all relevant chemical features, particularly those involved in more complex molecular interactions. The choice of descriptor parameters, such as the number and type of descriptors, plays a significant role in the model's ability to predict binding affinities accurately.

### **Molecular Docking to Predict Binding Affinities**

To predict the binding affinities of the ligands for the PPAR receptor, molecular docking simulations using AutoDock Vina were employed. This tool is widely used in computational chemistry for its efficiency and accuracy in predicting ligand-receptor binding interactions. The docking results provided predicted binding affinities, which were integral for training the predictive model.

Although molecular docking is a valuable method for affinity prediction, it is subject to certain limitations. The accuracy of docking results can be influenced by factors such as receptor structure quality, docking parameters, and the precision of the binding site used in the

simulations. While the receptor was adequately prepared for docking in this study, real-world applications may face challenges in maintaining docking accuracy due to these factors.

## **Model Development and Evaluation**

The central task of this study involved developing a deep learning model to predict the binding affinity of PPAR inhibitors. The model was trained using 2D descriptors as input features and normalized binding affinities as output. The deep learning model consisted of three hidden layers, each using the ReLU activation function to capture complex relationships between the molecular features and predicted binding affinity. Model performance was evaluated using key metrics including R-squared ( $R^2$ ), Mean Squared Error (MSE), and Mean Absolute Error (MAE), all of which provide insight into the accuracy and reliability of the model's predictions.

## **Performance Analysis**

The model demonstrated strong performance on the training dataset, with an  $R^2$  value of 0.862, suggesting that it explained most of the variance in the binding affinity data. However, the  $R^2$  value on the test set dropped to 0.655, indicating that the model was able to generalize reasonably well to new, unseen data. The drop in performance from training to test data is common in machine learning models, especially when the model is complex or trained on a limited dataset, and suggests there is potential for improvement, particularly in enhancing generalization.

The Mean Squared Error (MSE) value of 0.361 indicates that the model's predictions were relatively close to the actual binding affinities on average. However, MSE is sensitive to outliers, meaning that a few extreme errors may have contributed to the value. To further improve the model, addressing these outliers or refining the model's handling of complex molecular interactions might be necessary.

The Mean Absolute Error (MAE) value of 0.436 further supports the model's reliability, as it shows that the average prediction error is relatively small. Since MAE is less sensitive to outliers than MSE, it serves as a robust indicator of overall prediction accuracy. Although the MAE suggests that the model is generally reliable, there is room for improvement to reduce prediction errors further.

The high  $R^2$  value for the training set (0.862) indicates that the 2D descriptors used as features were highly informative in learning the relationships between the ligands' molecular structures and their binding affinity. The  $R^2$  value of 0.655 on the test set shows that the model generalizes well to new data, although the drop between the training and test sets suggests that model refinement could improve its ability to predict binding affinity more consistently across diverse datasets.

## **Conclusion**

This study successfully developed a deep learning model to predict the binding affinity of ligands targeting the PPAR receptors, using 2D molecular descriptors derived from SMILES

notation. The model was trained using data from the ChEMBL database, which provides information on ligands with experimentally validated binding affinities. Through rigorous data cleaning, the dataset used for training contained 9,947 ligands with valid IC50 values, ensuring the quality of the data used for model training.

2D molecular descriptors were employed to represent the molecular structure of the ligands, providing an effective representation of their structural and physicochemical features. Molecular docking results using AutoDock Vina provided the binding affinities used to train the predictive model. The developed deep learning model demonstrated good performance in predicting binding affinities, with an  $R^2$  value of 0.862 on the training set and 0.655 on the test set. Although there was a decrease in performance between the training and test sets, the model still showed good generalization capability on previously unseen data.

Evaluation results using MSE and MAE indicate that the model can predict binding affinities with reasonable accuracy, though some predictions exhibited larger errors that need further refinement. Overall, the model shows strong potential in predicting PPAR ligand-receptor interactions and can be applied to further research for more effective ligand-based drug design.

Moving forward, model improvements, including the selection of molecular descriptors and handling of extreme data, can enhance prediction accuracy and expand the model's capabilities for real-world applications, such as drug development for diseases related to PPAR.

## **Acknowledgments**

We would like to express our sincere gratitude to the Fugaku Supercomputer facility for providing the essential computational resources that enabled the molecular docking simulations conducted in this study. The high-performance computing capabilities of Fugaku were crucial in efficiently calculating the binding affinities for ligands targeting the PPAR receptor family. This research would not have been possible without their generous support. We also extend our thanks to the ChEMBL database for supplying the valuable data that formed the cornerstone of this work.

## **Conflicts of Interest Statement**

The authors declare no conflicts of interest.

## **Authors' Contributions**

All authors equally contributed to the conception, design, and execution of this study. All authors have read and approved the final version of the manuscript.
