### ABSTRACT

We analyze the parameter estimation accuracy that can be achieved for the mass and spin of SgrA\*, the SMBH in our Galactic Center, by detecting multiple extremely large mass-ratio inspirals (XMRIs). XMRIs are formed by brown dwarfs (BD) inspiraling into a supermassive black hole (SMBH), thus emitting gravitational waves (GWs) inside the detection band of future space-based detectors such as LISA and TianQin. Theoretical estimates suggest the presence of approximately 10 XMRIs emitting detectable GWs, making them some of the most promising candidates for space-based GW detectors. Our analysis indicates that even if individual sources have low SNRs ( $\approx 10$ ), high-precision parameter estimates can still be achieved by detecting multiple sources. In this case, the accuracy of the parameter estimates increases by approximately one to two orders of magnitude, at least. Moreover, by analyzing a small sample of 400 initial conditions for XMRIs formed in the Galactic Center, we estimate that almost 80% of the detectable XMRIs orbiting SgrA\* will have eccentricities between 0.43 to 0.95 and an  $\text{SNR} \in [10, 100]$ . The remaining  $\sim 20\%$  of the sources have an  $\text{SNR} \in [100, 1000]$  and eccentricities ranging from 0.25 to 0.92. Additionally, some XMRIs with high SNR are far from being circular. These loud sources with  $\text{SNR} \approx 1000$  can have eccentricities as high as  $e \approx 0.7$ ; although their detection chances are low, representing  $\lesssim 2\%$  of the detectable sources, their presence is not ruled out.

### 1. INTRODUCTION

Extremely large mass ratio inspirals (XMRIs) are inspiraling systems with a mass ratio of  $q \sim 10^8$  composed of a brown dwarf (BD) and a supermassive black hole (SMBH) (Amaro-Seoane 2019) that emit gravitational waves (GWs) within the detection band of the space-based GW detectors such as LISA (Amaro-Seoane & et al. 2017; Colpi et al. 2024) or TianQin (Luo et al. 2016; Mei & et al. 2021; Li et al. 2024). Their long merger timescales of about  $10^8$  yr allow these sources to accumulate within their host systems; this distinctive characteristic makes their detection highly promising. Moreover, their formation and evolution models indicate that XMRIs emitting gravitational waves are currently present at the center of our Galaxy (Amaro-Seoane 2019), placing them among the closest sources that the space-based

detectors will detect. In our previous work (Vázquez-Aceves et al. 2023), we derived the number of circular and eccentric XMRIs emitting detectable GWs for different values of the spin of SgrA\* and obtained the accuracy that can be achieved in the measurements of the spin and mass of SgrA\* if a single source with high signal-to-noise ratio (SNR) of about 30 to 2000 is detected.

In this work, we expand our approach to include a more conservative scenario by considering the simultaneous detection of multiple lower-SNR XMRIs ( $\text{SNR} \lesssim 200$ ) to perform the accuracy analysis. We generate a set of 400 orbital parameters for XMRIs and randomly select systems with an SNR within two specified ranges, regardless of the orbital parameters. The first range corresponds to sources with a low SNR of around 20, while the second SNR range represents moderate SNR values,  $\text{SNR} \approx 100$ . We generate the waveforms of the XMRIs using a model developed for high mass ratio sources, including Post Newtonian (PN) corrections up to an or-

der of 2.5 (Barack & Cutler 2004). Furthermore, we perform a Fisher matrix analysis (Coe 2009) assuming five sources are detected simultaneously but with distinguishable signals to estimate the accuracy of measuring the spin and mass of SgrA\*. The Fisher information matrix captures how sensitive the GW signal is to various parameters, quantifying the expected errors in their measurement; it assumes Gaussian noise, making it suitable for a first-order approximation of uncertainties in parameter estimation.

In section 2, we describe the properties of the inspiraling systems we focus on: XMRI formed in the Galactic Center orbiting SgrA\*. In Section 3, we obtain the number of XMRI expected to orbit around SgrA\* with different SNR, showing that almost 80% of the detectable XMRI will have an SNR  $\in [10, 100]$  and about 20%, an SNR  $\in [100, 1000]$ . We give their eccentricity range and show that only about 2% of the detectable sources will have higher SNRs above 1000. In Section 4, we show that by detecting multiple XMRI, the accuracy of parameter estimation can be enhanced. The accuracy for the spin,  $\Delta s$ , and the mass,  $\Delta M$ , increases with N, the number of detected XMRI. We present our results for the Fisher matrix analysis considering up to N=5 simultaneous XMRI and discuss our results to finally give our conclusions in Section 5.

## 2. GALACTIC XMRI

Models of galactic density distributions (Bahcall & Wolf 1977) and two-body relaxation processes suggest that XMRI can form (Sigurdsson & Rees 1997; Hopman & Alexander 2005; Amaro-Seoane et al. 2007; Amaro-Seoane 2019, 2020) in the center of galaxies, and detecting them within our Galaxy provides a unique opportunity to test and refine these models. The results obtained can then be applied to other galaxies with similar characteristics to get a general understanding of their structure and dynamics. However, if it is not via GWs, the direct detection of XMRI might not be achievable in our galactic center and even less in other galaxies. Therefore, these systems are among several difficult-to-observe phenomena we expect to reveal with future space-based gravitational wave detectors. Detecting the GW emission of galactic XMRI will, furthermore, enable us to map the spacetime around SgrA\*, offering unprecedented insight into the properties of the SMBH. In particular, it will help us determine the magnitude of SgrA\*'s spin, a parameter that is difficult to measure using electromagnetic observations.

We focus on XMRI formed via two-body relaxation processes at the center of our galaxy. According to our previous estimates (Vázquez-Aceves et al. 2023) and

those presented by Amaro-Seoane (2019), there is a population of  $N \approx 15$  XMRI around SgrA\* emitting GWs in the band of space-based detectors right now, with eccentric sources being more abundant ( $N \approx 8-15$ ) than circular sources ( $N \approx 1-5$ ). These XMRI have random orbital parameters, yet all have a semimajor axis that is smaller than the critical semimajor axis required to create an inspiraling system (Hopman & Alexander 2005; Amaro-Seoane 2020). For BDs, the average critical semimajor axis is  $a_{\text{crit}} \approx 10^{-3}$  pc. However, the parameters of inspiraling systems are also influenced by the spin magnitude of the SMBH and the orbital inclination of each orbit (Amaro-Seoane et al. 2013).

The semimajor axis  $a$ , and pericenter  $r_p = a(1 - e)$ , of newly formed XMRI must satisfy  $a \lesssim a_{\text{crit}}$  and  $r_p > r_{\text{tidal}}$ , where  $r_{\text{tidal}}$  is the tidal radius; otherwise, the BD will be disrupted by the tidal forces of the SgrA\*. Additionally,  $r_p$  also must lie outside the position of the last stable orbit (LSO),  $r_{\text{LSO}}$ , or the BD will plunge into the SMBH without performing an inspiraling process when reaching the pericenter. This defines a maximum eccentricity  $e \lesssim e_{\text{max}}$  given by

$$e_{\text{max}} = 1 - \frac{R_L}{a}; \quad (1)$$

where  $R_L$  is the maximum value between  $r_{\text{LSO}}$  and  $r_{\text{tidal}}$ . Assuming a BD with mass  $m_{\text{BD}} = 0.05 M_{\odot}$  and radius  $r_{\text{BD}} = 0.083 R_{\odot}$  (Sorahana et al. 2013), we get

$$r_{\text{tidal}} = \left( 2 \frac{(5-n)M_{\text{SgrA}^*}}{3m_{\text{BD}}} \right)^{1/3} r_{\text{BD}} \approx 2.8 R_S, \quad (2)$$

where we used a polytropic index  $n = 1.5$  (Shapiro & Teukolsky 1983).

The position of the LSO depends on the spin magnitude of the SMBH and the orbital inclination,  $\iota$ , of the inspiraling object's orbit with respect to the spin axis. An inspiraling system in a prograde orbit around a highly spinning SMBH can reach smaller pericentre distances and higher eccentricities than one formed around a slowly spinning SMBH. The influence that the spin of the SMBH has on the formation of GW sources as well as on their event rates was studied by Amaro-Seoane et al. (2013). This effect applies to all inspiraling systems, so the spin magnitude also influences the event rates and the initial orbital parameters of an XMRI. We obtain the position of the LSO of a Kerr black hole as  $R_{\text{LSO}} = 4R_S \mathcal{W}(\iota, s)$ , where  $R_S = 2GM/c^2$  is the Schwarzschild radius,  $G$  is the gravitational constant,  $c$  is the speed of light in vacuum, and  $\mathcal{W}(\iota, s)$  is a function, introduced in Amaro-Seoane et al. (2013), that accounts for effect of the spin magnitude and the orbital inclination of the inspiraling object.

We set SgrA\* to be located at 8 kpc, to have a mass of  $4 \times 10^6 M_\odot$  (Ghez et al. 2008; Gillessen et al. 2009), and its spin to be aligned with the line-of-sight following the results of the Event Horizon Telescope (Akiyama & et al. 2022a,b,c,d,e,f). These results seem to indicate that the spin of SgrA\* is pointing at a small angle ( $< \pi/6$  rad) towards Earth and that the spin magnitude is  $s > 0.5$ . However, estimates for the spin magnitude of SgrA\* remain controversial. Based on dark spots identified in Event Horizon Telescope images, Dokuchaev (2023) estimates the spin magnitude to range between 0.65 and 0.9, while Daly et al. (2024) gives an estimate of 0.87 to 0.90 based on X-ray and radio data. These results differ significantly from those of Fragione & Loeb (2020, 2022), who estimate  $s \lesssim 0.1$  based on the spatial distribution of the S-stars. Therefore, our analysis considers spin magnitudes of  $s = 0.1$  and  $s = 0.9$ ; this also gives a lower and upper limit for the accuracy estimates if the spin magnitude takes an intermediate value.

### 3. PHASE SPACE AND SIGNAL-TO-NOISE RATIO

The extremely large mass-ratio of XMRI,  $q \sim 10^8$ , provides a few advantages in comparison with other inspiraling systems: the motion of the BD can be approximated as being nearly geodesic, and the merger timescale is usually long  $T_{\text{GW}} \approx 10^8$  years. This long evolution period implies that the systems (1) can accumulate, giving rise to the estimates for the number of XMRI emitting GWs in our Galactic Center at this moment, and (2) the frequency of the emitted GWs remains nearly constant during the detection period of the space-based detectors. These characteristics allow for a more straightforward computation of the waveforms, which we generate by implementing Post-Newtonian (PN) corrections up to 2.5 order according to Barack & Cutler (2004) and Fang & Huang (2020), and estimate the XMRI SNR as in Barack & Cutler (2004); Finn & Thorne (2000)

$$(\text{SNR})^2 = \int \frac{h_{c,n}^2}{5f^2 S_n(f)} d \ln f \quad (3)$$

where  $h_{c,n}$  is the characteristic strain,  $S_n$  is the noise spectral density, and the factor of 5 comes from sky-averaging.

The initial semimajor axis and eccentricity of an inspiraling system are always assumed to be such that the pericenter lies outside  $R_L = \max(r_{\text{LSO}}, r_{\text{tidal}})$  to ensure that the object will not plunge or be tidally disrupted at the pericenter. For this reason, the typical values for  $a$  and  $e$  are obtained by assuming  $a \approx a_{\text{crit}}$  and  $e \approx e_{\text{max}}$ . However, for each  $a \lesssim a_{\text{crit}}$ , there is a range of eccentricities that an XMRI can take as long as the merger timescale,  $T_{\text{GW}}$ , is shorter than the local

relaxation timescale,  $T_{\text{rlx}}$ , multiplied by a factor that depends on the eccentricity,  $T_{\text{GW}} < T_{\text{rlx}}(1 - e^2)$  (Amaro-Seoane 2018); this ensures that the system can inspiral and merge before two-body relaxation can perturb the pericenter of the orbit. Following the description provided in our previous work Vázquez-Aceves et al. (2023), we sample the phase space and obtain a set of 200 possible orbital parameters for different orbital inclinations,  $\iota = [01, 0.4, 07, 1.0, 1.57]$  rad, per spin magnitude; thus, in total, we obtained a sample of 400 initial orbital parameters which will be used to obtain an average of the number of detectable sources with  $\text{SNR} \approx 10, 100$  and 1000. To do this, we approximate the SNR (Equation 3) as

$$(\text{SNR})^2 \approx \sum_n \frac{h_{c,n}^2 \dot{f}_n}{5f_n^2 S_n(f)} T_{\text{obs}}, \quad (4)$$

where  $T_{\text{obs}}$  is the observation time, and use Equations 5 and 6 (Peters 1964; Barack & Cutler 2004)

$$\frac{de}{dt} = -\frac{e}{15} \frac{m}{M^2} \frac{(2\pi M f_{\text{orb}})^{8/3}}{(1 - e^2)^{5/2}} [304 + 121e^2], \quad (5)$$

with  $m$  the mass of the BD,  $M$  the mass of SgrA\*, and  $f_{\text{orb}}$  the orbital frequency,

$$\frac{df_{\text{orb}}}{dt} = \frac{96}{10\pi} \frac{m}{M} \frac{(2\pi M)^{11/3}}{(1 - e)^{7/2}} \left[ 1 + \frac{73}{24}e^2 + \frac{37}{96}e^4 \right], \quad (6)$$

to evolve the 400 sources up to when Equation 4 gives  $\text{SNR} \approx 10, \text{SNR} \approx 100$  and  $\text{SNR} \approx 1000$  assuming an observation time of 2 years. This estimate is only valid because the frequency of XMRI does not change significantly during  $T_{\text{obs}}$ , and  $\dot{f}_n \approx n \dot{f}_{\text{orb}}$ , so Equation 4 can be written in terms of the orbital frequency  $f_{\text{orb}}$  and for a given value of SNR, together with Equations 5 and 6, we can obtain the corresponding orbital parameters  $(a_{10i}, e_{10i})$ ,  $(a_{100i}, e_{100i})$ , and  $(a_{1000i}, e_{1000i})$ , where the subindex indicates the SNR of the source and  $i \in [1, 400]$ . With these orbital parameters, we apply the description given by Amaro-Seoane (2019) to estimate the number of sources distributed between given values of semimajor axes to obtain an average number of XMRI orbiting SgrA\* for each value of the SNR. The total number of detectable sources that we obtain is not far from previous results; we obtain an average of  $N_{\text{tot}} = 16_{-5}^{+3}$  for a spin magnitude of  $s = 0.9$  and of  $N_{\text{tot}} = 9_{-4}^{+6}$  for  $s = 0.1$ . However, the broad sampling of the phase space shows that sources with  $\text{SNR} \approx 10$ , which represent 76% of the total number of detectable sources, can take eccentricities ranging between  $e \lesssim 0.5$  to  $e \gtrsim 0.98$ , while sources with  $\text{SNR} \approx 100$  that represent 22% of the total number of sources, can have eccentricities between  $e \lesssim 0.2$  and  $e \gtrsim 0.9$ . Finally, loud sources

SNR	s=0.1	s=0.9	$N_{\text{SNR}}/N_{\text{tot}}$
$\gtrsim 10$	$e \in (0.51 - 0.97)$	$e \in (0.43 - 0.98)$	0.76
$\approx 100$	$e \in (0.25 - 0.92)$	$e \in (0.21 - 0.95)$	0.22
$\gtrsim 1000$	$e \in (0.11 - 0.67)$	$e \in (0.09 - 0.73)$	0.02

**Table 1.** Eccentricity range and ratio  $N_{\text{SNR}}/N_{\text{tot}}$  for each spin magnitude, where  $N_{\text{SNR}}$  is the number of sources with an average SNR of  $\gtrsim 10$ ,  $\approx 100$ , and  $\gtrsim 1000$  obtained from the set of 400 initial orbital parameters.

with  $\text{SNR} \approx 1000$  and eccentricity range from  $e \approx 0$  to 0.7 represent just 2% of the total number of detectable sources, reducing detection chances. This is no surprise as the most likely detectable sources are sources with a long merger timescale, and sources with higher SNR are, in this case, closer to the merger. Table 1 summarizes these results and shows that not all the detectable sources are highly eccentric, highlighting the fact that future searches for XMRI GW signals should not focus only on highly eccentric systems.

#### 4. ACCURACY OF MASS AND SPIN ESTIMATES FOR SgrA\* WITH MULTIPLE XMRI

We evaluate the precision with which the spin and mass of SgrA\* can be determined by conducting a Fisher matrix analysis (Coe 2009). This method provides a linearized approximation for the measurement uncertainties and approaches the actual errors in the high-SNR regime. The Fisher matrix for an individual XMRI can be expressed as

$$(\Gamma_N)_{i,j} := \left\langle \frac{\partial h(\boldsymbol{\theta}_N)}{\partial \theta_i}, \frac{\partial h(\boldsymbol{\theta}_N)}{\partial \theta_j} \right\rangle, \quad (7)$$

where  $\boldsymbol{\theta}_N := (\theta_{N,1}, \dots, \theta_{N,n})$  is the vector corresponding to the  $N$ -th XMRI in the  $n$ -dimensional parameter space and  $\langle \cdot, \cdot \rangle$  is the noise-weighted inner product (Finn 1992; Klein et al. 2016). As the harmonics of the different XMRI almost do not evolve during the observation time, we assume their frequencies can be separated clearly during detection. Using this fact together with the linearity of the Fisher matrix, the Fisher matrix of the combined signal takes the form (Isoyama et al. 2018; Torres-Orjuela et al. 2024)

$$\Gamma_{\text{tot}} = \sum_N \Gamma_N. \quad (8)$$

To perform the accuracy analysis, we consider 20 random sources in total, separated into two sets of 10 sources per spin magnitude,  $s = [0.1, 0.9]$ . From the set of 400 sources, we take five sources with  $\text{SNR} \approx 20$ , and five more with  $\text{SNR} \approx 100$ . The lower limit in this range represents sources above the detection thresh-

$s$	$\iota$	$e$	$r_p [r_S]$	$n_h$	SNR
0.1	0.1	0.852888	7.53890	19-118 (100)	29.7

	1.57	0.316318	6.55430	1-15 (15)	70

**Table 2.** XMRI considered for the accuracy analysis: For each system, we show (from left to right) the spin magnitude of SgrA\*  $s$ , the orbital inclination  $\iota$ , the eccentricity  $e$ , the pericenter distance  $r_p$ , the range of harmonics calculated (with the total number of harmonics in the parenthesis), and the SNR obtained from the noise-weighted inner product.

old<sup>1</sup> (Babak et al. 2017), while the upper limit represents a moderate SNR value well above the detection threshold. A deeper study would involve a full posterior sampling considering all the parameters of the source (Li 2013; Ye et al. 2024), but we restrict ourselves to a Fisher matrix analysis because its lower computational costs allow us to explore the combination of multiple sources more easily.

We obtain the waveforms of the sources considering up to 2.5 PN corrections (Barack & Cutler 2004), but to reduce the computational cost of calculating them, we first use Equation 4 to estimate the contribution of each harmonic and select the harmonics that contribute in total to the 90% of the emitted power. The considered harmonics and orbital parameters for each of the 20 selected sources are shown in Table 2; the actual SNR of

<sup>1</sup> We use the detection threshold of extreme mass ratio inspirals here as they are the most similar sources while there is no comparable estimate for XMRI.

**Figure 1.** XMRIs orbital parameters and their approximated SNR. The dot, triangle, and star markers on the main plot show XMRIs evolved from the initial conditions highlighted in orange in the upper right subplot, where we show a set of initial parameters obtained for both spin magnitudes  $s=0.1$  (teal color) and  $s=0.9$  (purple color). We use the systems with  $\text{SNR} \approx 20$  and  $\text{SNR} \approx 100$  for the accuracy analysis.

each source is computed from the waveform using Equation 3 and is shown in the right panel of the same table.

In figure 1, we show the orbital parameters of the sources used for the accuracy analysis. The subplot in the upper right corner shows the set of initial orbital parameters with which the XMRIs are formed considering the two different spin magnitudes where the subset of 20 sources that are evolved up to the predefined SNR values is highlighted in orange. We also plot the loud sources with  $\text{SNR} \approx 1000$  in Figure 1; nevertheless, we exclude these loud sources from the accuracy analysis as detecting even one of these will provide an accurate value when performing a parameter extraction, and it will not significantly benefit from detecting several sources.

Figure 2 shows the detection error for the spin  $\Delta s$  and the mass of SgrA\*  $\Delta M$  as the number of sources increases. As expected, sources with higher SNR provide higher accuracy than sources with lower SNR. We see that the accuracy is enhanced as  $N$  grows in all cases; however, the spin accuracy is the quantity that benefits the most from detecting several sources. For low SNR ( $\approx 20$ ), the accuracy of the spin increases one order of magnitude for  $N=3$ , and there is already an important improvement with just two sources, especially for the highly spinning case. After that, increasing the number

**Figure 2.** Accuracy of measuring the spin  $s$  (upper panel) and the mass  $M$  (lower panel) of SgrA\* as a function of number of detected XMRIs.

of sources does not significantly improve the accuracy; it remains nearly constant and takes roughly the same value,  $\Delta s \approx 10^{-4}$ , independently of the spin magnitude. In the case of sources with  $\text{SNR} \approx 100$ , the highly spinning case,  $s = 0.9$ , benefits the most from detecting several sources; when  $N=5$ , the accuracy  $\Delta s$  increases two orders of magnitude, reaching  $\Delta s \approx 10^{-7}$ . Meanwhile, the accuracy for the slow spinning case,  $s = 0.1$ , gets better by almost an order of magnitude for  $N=5$ .

The increasing number of sources also enhances the detection accuracy for the mass  $\Delta M$ . Systems with  $s = 0.9$  achieve a better mass estimation precision than the slow-spinning case, and for  $N=5$ , the accuracy is improved by roughly one order of magnitude in all cases. To compare the contribution of each XMRI to the total accuracy, we show in Table 3, the ratio between the accuracy obtained with a single XMRI to the total accuracy  $(\Delta s)_{\text{tot}}$  and  $(\Delta M)_{\text{tot}}$  obtained with the set of  $N=5$  XMRIs. The XMRIs that improve the accuracy the most are not always the ones with the highest SNR; although a combination of  $e$  and  $r_p$  is important, the position of the pericenter distance is the parameter that

$s$	$\iota$	SNR	$\Delta s/(\Delta s)_{\text{tot}}$	$\Delta M/(\Delta M)_{\text{tot}}$
0.1	0.1	29.7	13.6	4.00
	0.4	28.0	5.59	4.88
	0.7	25.0	2.54	4.84
	1.0	17.5	45.1	3.51
	1.57	11.0	1.62	4.67
0.9	0.1	30.0	53.7	3.50
	0.4	28.2	4.08	6.22
	0.7	24.3	1.77	3.75
	1.0	17.6	9.87	4.06
	1.57	11.6	2.72	6.50
0.1	0.1	169	6.58	4.39
	0.4	172	4.40	4.00
	0.7	163	2.37	3.06
	1.0	96	1.48	1.79
	1.57	73	3.58	3.34
0.9	0.1	152	41.5	4.61
	0.4	148	17.5	5.01
	0.7	149	1.66	2.98
	1.0	105	4.29	2.98
	1.57	70	1.38	5.05

**Table 3.** Contribution of each source in a system of five sources. The contribution is shown in the last two columns as the ratio of the accuracy of a single XMRI  $\Delta\theta(\theta = s, M)$  to the accuracy of a system of five XMRIs with similar SNRs  $(\Delta\theta)_{\text{tot}}$ .

influences  $\Delta s$  the most. On the other hand, the contribution of a single XMRI to the total accuracy  $(\Delta M)_{\text{tot}}$  does not vary too much from source to source, the ratio  $\Delta M/(\Delta M)_{\text{tot}}$  remains between 1.79 and 6.50, while in the case of the spin, this ratio can reach up to 53.7.

## 5. CONCLUSIONS

Increasing the number of sources consistently improves the precision for both spin and mass estimation, demonstrating the value of multi-source analysis.

By performing a Fisher matrix analysis, we predict the accuracy with which key properties, such as the mass and spin of SgrA\*, can be determined. We have shown that even when the sources' SNR is relatively low ( $\approx 20$ ), the accuracy of the parameters extraction can be significantly enhanced by detecting more than one source. For the slowly spinning case  $s = 0.1$ , we get that the spin accuracy  $\Delta s$  is around one order of magnitude better when using five sources for the analysis, while for the highly spinning case  $s = 0.9$ , the accuracy improves by even two orders of magnitude. The improvement of using multiple sources for the detection accuracy of the mass  $\Delta M$  is around one order of magnitude indepen-

dent of the spin. How much adding one source to the analysis contributes to improving the accuracy depends on the properties of the inspiraling systems. For the spin, the improvement of its accuracy  $\Delta s$  varies from 1.62 to 45.1 when adding one source to the analysis in the case of  $s = 0.1$ , and from 1.77 to up to 53.7 for  $s = 0.9$ . The accuracy of the mass  $\Delta M$  improves, on average, by around 4 regardless of the value of the spin and the orbital parameters of the XMRIs.

We estimate the total number of sources inspiraling towards SgrA\* for two different spin values. For a spin of  $s = 0.9$ , we obtain  $N_{\text{tot}} = 16_{-5}^{+3}$  and for a spin of  $s = 0.1$ , we obtain  $N_{\text{tot}} = 9_{-4}^{+6}$ . From these sources, nearly 80% have an SNR of  $\approx 10$ -100 and around 20% an SNR  $\approx 100$ -1000. These results are not significantly different from previous findings (Amaro-Seoane 2019; Vázquez-Aceves et al. 2023). However, while previous estimates suggest that XMRIs orbiting SgrA\* are highly eccentric, we find that the eccentricity of detectable systems ranges from 0.5 to 0.97 for XMRIs with SNR  $\approx 10 - 100$  and from 0.2 to 0.92 for systems with SNR  $\approx 100$ -1000; indicating that some of the detectable XMRIs that might be orbiting SgrA\* at the moment can have moderate eccentricity values. Additionally, we identify loud sources with SNR  $\gtrsim 1000$  and eccentricities of around  $e \approx 0.7$ . However, the expected number of such sources remains low, representing only  $\lesssim 2\%$  of the total number of detectable sources orbiting SgrA\*. While the characteristics of gravitational wave sources in nature cannot be controlled, having prior knowledge of likely orbital parameters and SNRs helps refine search techniques and develop more accurate waveform models. These models are essential for detecting signals in the data expected from future space-based gravitational wave detectors. Thus, these eccentricity ranges should be considered when searching for XMRIs signals.

## ACKNOWLEDGEMENTS

We thank Pau Amaro-Seoane and Xian Chen for their helpful comments and interesting discussions. VVA acknowledges support from the Boya postdoctoral fellowship program of Peking University. YL is supported by the National Science Foundation of China (Grant No. 11873022) and the National Key Research and Development Program of China (Grant No. 2021YFC2203002). ATO acknowledges support from the Key Laboratory of TianQin Project (Sun Yat-sen University), Ministry of Education (China).
