Abstract

The bulk phase of transition metal nitrides (TMNs) has long been a subject of extensive investigation due to their utility as coating materials, electrocatalysts, and diffusion barriers, attributed to their high conductivity and refractory properties. Downscaling TMNs into two-dimensional (2D) forms would provide valuable members to the existing 2D materials repertoire, with potential enhancements across various applications. Moreover, calculations have anticipated the emergence of uncommon physical phenomena in TMNs at the 2D limit. In this study, we use the atomic substitution approach to synthesize 2D W₅N₆ with tunable thicknesses from tens of nanometers down to 2.9 nm. The obtained flakes exhibit high crystallinity and smooth surfaces. Electrical measurements on 15 samples show an average electrical conductivity of 161.1 S/cm, which persists while thickness decreases from 45.6 nm to 2.9 nm. The observed weak gate tuning effect suggests the semimetallic nature of the synthesized 2D W_5N_6 . Further investigation into the conversion mechanism elucidates the crucial role of chalcogen vacancies in the precursor for initiating the reaction and strain in propagating the conversion. Our work introduces a desired semimetallic crystal to the 2D material library with mechanistic insights for future design of the synthesis.

Non van der Waals 2D materials, 2D electronics, 2D semimetal, atomic substitution, electrical property

Introduction

Transition metal nitrides (TMNs) have been studied for decades owing to their excellent physical and chemical properties such as high electrical and thermal conductivity,^{1,2} high hardness,²⁻⁴ and outstanding refractory nature.⁵ Taking advantage of these excellent properties, TMNs have been used in various applications including electrocatalysts,⁶ energy storage,^{7,8} and diffusion barriers.^{9,10} Despite the demands of these properties in twodimensional (2D) materials family for robust and high performance electronics,^{11,12} downscaling TMNs into 2D form remains a challenging task. Majority of TMNs are non van der Waals (vdW) crystals with strong interaction along all directions across the lattice,^{13,14} imposing technical difficulties in creating 2D layers from a bulk crystal. Conventional bottom-up techniques including chemical vapor deposition (CVD), magnetron sputtering, and molecular beam epitaxy (MBE) have been used to prepare thin films of TMNs,^{1,15} but the synthesis of few-nm thick films has been limited by rough surface due to the island-like growth mechanism.^{16,17} Intriguingly, recent theoretical studies predicted new properties in the 2D form of tungsten nitrides (WN_x, where the subscript x refers to different stoichiometries) compared to their bulk counterparts. For example, Chen et al. and Campi et al. predicted the emergence of nontrivial topological states in 2D WN_x.^{18,19} Namely, 2D W₃N₄ and W₂N₃ are predicted to exhibit topological superconductivity with critical temperature as high as 11 K and 21 K, respectively.^{18,19} Chen et al. also predicted the presence of nodal lines in 2D W₃N₄ that were robust against spin-orbital coupling, which was uncommon in bulk WN_x or any other materials.¹⁸ Chin et al. and Zhao et al. further showed 2D W₅N₆ to be a semimetal, which has low density of states (DOS) around Fermi level (E_F) .^{14,20} This last property is particular interesting for 2D semiconductor contacts and for future interconnects. Indeed, Shen *et al.* recently reported that using semimetallic bismuth as contact electrodes material to 2D semiconductors efficiently reduces metal-induced gap states (MIGS) at the metal-semiconductor interfaces,²¹ and there is mounting evidence that topological semimetals can be useful for enhanced electronic transport at the nanoscale.^{22,23} Therefore, experimentally realizing 2D WN_x will open up tremendous opportunities to explore their exotic quantum properties and applications in electronics.

To this end, a few methods have been reported to obtain 2D WN_x. For instance, WN, W₂N, and W₂N₃ nanosheets have been achieved through a template-assisted ammonization process on various compounds containing tungsten;^{24–26} ultra-thin films of W_5N_6 have been obtained through a vapor-liquid-solid growth process;^{20,27} 2D WN flakes have been synthesized through a salt-assisted CVD approach.²⁸ A few applications including supercapacitors,²⁵ surface-enhanced Raman spectroscopy (SERS),²⁶ and electrochemical catalysis have been demonstrated with excellent performances using the synthesized samples.^{24,29,30} Moreover, Chin et al. reported improved performance of MoS₂ field effect transistors (FETs) with 2D W₅N₆/MoS₂ contact compared to the conventional Au/MoS₂ contact.²⁰ However, the 2D WN_x prepared in these works usually possess a rough and non-uniform surface and small grain sizes. The limited sample lateral sizes ($< 5 \mu m$) foster technical difficulties in device fabrication and hinder the measurements on individual crystalline flakes. The rough surface also prohibits the effective integration between the samples and other 2D materials due to weak adhesion. Furthermore, rough surface causes severe charge scattering especially at the 2D limit and raises the electrical resistivity of the material.³¹ This also restricts the miniaturization of conventional interconnect materials for nanoelectronic applications.³²

Very recently, an atomic substitution approach has been developed to obtain high quality 2D TMNs for the study of nanoelectronics. Cao et al. demonstrated the conversion of 2D MoS₂ into 2D Mo₅N₆, where the 2D nature, high crystallinity, and smooth surface of MoS₂ is preserved in Mo₅N₆.³³ While it is promising to realize other metal nitrides using this approach,^{33–35} the investigation on the atomic substitution of tungsten dichalcogenides for WN_x is very limited. In this work, we investigate the nitrogen substitution of WX_2 (X=S, Se and Te). 2D W_5N_6 with the desired quality for nanoelectronics is obtained using WSe₂ as a precursor in the atomic substitution process. The surfaces of the obtained 2D W_5N_6 are as smooth as that of the WSe₂ precursor, which plays a crucial role in the persistence of its relatively high electrical conductivity down to sample thicknesses of 2.9 nm. A weak gate tuning effect of conductance indicates the semimetallic nature of synthesized 2D W_5N_6 . Moreover, by comparing the results from using different tungsten-based transition metal dichalcogenides (W-TMDs) as precursors, we show a positive correlation between the reaction threshold temperature and the formation energies of chalcogen vacancies. A mechanistic understanding of the conversion process, highlighting the importance of chalcogen vacancies in initiating the process and the strain in driving the reaction, is further proposed.

Results and Discussion

Figure 1a shows side and top views of the crystal structure of WSe₂ precursor and the converted W_5N_6 . Unlike WSe₂, vdW gaps are missing in W_5N_6 , and chemical bonds extend along all three dimensions instead. The W_5N_6 crystal is composed of W atoms in a hexagonal close-packed structure, with N atoms occupying the interstitial sites.¹⁴ If all interstitial sites are occupied by N atoms, the WN phase will form. In the structure of W_5N_6 , a W vacancy appears in one of every six W sites, resulting in W_5N_6 phase with a non-unity

Figure 1 Crystal structure, optical and AFM images, and spectroscopy characterizations of 2D W_5N_6 . (a) Illustration of the conversion from WSe₂ to W_5N_6 through a nitridation reaction. (b, d) Optical images of the WSe₂ and converted flake. (c, e) AFM image of the area labeled by red squares in (b) and (d). (f) Raman spectra of WSe₂ precursor and the converted flake. (g, h) W and N orbital of XPS spectrum measured on converted flakes.

stoichiometry of W and N. Owing to the elimination of vdW gaps, the distance between two adjacent W layers (along the c-axis) decreased from 7.53 Å to 2.82 Å. Thus, the thickness of the flake is expected to decrease to 37.5% of its original value after the conversion process.

As shown in Figures 1b and 1d, a substantial change in optical contrast is observed in the flake after the reaction due to the distinct optical properties of the W_5N_6 from WSe_2 , consistent with our previous observation on the MoS_2 -to- MoN_x conversions.^{33,35} Atomic force microscopy (AFM) images of the flakes show a smooth surface inherited from the WSe_2 precursors (Figure 1c and 1e). The arithmetic average roughness (R_a) of W_5N_6 (0.25 nm) is comparable with that of the WSe_2 precursors (0.26 nm). AFM measurements also show that the thickness of the flake decreased from 8.2 nm (WSe_2) to 3.5 nm (W_5N_6), corresponding to the vanishing of vdW gaps between each atomic layer. The experimental thickness decrement of 42.7% also matches well with the theoretical value of 37.5%.

To characterize the composition of the converted flakes, we perform Raman spectroscopy and X-ray photoelectron spectroscopy (XPS) characterizations. Figure 1f shows the typical Raman spectrum of converted flake measured on a 16.1 nm thick sample and the comparison with the Raman spectrum of the WSe₂ precursor. Raman signatures from the SiO₂/Si substrate are labelled with an asterisk. The characteristic peaks of WSe₂ at 248.6 and 255.9 cm⁻¹ vanished after the reaction,³⁶ whereas a new peak centred around 256 cm⁻¹ with weaker intensity arouse after the conversion. Note that a plateau appears on the lower wavenumber side of the emerging Raman peak in the converted samples, which indicates the presence of multiple Raman bands in this range as supported by our phonon dispersion calculation in Figure S1a. Multiple phonon bands between 150 cm⁻¹ and 200

 cm^{-1} are present according to the calculation. The arising Raman peak matches the Raman signature of W_5N_6 reported in other works.^{20,33}

Apart from WSe₂, we also performed the nitridation reaction on WS₂ and WTe₂. To distinguish the conversion on different W-TMDs, we label the converted flakes as WN_x-S, WN_x-Se, and WN_x-Te for WS₂, WSe₂, and WTe₂ precursors, respectively. We observed three characteristic Raman peaks in the converted WN_x flakes, whose intensities vary with the reaction conditions and precursors (Figure S2). Given the rich isomers of WN_x and their close formation energies,^{14,37} we attribute the variable intensities of Raman peaks to the phase transitions between the isomers of WN_x. More details are provided in the supplementary information. We also noticed that the threshold temperature of the reaction varies with precursors. We will discuss this in a later section. The conversion of WSe₂ to W₅N₆ is further confirmed with XPS and transmission electron microscopy (TEM) described below.

An XPS survey of the synthesized flakes confirms the complete substitution reaction as no signals from Se are observed, while signals from N appear (see Figure S3). High-resolution XPS shown in Figures 1g and 1h clearly demonstrates strong signals from W and N orbitals after conversion. The W spectrum can be fitted into three peaks, *i.e.*, W $4f_{7/2}$ (32.2 eV), W $4f_{5/2}$ (34.4 eV), and W $5p_{3/2}$ (37.2 eV). The W $4f_{7/2}$ peak position is slightly lower than the values reported on WS₂ (32.8 eV), WSe₂ (32.6 eV) and WO₂ (33.0 eV), indicating an oxidation state slightly lower than +4 in the synthesized flakes.^{38–40} This matches with the average oxidation state of +3.6 for W in W₅N₆. Note that the N 1s core level signal fits well with two instead of just one peak, with a strong peak centered at 397.7 eV and a secondary peak at 396.7 eV. The strong peak is attributed to W-N bonding,^{20,41}

and the secondary peak at lower binding energy is attributed to nitrogen adsorbates on the surface of the flakes,⁴² which is possibly introduced during the synthesis process.

Figure 2 TEM characterization and structure simulations. (a) SAED of 2D W_5N_6 crystal taken along (001) direction. (b) Simulated SAED pattern of a 28 nm thick W_5N_6 with incident electron beam along [001] crystal direction. Black and grey spots represent predicted diffraction spots with high and low intensity, respectively. (c) Crosssectional HAADF-STEM image. The distance is measured across ten W atomic layers along (001) direction. (d-f) Low magnification HAADF (d), N (e) and W (f) element mapping of W_5N_6 in cross-sectional STEM image. The scale bars are 5 nm. (g) Structure of two phases (*i.e.*, AA and AB) of W_5N_6 with different stacking orders of N atoms. The calculated binding energy of each phase is shown.

To characterize the crystal structure of synthesized flakes, we perform TEM measurements. The low-magnification TEM of a W_5N_6 flake is shown in Figure S4. The selected area electron diffraction (SAED) pattern (Figure 2a) of planar TEM image shows sharp diffraction points with hexagon patterns, suggesting the high crystallinity of

converted flakes. As label in Figure 2a, a sharp set of diffraction patterns from different crystal planes is observed, matching with the simulation results with incident electrons along the [001] crystal orientation of W_5N_6 (Figure 2b). A wavevector value of 4.34 nm⁻¹ is measured from the smallest set of bright diffraction spots (labelled as ($\overline{110}$)), corresponding to the interplanar distance of 2.30 Å. This matches with the interplanar distance between (110) planes (d_{110}) of W_5N_6 (*i.e.*, 2.45 Å).¹⁴ It is worth noting that another set of weak spots are observed with smaller wavevectors, attributed to the {100} planes from simulation results. As W_5N_6 structure can be viewed as the WN structure with periodic W vacancies, we also simulate the SAED pattern for defect-free WN crystals (Figure S5), where the {100} diffraction spots are missing. Hence the emergence of {100} diffraction spots serve as evidence for W vacancies. Secondary diffraction patterns from the {300} group are also observed with lower intensity, matching with the simulation results.

In addition to the planar TEM, we also perform cross-sectional scanning TEM (STEM) characterization on the obtained 2D W_5N_6 flakes. Individual layers of W atoms can be clearly recognized in Figure 2c via high-angle annular dark field (HAADF)-STEM imaging. The average distance between two adjacent W layers along the c-axis is extracted to be 2.84 Å, which is in good agreement with the theoretical value (*i.e.*, 2.82 Å).¹⁴ This value is 42.4% of the corresponding value in WSe₂ (6.7 Å), resulting from elimination of the vdW gap.⁴³ We also show the elemental mapping of W and N in a cross-sectional image (Figure 2d-2f). N and W are uniformly distributed across the atomic layers. The results further confirm the synthesized flakes as W_5N_6 with high crystallinity.

Although STEM images provide clear measurements of the spatial distribution of W atoms, N atoms are not resolved due to the weak signal intensity from their low atomic number. To understand the occupancy of interstitial N atoms, we calculate the binding energies of two different phases of W₅N₆, where they differ from each other in the coordinate environment of the $[WN_6]$ complexes. We label these two phases as AA-W₅N₆ (trigonal prismatic [WN₆] complex) and AB-W₅N₆ (octahedral [WN₆] complex), and show the side views of the calculated structures in Figure 2g. In AA-W₅N₆, the N atoms in the top layer of the unit cell are located right above the N atoms in the bottom layer, while a misalignment of the top and bottom N atomic layers occurs in $AB-W_5N_6$. The red dashed lines in Figure 2g distinguish the AA and AB stacking order. Our phonon dispersion calculations (Figure S1) of AA-W₅N₆ and AB-W₅N₆ show that both are dynamically stable structure, as there are no phonon bands with negative frequency. We further calculate the binding energy (E_b , defined as the energy change during the formation of crystal from individual atoms) of both phases with density functional theory (DFT), where the E_b of AA-W₅N₆ (-8.98 eV/unit cell) is found lower than that of AB-W₅N₆ (-8.11 eV/unit cell). Hence, the AA stacking order of interstitial N atoms is thermodynamically more stable in W5N6.

To investigate the electrical properties of as-synthesized 2D W_5N_6 , we fabricate 5/45 nm Cr/Au electrodes on 15 W_5N_6 flakes with different thicknesses using a cleanroom in a glovebox to minimize contaminants.⁴⁴ As shown in Figure 3a, four-point measurements are performed to eliminate the influence of contact resistances. Figure 3b shows the back-gate measurements configuration. Typical I-V characteristic curves of samples with different thicknesses are presented in Figure 3c, where a linear trend was

observed, indicating the formation of Ohmic contact between W_5N_6 and Cr/Au electrodes.³⁵ We further extract electrical conductivity of each sample after considering the dimension factors (*i.e.*, channel length, width, and height). As shown in the inset of Figure 3c, the electrical conductivity of W_5N_6 is 161.1 ± 42.1 S/cm.

Figure 3 Electrical measurements. (a, b) Optical image (a) and schematic drawing (b) of W_5N_6 with Cr/Au electrodes. (c) I-V characteristic curves of W_5N_6 of various thicknesses with no gate voltages. Inset presents the electrical conductivity extracted from each sample. (d) Transfer curves of W_5N_6 with various thicknesses. $V_{DS} = 0.5$ V. I_{DS} is normalized to the corresponding values with $V_{GS} = 0$ V.

Moreover, we performed transfer characteristics measurements with application of a gate voltage (V_g) to verify the semimetallic properties of synthesized 2D W₅N₆. A weak tuning effect of conductance is observed as shown in Figure 3d. Three typical transfer characteristic curves measured on different thicknesses are presented. Drain-source current (I_{DS}) decreases from 12.08 μ A at V_{GS} = -50 V to 11.88 μ A at V_{GS} = +50 V on a 4.5-nmthick sample, corresponding to the ratios of 1.009 and 0.992 in comparison to I_{DS} at V_{GS} = 0 V. The decrement in current at higher electron doping (*i.e.*, positive V_{GS}) indicates that the charge transport in 2D W₅N₆ is dominated by positive charge carriers (*i.e.*, holes).⁴⁵ The weak gate tunability is attributed to the semimetallic nature (low DOS at E_F) of W₅N₆, which has been predicted and verified in previous reports.^{14,20} We also observe a decreased gate tuning on thicker samples, which is attributed to the screening effect from the bottom layers to top layers of W₅N₆, similar to that reported on graphene and MoS₂.^{46,47} Taking advantage of the semimetallic properties of W₅N₆, we fabricate MoS₂ transistors with W₅N₆ contacts and find a much lower resistance compared to Au contacts (Figure S6)

It is worth noting that the conductivity values of synthesized W_5N_6 samples exhibit small fluctuation during the downscaling of thicknesses from 45.6 nm to 2.9 nm (Figure S7). Such scaling trend is distinct from metal thin films prepared by vacuum deposition. For example, the electrical conductivity of Cu dropped by five orders of magnitude from 1.4×10^5 S/cm to 0.84 S/cm when thickness decreased from 12.3 nm to 4.2 nm (Figure S7).³¹ The degradation of electrical conductivity in metal thin films is usually due to: (1) prominent surface scattering with low film thickness,³² (2) smaller grain size and consequentially more frequent grain boundary scattering at reduced thicknesses,^{32,48} and (3) introduction of voids during deposition, which significantly decreases the scattering time and reduces the mean free path of charge carriers.⁴⁹ Therefore, the electrical resistivity of ultra-thin films with thicknesses lower than the critical thickness (typically below 10 nm) is usually much higher than their bulk values.^{31,49} To mitigate the scaling effect on resistivity, one approach is to prepare sample with smooth surface to alleviate the surface scattering.

Figure 4 Surface roughness measurements. (a-c) Large area (10 μ m × 10 μ m) AFM scans of TMDs precursor (a), WN_x-S (b) and WN_x-Se (c). Image in (a-c) share the same scale bar. (d-f) Zoom-in AFM scans (1 μ m × 1 μ m) of the areas in (a-c) labeled by the yellow square. Image in (d-f) share the same scale bar. (g) Summary of roughness of precursors and WN_x.

Hereby, we perform AFM measurements on WN_x of various thicknesses to investigate their surface roughness. We also measured the SiO₂/Si surface as a reference (Figure S). Figure 4a-4c show the AFM images of a large area (*i.e.*, 10 µm × 10 µm), where smooth surfaces are observed on WSe₂ precursor, WN_x-S, and WN_x-Se. Images of small areas (1 µm × 1 µm) are shown in Figure 4d-4f for the roughness measurements. Figure 4g summarizes the R_a value of each sample. It is worth noting that for thin (< 20 nm) WN_x, the surface is smooth ($R_a = 0.39 \pm 0.08$ nm) and comparable to the TMDs precursors ($R_a = 0.34 \pm 0.07$ nm). For WN_x thicker than 20 nm, the surface roughness ($R_a = 0.61 \pm 0.12$ nm) is much higher than thinner flakes. This can be attributed to excessive strain induced by lattice reconstruction during the reaction.⁵⁰ Note that all R_a values are well below that of Cu film deposited at ultra-high vacuum ($R_a = 1.82$ nm at thickness of 60 nm).⁵¹ Cu films usually exhibit island-like growth in the sub-10-nm regime during deposition,¹⁶ which produce rough surface and significant thickness fluctuations that deteriorates their electrical properties. Benefiting from the smooth surface, charge scattering is significantly reduced and the resistivity of the synthesized W₅N₆ flakes does not exhibit drastic increase at the ultra-thin regime (Figure S7). We also measured the roughness of WN_x-Te (Figure S9) and extracted a much higher R_a value (1.54 ± 0.66 nm) than WN_x-S and WN_x-Se. This is probably due to the large lattice mismatch between WTe₂ and WN_x and hence a large distortion during the reaction.⁵²

Atomic substitution has been demonstrated as an effective approach to obtain non vdW 2D crystals, including GaN,³⁴ Mo₅N₆,^{33,35} Mo₂C,⁵³ InF₃,⁵⁴ MoP,⁵⁰ CdS,⁵⁵ and several metal oxides.^{56–58} The method also allows the fabrication of vertical and lateral heterostructures between vdW and non vdW 2D materials with clean interfaces.^{57,59,60} Nevertheless, there is little study focusing on understanding how the substitution works at atomic level. As reported in previous studies, the metal skeleton remains during the substitution reaction, while the chalcogen elements are replaced with other elements (N, C, F, etc.).^{33,50,53,54} Li *et al.* revealed from *in-situ* TEM characterizations that the substitution reaction can initiate at both edge and surface of an MoS₂ flake,⁵⁹ which is attributed to dangling bonds and S vacancies on the surface. Hereby, through the comparison

investigation of the reactivity of various W-TMDs (*i.e.*, WS₂, WSe₂ and WTe₂) in the conversion process, we gain an in-depth understanding on the mechanism of this substitution reaction.

Optical images of precursors and converted flakes are shown in Figure S10. We observe that the threshold temperature to initiate the reaction (T_{th}) decreases from WS₂ (740 °C) to WSe₂ (640 °C) and gets lower with WTe₂ (500 °C). This suggests increasing reactivity with NH₃ while chalcogen element goes downward along the periodic table in W-TMDs. Furthermore, we perform the reaction on all three TMDs at the same temperature (Figure 5a-f). At 700 °C, WTe₂ is fully converted in 30 minutes, while WSe₂ is partially converted, and no signs of conversion are observed for WS₂ within the same time scale as shown in Figure S11. This suggests that the reaction rate increases as chalcogen element goes downward.

To interpret the impact of chalcogen elements on the reactivity, we propose a defect-initiated and strain-driven mechanism in a microscopic picture, as demonstrated in Figure 5a: (i.-ii.) Creation of a chalcogen vacancy (V_x). Chalcogen atom gains excess energy at high temperature to break the W-chalcogen bonds and leave a V_x at its lattice site. (ii.-iii.) Formation of W-N bonds. The V_x serve as an active site for NH₃ to react with the W-TMDs precursors. A nitrogen atom occupies the V_x site and bond with adjacent W atoms to form W-N bonds. In this step, the formation of W-N bonds will introduce tensile strain to adjacent W-chalcogen bonds given the shorter bond length of W-N (2.12 Å) than the replaced W-chalcogen bonds (2.43 Å ~ 2.74 Å).^{14,61} (iii.-iv.) Generation of more V_x at the strained sites, as the tensile strain introduced in step (ii.-iii.) lowers the formation energy of V_x.⁶² (iv.-v.) Nitrogen atoms occupy V_x sites and bond with adjacent W atoms,

consequently introducing more strained sites around the new formed W-N bonds. (v.-vi.) Construction of WN_x crystal through the iteration of step (i.-ii.) to (iv.-v.).

In the proposed reaction procedure, changing the chalcogen elements in W-TMDs precursors has the most prominent impact on step (i.-ii.) since the formation energy of V_x varies significantly with different chalcogen elements.⁶³ We compare the formation energy of V_x (adapted from Komsa *et al.*'s work)⁶³ along with the T_{th} of WS₂, WSe₂ and WTe₂ in Figure 5b. A positive correlation is observed where the T_{th} increases with the formation energy of V_x . The higher formation energy elevates the temperature required for the generation of V_x . Thus, the chalcogen atoms in the TMDs can serve as a useful knob to tune the conversion condition for desired applications.

Apart from theoretical analysis, we also experimentally demonstrate the important role of chalcogen vacancies in initiating the conversion process. We performed conversion on WSe₂ flake at a gentle condition (e.g. 700 °C for 10 minutes each run, and iterate for three times). Optical images of the flake at different stages are presented in Figure 5c-f. As shown in Figure 5d, clear sign of reaction proceeding from edge to middle is observed with minimum reaction in the middle of the flake after 10 minutes of reaction. After 20 minutes of the reaction (Figure 5e), the reaction proceeds progressively from edge to the center compared to 10 minutes result. Additionally, circular spots of the converted areas show up on the surface, far from the edges of the flake. Larger portion of the flake is converted in a similar fashion after 30 minutes of reaction. In pristine WSe₂ flakes, the surface of the flake contains minimal V_{Se} density while the edge of the flake is rich of V_{Se} . Therefore, majority of the conversion happens at the edge of the flake, which is consistent with the proposed defect-initiated process. After 10 minutes of reaction, more V_{Se} are generated on the surface

due to thermal activation of Se atoms, creating initiating spots of the reaction on the surface far from the edge of the WSe₂ flake. Hence the conversion is also observed in the middle of the surface.

To support the strain-driven conversion mechanism, we performed TEM characterization on an intermediate state of the conversion. The TEM image in Figure 5g provides detailed view of the WSe₂-W₅N₆ lateral heterostructure with a sharp interface. Inset of Figure 5g shows the optical image of the sample. SAED patterns are obtained at different locations of the sample including the unconverted WSe₂ region (Figure 5h), the WSe₂-W₅N₆ interface (Figure 5i), and the fully converted WSe₂ region (Figure 5j). Moreover, we extracted the interplanar distance between (100) planes (d₁₀₀) of WSe₂ from diffraction spots in Figure 5h and 5i, and show the values in Table S1. A larger d₁₀₀ of WSe₂ is observed at the WSe₂-W₅N₆ interface (*i.e.*, 2.95 Å) compared to the region containing solely unconverted WSe₂ (*i.e.*, 2.93 Å), revealing the WSe₂ lattice expansion at the interface. This is attributed to the tensile strain applied onto WSe₂ lattice by the formation of W-N bonds, as the bond length of W-N (*i.e.*, 2.12 Å) is shorter than that of W-Se (*i.e.*, 2.43 Å ~ 2.74 Å). ^{14,61} This result further supports our strain-driven conversion mechanism.

Figure 5 The role of chalcogen atoms in W-TMDs in the conversion process for WN_x. (a) Schematic illustration of the proposed reaction progress. Top view in the first row and side view in the second row. (i.-ii.) Generation of chalcogen vacancy. (ii.-iii.) Chalcogen vacancy occupied by nitrogen atom and introduce strain to adjacent chalcogen sites. (iii.-iv.) Liberation of strained chalcogen atoms and creating vacancy. (iv.-v.) Chalcogen vacancies occupied by nitrogen atoms resulting in progressive reaction. (v.-vi.) Conversion of entire crystal by iteration of above steps. (b) Correlation between reactivity and the formation energy of chalcogen vacancies in different W-TMDs. y-axis presents the threshold temperature of the nitridation reaction of each W-TMDs. X-axis presents the formation energy of chalcogen vacancies adapted from calculation reported by Komsa et al.63 (c-f) Optical images of WSe₂ at intermediate conversion states. The sample is converted at 700 °C with iteration of 10 minutes: (c) pristine, (d) 10 minutes, (e) 20 minutes, (f) 30 minutes. All images share the same scale bar in (c) (10 μ m). (g) TEM image of the WSe₂-W₅N₆ heterostructure. Inset shows the optical image of the sample on TEM grid. The TEM image is taken in the squared area labeled in the inset. (h-j) SAED patterns taken at different locations: (h) unconverted WSe_2 , (i) WSe_2 - W_5N_6 interface, and (j) converted W_5N_6 . Each location is labeled in (g).

Conclusion

We report the downscaling of non vdW W_5N_6 material with tunable thicknesses in the range from 2.9 nm to 45.6 nm through an atomic substitution reaction from WSe₂ crystals. The obtained ultrathin W_5N_6 flakes exhibit high crystallinity and smooth surfaces, in contrast to the rough surface of the thin films of other non vdW materials such as Cu at similar thicknesses. From electrical measurements, we show that the conductivity of 2D W_5N_6 persists from 45.6 nm to 2.9 nm, in contrast to the significant resistivity scaling of vacuum deposited Cu thin films in a similar thickness region. We also observed a weak gate tunability of the conductivity of 2D W_5N_6 , attributed to the semimetallic band structure of the material. Additionally, we propose a chalcogen vacancy-initiated and strain-driven substitution reaction, highlighting the role of chalcogen anion in controlling the reactivity and the conversion temperature. Thus, various W-TMDs precursors with different chalcogen anion could offer a useful knob to tune the downscaling process, enhancing the potential for materials manufacturing and integration.

Methods

Synthesis of 2D WN_x: WS₂, WS₂, and WTe₂ flakes of various thicknesses were mechanically exfoliated from their bulk crystals using a scotch tape, and then transferred onto a SiO₂/Si substrate with a SiO₂ layer of 300 nm thick. The substrates were cleaned using similar method in our previous work.^{35,64} The conversion is conducted in a quartz tube with Argon (50 sccm) as the carrier gas, heated by a tube furnace. A flask containing ammonium hydroxide aqua solution (30 wt%, Thermo Fisher) is mounted at the upper stream of gas line to generate ammonia gas through evaporation, and the SiO₂/Si chip with W-TMDs flakes on it is placed in the middle of the heating zone. The temperature is set to ramp from room temperature to the target temperature (500 ~ 950 °C) under the rate of 50 °C/min, followed by maintaining at the target temperature for 30 minutes for the conversion. Afterwards, the furnace is cooled to room temperature rapidly by a fan with lid of the furnace opened.

Materials characterizations: As-prepared W_5N_6 were characterized using AFM, Raman spectroscopy, XPS, and high-resolution TEM. The AFM topography was acquired using a Bruker Dimension system. Raman measurements were performed on a Renishaw inVia Raman microscope equipped with a 532 nm laser line. All spectra were taken using the same condition with a laser power of 1.6 mW, beam diameter of 1 μ m, and acquisition time of 60 s. The XPS is carried out on Nexsa G2, from Thermo Fisher Scientific. The spot size of the X-ray that shined on the material surface is 100 μ m in diameter in the measurements. Planar TEM measurements were performed using a FEI Tecnai Osiris transmission electron microscope, operating at a 200-kV accelerating voltage.

For the cross-sectional STEM measurements, the electron beam transparent specimen was prepared using the Thermo Scientific Scios 2 DualBeam focused ion beam scanning electron microscopy, and the images were taken using FEI Titan3 G2 aberration-corrected TEM/STEM, operating at a 300-kV accelerating voltage with a high-angle annular dark-field (HAADF) detector.

Electrode fabrication and electrical measurements: All the electrodes were fabricated inside a cleanroom-in-a-glovebox.⁴⁴ The electrode patterning was done using a bilayer photoresist (LOR1A/S1805) and with a maskless laser lithography system (Heidelberg Instruments). Then the Cr/Au (5 nm/45 nm) were deposited using e-beam evaporation (Angstrom Engineering) followed by lift-off using Remover PG (Kayaku). I-V characteristic curves are measured using a Keithley 2400 source meter under ambient conditions (room temperature in air).

*Fabrication of MoS*₂ *transistors with Au and W*₅*N*₆ *contacts:* MoS₂ with Au contact is fabricated by laser lithography followed by metal deposition, similar to the description in the *Electrode fabrication and electrical measurements* section. MoS₂ with W₅N₆ contacts are fabricated by the following steps, as shown in Figure S12: (1) Etch WSe₂ precursor flakes into stripes with gaps in the middle. (2) Convert etched WSe₂ into W₅N₆. (3) Fabricate Ti/Au electrodes on W₅N₆ by lithography and deposition. (4) Fabricate insulating Al₂O₃ layer on the Au electrode to avoid direct contact between Au and MoS₂. (5) Transfer and stack a monolayer MoS₂ flake onto W₅N₆ to form the W₅N₆-MoS₂ vdW heterostructure. The stacked sample is then annealed in vacuum (30 mTorr, 200 °C, 30 minutes) to improve adhesion of the flake. *Binding energy calculations:* The ground-state total energy of the AA- and AB-W₅N₆ are calculated using the density functional theory with the Quantum ESPRESSO package.⁶⁵ We use a cut-off energy of about 60 Ry for the plane wave and a k-point mesh of $8 \times 8 \times 8$ for Brillouin zone integration. The valence electron-ion core interactions and the exchange-correlation functional are adopted by the projector augmented wave potentials (PAW) and Perdew–Burke–Ernzerhof (PBE) approximation,^{66,67} respectively. The atomic structures are optimized by the Broyden-Fretcher-Goldfarb–Shanno algorithm,⁶⁸ in which convergence criteria are 1×10^{-5} Ry/a.u. for atomic forces and 5×10^{-2} GPa for all stress components. The binding energy is given by $E_b(S) = E_{total}(S) - 5E(W) - 6E(N)$, where $E_{total}(S)$ are calculated ground-state total energies of $S = AA-W_5N_6$ or $AB-W_5N_6$ per unit cell, and E(W) and E(N) are the total energies of a W atom in the body-centered-cubic crystal and a N atom in the N₂ molecule, respectively.

Phonon calculations: The phonon dispersions of AA- and AB-W₅N₆ are calculated using the density-functional perturbation theory (DFPT).⁶⁹ The q-point mesh of $4 \times 4 \times 4$ is selected based on the phonon frequency convergence.

Supporting Information

The Supporting Information is available free of charge online. Supporting information presents supplementary data of W_5N_6 phonon calculations, Raman spectra, XPS survey, TEM images, simulated SAED patterns, W_5N_6/MoS_2 FET measurements, surface roughness measurements, and optical images of conversion of different W-TMDs. A table in supporting information also summarizes the lattice constant of WSe₂ in the unconverted WSe₂ region and at the WSe₂-W₅N₆ interface.

Evolution of WNx Raman spectra

As discussed in the spectroscopy characterization section, we performed the nitridation reaction on WS₂, WSe₂ and WTe₂. To distinguish the conversion on different TMDs, we label the converted flakes as WN_x-S, WN_x-Se, and WN_x-Te for WS₂, WSe₂, and WTe₂ precursors, respectively. The Raman spectra of reaction from different TMDs precursors are shown in Figure S2, and the reaction duration is 30 minutes in each experiment. Three characteristic Raman signals are observed in WN_x converted from different precursors: peaks centred at 198 cm⁻¹ (phase 3), 228 cm⁻¹ (phase 1), and 256 cm⁻¹ (phase 2, *i.e.*, W₅N₆) are observed with variable intensities under different conditions. The phase order is assigned based on the transition temperature. Namely, phase 1 emerges at lowest temperature, and transit to phase 2 and 3 at elevated temperatures. Note that in most spectra (except for WNx-Te at 600°C), the Raman signatures of more than one phase of WNx are observed, suggesting the phase transition is not complete.

We will focus on WN_x -Te for the phase transition since it allows the widest conversion temperature range. In WN_x -Te, the 228 cm⁻¹ peak is the only feature observed below 600 °C and labeled as phase 1. As conversion temperature raises to 640 °C, a shoulder emerges around 256 cm⁻¹ and dominates the spectra once temperature exceeds 750 °C. This suggests a phase transition from phase 1 to W_5N_6 . With temperature keeps increasing, the Raman signal associated to phase 3 emerges at around 198 cm⁻¹. For WN_x -Se, the converted flakes started with W_5N_6 dominating the spectra with a shoulder around 230 cm⁻¹ suggesting the coexistence of phase 1 and W_5N_6 at 700 °C. As temperature raises, W_5N_6 becomes the only phase presented (740 and 800 °C) and eventually taken over by phase 3 (900 °C). Coexistence of multiple phases is always observed from Raman. Such phase transition is attributed to the structural change between isomers of WN_x given their close formation energies.^{1,2}

It is worth noting that only W_5N_6 have been successfully synthesized with high phase purity and crystallinity using WSe₂ as precursor. Although phase 1 can be synthesized using WTe₂ precursors with high phase purity, the converted flakes exhibit amorphous crystallinity and hence challenging to identify its crystal structure. As for phase 3, there is always residue from phase 3 and W_5N_6 . It is also challenging to probe phase 3 without interference from other phases. Therefore, we focus on W_5N_6 converted from WSe₂ precursors in this work.

Figure S2 Raman spectra of WN_X -Te, WN_X -Se, and WN_X -S converted at different temperatures for 30 minutes.

XPS characterization of W5N6

High resolution XPS scans of W and N orbitals are presented in the main text. Figure S2 shows an XPS survey of the W_5N_6 samples, where the Si and O signals are attributed to the SiO₂/Si substrate, C signals are attributed to the measurement chamber, and W and N signals are attributed to the converted flakes. Note that we did not observe any signals from Se (indicated by the dotted line), confirming a complete substitution reaction.

Figure S3 XPS survey of W_5N_6 . The binding energy of Se 3d orbital is labeled by a dashed line to show the complete removal of Se in the sample.

Figure S4 Low-magnification TEM image of W_5N_6 . The contrast difference of the image suggests different thickness of the flake, which inherits from the WSe₂ precursor.

Figure S5 Simulated SAED pattern of defect-free WN crystal.

MoS₂ transistors with W₅N₆ and Au contacts

To take advantage of the semimetallic properties of W_5N_6 , we investigate the performance of W_5N_6 as a contact electrode to 2D semiconductors (*i.e.*, MoS₂). We fabricate MoS₂ transistors with W_5N_6 and Au contacts and compare their performance. Details of the fabrication of the heterostructures are presented in the Method section. We present the charge transport characteristics of W_5N_6 -MoS₂ and Au-MoS₂ devices with application of different gate voltage (V_{GS}) in Figure S6. From Figure S6a, asymmetric I-V characteristic curves are observed under different V_{GS}, indicating the presence of Schottky barrier at the W_5N_6 -MoS₂ and Au-MoS₂ interfaces. It is worth noting that with similar device dimensions, W_5N_6 -MoS₂ device exhibit approximately ten times higher current compared to the Au-MoS₂ device. Moreover, n-type semiconductor behavior is observed from the transfer curve (Figure S6b) in both W_5N_6 -MoS₂ and Au-MoS₂ devices. The W_5N_6 -MoS₂ exhibits ~60 folds higher on-current compared to the Au-MoS₂ device. Both charge transport and transfer curve measurements indicate that a much lower contact resistance is present at the W_5N_6 -MoS₂ interface compared to the Au-MoS₂ interface.

Figure S6 Electrical measurements of MoS_2 FET device with W_5N_6 contact and Au contact. (a) Charge transport curves measured at different V_{GS} . The I-V curves are measured at V_{GS} = +20 V, +40 V, +60 V, +80 V, respectively from bottom to top using both W_5N_6 and Au contacts. (b) Transfer characteristic curves of the MoS_2 FET device with W_5N_6 and Au contacts.
