Equilibria in Network Constrained Markets with Market Maker

Giacomo Como, *Member, IEEE,* Fabio Fagnani, Leonardo Massai, and Martina Vanelli *Member, IEEE,*

*Abstract***— We study a networked economic system composed of** n **producers supplying a single homogeneous good to a number of geographically separated markets and of a centralized authority, called the market maker. Producers compete** *à la* **Cournot, by choosing the quantities of good to supply to each market they have access to in order to maximize their profit. Every market is characterized by its inverse demand functions returning the unit price of the considered good as a function of the total available quantity. Markets are interconnected by a dispatch network through which quantities of the considered good can flow within finite capacity constraints. Such flows are determined by the market maker, who aims at maximizing a designated welfare function.**

We model such competition as a strategic game with n+1 **players: the producers and the market game. For this game, we first establish the existence of Nash equilibria under standard concavity assumptions. We then identify sufficient conditions for the game to be potential with an essentially unique Nash equilibrium. Next, we present a general result that connects the optimal action of the market maker with the capacity constraints imposed on the network. For the commonly used Walrasian welfare, our finding proves a connection between capacity bottlenecks in the market network and the emergence of price differences between markets separated by saturated lines. This phenomenon is frequently observed in real-world scenarios, for instance in power networks. Finally, we validate the model with data from the Italian day-ahead electricity market.**

a growing body of literature underscores the limitations of classical competition models, which typically depict multiple producers operating within a single, isolated market. These models often overlook the increasing interconnectedness that characterizes power systems [3], transportation and infrastructure networks, global supply chains and the internet, and they fail to describe emergent features of such networked systems. Consequently, several works in literature are devoted to extend classical oligopoly models [4], such as Bertrand, Cournot and Stackelberg competitions, to include network structures that reflect real-world market interdependencies.

Our paper specifically contributes to the expanding literature on networked Cournot competition. Originally introduced in 1838 [5], the Cournot competition is a fundamental economic model wherein firms compete in a single market by selling a homogeneous good. In this model, each firm sets the amount of production in order to maximize its profit. The effect of networks in Cournot competitions was first studied in [6] and subsequently in [7], [8]. In these works, the classical model of Cournot competition is extended by considering multiple firms operating in different markets: producers and markets are coupled via a bipartite graph, where edges indicate the markets each producer can supply to. Moreover, producer's cost function are assumed to be non-separable with respect to the markets it participates in.

Our work differs from the classical setting and in particular takes a clue from [9], [10], where a networked Cournot competition among multiple producers is studied together with the presence of an additional player called market maker: this is a centralized authority that moves supply between geographically separated markets via the constrained network to achieve a desirable state of the system.

This setting is particularly relevant in energy markets [3] and contrasts with other popular Cournot game schemes where producers decide their production quantities (a vector) over a whole set of markets. In this latter framework, producers take into account both the production and distribution of a specific good in their decision-making process, thereby eliminating the need for a market maker within the game. The aforementioned approach is considered for example in [11]–[14]. However, a competition without intermediaries nor market-to-market energy exchange is not realistic when modeling an energy market. The complexity of energy marketplaces as well their significative impact on a government's overall environmental and economic policy often lead to the emergence of intermediaries. In these markets, a centralized authority typically solves a dispatch problem by leveraging the offers and bids

from generators and retailers, with the objective of maximizing a specific metric of social welfare, under the operational constraints of the grid. This is precisely the model we aim to capture by introducing a market maker that is in charge of matching the demand and supply of goods and of their transportation between different markets. The market maker acts as an independent regulated entity and, through the design of its utility function, it mitigates the potential exercise of market power by producers.

In this paper, we consider a constrained dispatch network modelled by a graph where nodes indicate the markets and links represent the finite-capacity physical lines connecting them. Producers engage in a networked Cournot game within this framework alongside a market maker that can move the good among different markets along the available links, while striving to maximize a specific welfare function. In contrast to [9], in our study firms are allowed to sell in multiple markets and a more general class of price, cost and welfare functions is considered. Additionally, the focus of our analysis is not on the design of the market maker's utility function, but it is rather directed to studying the Nash equilibria of the game, particularly the influence that the network and the capacity constraints have on these equilibria

Our main contributions are the following. We first establish the existence of Nash equilibria under standard concavity hypotheses. In the special case when the market maker's utility function is the Walrasian welfare (see [15] and [9]) and the price functions are affine, we show that the considered game is potential. Moreover, the specific form of the potential guarantees that in this case the Nash equilibrium is essentially unique and can be efficiently computed by solving a concave optimization problem. Second, we characterize the general structure of the optimal flows chosen by the market maker and analyze the restrictions posed on such flows by the capacity constraints within the market network. Notably, these results hold quite in general, when the system is not necessarily in a Nash equilibrium, as they only require the market maker to be selecting an optimal flow. Restricting to the case where the market maker's utility function corresponds to the Walrasian welfare, we establish a key finding for optimal flows: any discrepancy between prices across different markets indicates the presence of critical links in the network that separate these markets, i.e. there exist links connecting markets with differing prices that are either fully utilized or completely empty, with flows consistently moving from lower to higher prices. This result formally connects price discrepancies with capacity constraints—a phenomenon frequently observed in real-world power networks [16], [17]. We further provide a sufficient condition to ensure non-negativity of demand in each market without requiring an explicit constraint to enforce this (and thus avoiding the use of Generalized Nash equilibria). Finally, we validate our model with real data from the Italian day-ahead electricity market.

A. Related work

Following insights from [6], Network Cournot Competitions (NCC) were first introduced in [7], where the authors considered bipartite graph models with firms on one side and markets on the other side, where edges indicate whether a firm has access to a market or not. They prove that the NCC with linear price functions is an ordinal potential game. The potential function is concave provided that the cost functions of the firms are convex. In [8], the NCC is studied in a simpler setting that features linear inverse demands and quadratic production costs. The authors provide an explicit characterization of how equilibrium quantities depend on the competition structure and explore the implications of entry, mergers, or changes in the environment's primitives on welfare.

Models of competitions in networks were also considered for Bertrand models [18], [19] and Supply Function Equilibria [20], [21]. In the two latter papers, in particular, the authors consider a transport-constrained network with local demand shocks where spatially distributed oligopoly producers compete with supply functions, as in wholesale electricity markets.

Our model of network competition is characterized by the presence of a market maker. As previously mentioned, this was done in [10] and [9] for Cournot models and in [22] for the Stackelberg competition. In the first two papers, the authors characterize the equilibrium outcomes, showing that it is significantly influenced by the market maker's objective function. Additionally, they provide sufficient conditions for the game to be a potential game.

The goal of the market maker is to maximize social welfare. Social welfare in competition models has been explored in several works. [15], [23] shed light on the robustness of the pricing mechanism in network resource allocation when users behave selfishly and anticipate the effects of their actions on prices. In [24], the authors delve into the concept of the "price of anarchy" in congestion games, examining how selfish behavior affects system efficiency. [25] examines the classical Cournot oligopoly model and investigates the potential gain in profits if the oligopolists were to collude, or conversely, the reduction in profits due to competition. Finally, [26] studies the impact of coalition formation on the efficiency of Cournot games in the presence of uncertainties.

In other studies where the market maker is not included, the satisfability of physical capacity bounds is guaranteed by introducing explicit constraints in the configuration space, thus leading to Generalized Nash Equilibria (GNE). Due to the presence of the shared constraints, computing a GNE is usually hard and distributed algorithms have been developed to efficiently compute equilibrium solutions [27]–[30]. In particular, in [11], [31], an operator splitting approach is proposed to compute GNE over network systems through a fully-distributed algorithm. In this setting, each player only needs to have local knowledge and share information with its neighbors. However, each player needs to observe the variables of its local objective function to evaluate its local gradient. The partial-information setting has been studied in [12], and several other scenarios have been considered, e.g., time-varying networks [13], [14] and stochastic cost functions [32].

Other works have focused on specific applications, particularly electricity power models where the physical network connecting different markets plays a crucial role [33]. In [34] and [35], the authors analyze a constrained power network that

connects various markets and producers under a Cournot competition framework. The authors develop an iterative algorithm to find the Nash equilibrium, which takes into account how the production at a specific node affects the whole network, consequently explaining the opportunities for the producers to exercise market power. In [3] a numerical analysis is presented regarding the sensitivity of Nash equilibria within a networked Cournot competition in a transmission-constrained electricity market, revealing that Cournot equilibria are indeed highly sensitive to assumptions regarding market design. A twosettlement electricity market incorporating both forward and spot markets is introduced in [36], which accounts for flow congestion, demand uncertainty, system contingencies, and market power. The model assumes linear demand functions, quadratic generation cost functions, and a lossless DC power network.

B. Structure of the paper and notation

The rest of the paper is organized as follows. The remainder of this section is devoted to the introduction of some notational conventions used throughout the paper. In Section [II,](#page-2-0) we present the model of networked Cournot competition with market maker that is the object of our study. In Section [III,](#page-6-0) we prove existence of Nash equilibria under standard concave hypotheses (see Assumption [1\)](#page-6-1). We further prove that the game with affine demand and Walrasian welfare is potential with a unique equilibrium. In Section [IV,](#page-7-0) we establish, under very mild assumptions on the market maker's utility function, a key connection between optimal actions of the market maker and saturated cuts in the distribution network. Moreover, for the Walrasian welfare, we prove that the emergence of price differences is linked with capacity bottlenecks and critical edges in the distribution network. In Section [V,](#page-9-0) we present a case study featuring the Italian day-ahead market. Finally, in Section [VI](#page-12-0) we draw some conclusions and discuss current and future research.

Throughout the paper, we shall denote vectors in lower case, matrices in upper case, and sets with calligraphic letters. We indicate with 1 the all-1 vector and with I the identity matrix, regardless of their dimension. The transpose of a matrix A in $\mathbb{R}^{m \times n}$ is denoted by A' in $\mathbb{R}^{n \times m}$. A subscript associated to vectors, for instance, $v_{\mathcal{U}}$, represents the sub-vector that is the restriction of the vector v in \mathbb{R}^n to the set of indices $\mathcal{U} \subseteq$ $\{1, \ldots, n\}.$

II. MODEL AND PROBLEM STATEMENT

A. Market Network, producers, and market maker

We consider a finite set $\mathcal{N} = \{1, \ldots, n\}$ of competing producers, each one selling some quantity of the same homogeneous good on a nonempty subset of a finite set of markets $\mathcal{M} = \{1, \ldots, m\}$. We assume that the markets are interconnected by a finite set of directed links $\mathcal{L} = \{1, \ldots, l\}.$ Every link k in $\mathcal L$ is to be interpreted as a physical connection that can carry flow of the considered good from its tail node σ_k in M to its head node τ_k in $\mathcal{M} \setminus {\sigma_k}$ up to a limited maximum flow capacity $c_k > 0$. We stack all the link capacity values in a vector c in \mathbb{R}^l_+ .

Fig. 1: The network of Example [1.](#page-2-1) The labels on the links represent their capacities.

The interconnection structure between producers and markets and among the latter is completely described by the producer-market adjacency matrix^{[1](#page-2-2)} A in $\{0,1\}^{n \times m}$, whose entries are defined by

$$
A_{ij} = \begin{cases} 1 & \text{if producer } i \text{ can sell on market } j \\ 0 & \text{if producer } i \text{ cannot sell on market } j \end{cases}
$$
 (1)

and the market-link incidence matrix B in $\{0,\pm 1\}^{m \times l}$, whose entries are defined by

$$
B_{jk} = \begin{cases} 1 & \text{if } \tau_k = j \\ -1 & \text{if } \sigma_k = j \\ 0 & \text{otherwise} \end{cases}
$$
 (2)

respectively. We shall refer to the triple (A, B, c) , with A in $\{0,1\}^{n \times m}$, *B* in $\{0,\pm 1\}^{m \times l}$, and *c* in \mathbb{R}^l_+ , as the *market network*.

Notice that we allow for the possibility of parallel links between markets (i.e., distinct links with both the same tail node and the same head node), but not for self-loops, i.e., links whose tail node coincides with their head node. Also, notice that, while we consider directed links, undirected links can be recovered as special case when, for every link k in \mathcal{L} , there exists a reverse link \overline{k} in $\mathcal L$ with $\sigma_{\overline{k}} = \tau_k$, $\tau_{\overline{k}} = \sigma_k$, and the same capacity $c_{\overline{k}} = c_k$.

Example [1](#page-2-3): The network (A, B, c) displayed in Figure 1 has $n = 3$ producers (represented as square nodes), $m = 4$ markets (represented as circle nodes), $l = 7$ links, producermarket adjacency matrix

$$
A = \left(\begin{array}{cccc} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 \end{array}\right) \,,
$$

market-link incidence matrix

$$
B = \left(\begin{array}{rrrrrrrr} 1 & -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & -1 & -1 & -1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & -1 \\ -1 & 0 & 0 & 0 & 0 & -1 & 1 \end{array} \right) ,
$$

and capacity vector

$$
c = (2, 2, 2, 1, 2, 1, 2).
$$

¹Notice that we allow producers to possibly sell on multiple markets. The setting studied in [9] —where every producer can sell on a single market can be recovered as a special case in our framework, with $\sum_{j \in \mathcal{M}} A_{ij} = 1$ for every i in N .

Notice that link 1 is directed from market 4 to market 1 and has capacity $c_1 = 2$, while links 2 and 3 can jointly be interpreted as an undirected connection between markets 1 and 2 of capacity $c_2 = c_3 = 2$ in both directions. On the other hand, links 4 and 5 are parallel, as they both point from market 2 to market 3, with capacities $c_4 = 1$ and $c_5 = 2$, respectively. Finally links 6 and 7 are one the reverse of the other, but with different capacities: $c_4 = 1$ from market 4 to market 3 and $c_7 = 2$ from market 3 to market 4.

We model producers as strategic competitors who choose the quantities of good to sell on the markets available to them, with the objective of maximizing their profits. Specifically, the quantity of good that a producer i in N sells on a market j in M that it has access to (i.e., such that $A_{ij} = 1$) is denoted by $x_{ij} \geq 0$. For mere notational convenience, we shall also introduce the variable $x_{ij} = 0$ for every producer i in N and market j in M not accessible to i (i.e., such that $A_{ij} = 0$). All these quantities are assembled in a vector $x_i = (x_{ij})_{j \in \mathcal{M}}$ that represents the action of producer i . The action set of producer i , to which all such vectors x_i belong, is defined as

$$
\mathcal{A}_i = \left\{ v \in \mathbb{R}_+^m : A_{ij} = 0 \Rightarrow v_j = 0 \right\} . \tag{3}
$$

Furthermore, we shall denote by $x = (x_{ij})_{i \in \mathcal{N}, j \in \mathcal{M}}$ in

$$
\mathcal{X} = \prod_{i \in \mathcal{N}} \mathcal{A}_i \subseteq \mathbb{R}_+^{n \times m},
$$

the matrix collecting all the quantities sold by the different producers in the different markets. For a producer i in N , we shall also use the notation

$$
x_{-i}=(x_{hj})_{h\in\mathcal{N}\setminus\{i\},j\in\mathcal{M}},
$$

to indicate the matrix in

$$
\mathcal{X}_{-i} = \prod_{i \in \mathcal{N} \setminus \{j\}} \mathcal{A}_i \subseteq \mathbb{R}_+^{(n-1) \times m},
$$

obtained by removing the *i*-th row from x: such matrix x_{-i} collects the actions of all producers but i .

A market maker joins the producers as an additional player choosing, for every link k in L, the flow of good y_k in $[0, c_k]$ that gets moved from the market σ_k corresponding to the tail node of link k to the market τ_k corresponding to the head node of link k . As such, the action of the market maker is a vector y belonging to the set

$$
\mathcal{Y} = \left\{ y \in \mathbb{R}^l : 0 \le y \le c \right\}. \tag{4}
$$

The quantities of good x sold by the producers and the flow y moved by the market maker jointly determine the total net consumption

$$
z_j = \sum_{i \in \mathcal{N}} A_{ij} x_{ij} + \sum_{k \in \mathcal{L}} B_{jk} y_k, \qquad (5)
$$

in every market j in M . Equation [\(5\)](#page-3-0) can be more compactly rewritten as

$$
z = \text{diag}(A'x) + By,\tag{6}
$$

where $z = (z_j)_{j \in \mathcal{M}}$ is the vector of the market's net consumptions.

Remark 1: Notice that, while the first addend in the righthand side of [\(5\)](#page-3-0) is always nonnegative, the second addend may be negative. In fact, we are allowing the quantity z_j defined in [\(5\)](#page-3-0) to possibly take also negative values. When $z_j < 0$, the opposite value $-z_j > 0$ is to be interpreted as a net quantity of good produced in market j , that is to be understood as a market of "prosumers". In Section [IV,](#page-7-0) we shall determine sufficient conditions for z_i to be nonnegative for every market j in M in equilibrium.

We shall assume that every producer i in N incurs in a production cost $\Psi_i(x_i)$ when choosing to sell a vector x_i of quantities in the different markets and that, the unit price for the good sold on a market j in M is a function $\Phi_i(z_i)$ of the total net consumption in such market. The net profit of every producer i in N is then given by the difference between its revenue $\sum_{j \in \mathcal{M}} A_{ij} x_{ij} \Phi_j(z_j)$ and the production cost $\Psi_i(x_i)$ it incurs. On the other hand, the market maker models a system operator aiming at maximizing the total welfare $\omega(z, x)$ that is a function of both the production quantity matrix x and the net consumption vector z. A special case of welfare function that is widely used in this framework (see, e.g., [15, Definition 1], or [9]) is the so-called Walrasian welfare

$$
\omega(x, z) = \sum_{j \in \mathcal{M}} \int_0^{z_j} \Phi_j(s) \, ds - \sum_{i \in \mathcal{N}} \Psi_i(x_i) \;, \qquad (7)
$$

that is the difference between the aggregate consumer surplus and the total production cost.

Example 2: For every producer i in N , consider the quadratic cost function

$$
\Psi_i(x_i) = \sum_{j,k \in \mathcal{M}} x_{ik} \theta_{jk}^{(i)} x_{ij} + \sum_{j \in \mathcal{M}} \gamma_j^{(i)} x_{ij}, \qquad (8)
$$

where $\Theta^{(i)} = (\theta_{jk}^{(i)})$ in $\mathbb{R}^{m \times m}_{+}$ is a symmetric nonnegative semi-definite matrix and $\gamma^{(i)}$ in \mathbb{R}^m_+ is a nonnegative vector. For every market j in M , consider the affine inverse demand function

$$
\Phi_j(z_j) = \alpha_j - \beta_j z_j \,,\tag{9}
$$

where $\alpha_j > 0$ and $\beta_j > 0$ are positive parameters. Then, the Walrasian welfare is given by

$$
w(x,z) = \sum_{j \in \mathcal{M}} \left(\alpha_j z_j - \frac{\beta_j}{2} z_j^2 - \sum_{i \in \mathcal{N}} \left(\gamma_j^{(i)} x_{ij} + \sum_{k \in \mathcal{M}} x_{ik} \theta_{jk}^{(i)} x_{ij} \right) \right).
$$

Remark 2: The general form of the production cost functions $\Psi_i(x_i)$ that we consider encompasses both the following scenarios: one in which producers incur separate costs for the quantities sold in the various markets, and another one in which they incur a single, aggregate cost that only depends on the sum of the quantities sold across the various markets. For instance, in Example [2,](#page-3-1) if $\Theta^{(i)}$ is a nonnegative diagonal matrix, then the cost function of producer i reduces to

$$
\Psi_i(x_i) = \sum_{j \in \mathcal{M}} \left(\theta_{jj}^{(i)} x_{ij}^2 + \gamma_j^{(i)} x_{ij} \right) ,
$$

i.e., the sum of separate quadratic costs of the quantities sold on the different markets. On the other hand, fr a rank-1

symmetric nonnegative matrix $\Theta^{(i)} = \eta \gamma^{(i)} (\gamma^{(i)})'$ for some $\eta > 0$, the cost function of producer *i* reduces to

$$
\Psi_i(x_i) = \eta \Big(\sum_{j \in \mathcal{M}} \gamma_j^{(i)} x_{ij}\Big)^2 + \sum_{j \in \mathcal{M}} \gamma_j^{(i)} x_{ij},
$$

i.e., it is a quadratic function of the weighted sum $\sum_{j \in \mathcal{M}} \gamma_j^{(i)} x_{ij}$ of the quantities sold on the different markets.

B. Network Cournot games with market maker

The competition is modeled as a strategic game with $n + 1$ players (the n producers plus the market maker) where every producer i in N chooses a quantity vector x_i in A_i aiming at maximizing its profit, whereas the market maker chooses a flow vector y in Y aiming at maximizing the total welfare $\omega(z, x)$. Precisely, we have the following definition.

Definition 1: A *network Cournot game with market maker (NCGMM)* on a network (A, B, c) , with production cost functions

$$
\Psi_i: \mathbb{R}_+^m \to \mathbb{R}_+, \qquad i \in \mathcal{N}, \tag{10}
$$

market inverse demand functions

$$
\Phi_j : \mathbb{R} \to \mathbb{R}, \qquad j \in \mathcal{M}, \tag{11}
$$

and welfare function

$$
\omega: \mathbb{R}_+^{n \times m} \times \mathbb{R}^m \to \mathbb{R}, \qquad (12)
$$

is a strategic game with player set $\{0\} \cup \mathcal{N} = \{0, 1, \ldots, n\},\$ where the action space of player 0 (the market maker) is Y as defined in [\(4\)](#page-3-2), the action space of every player i in $\mathcal N$ (the producers) is A_i as defined in [\(3\)](#page-3-3), and the utility functions are, respectively,

$$
u_0(y, x) = \omega(x, \text{diag}(A'x) + By), \qquad (13)
$$

for the market maker, and

$$
u_i(x, y) = u_i(x_i, x_{-i}, y)
$$

=
$$
\sum_{j \in \mathcal{M}} A_{ij} x_{ij} \Phi_j \left(\sum_{h \in \mathcal{N}} A_{hj} x_{hj} + \sum_{k \in \mathcal{L}} B_{jk} y_k \right) - \Psi_i (x_i),
$$

(14)

for every producer i in N .

Definition 2: For a NCGMM on a network (A, B, c) , with production cost functions [\(10\)](#page-4-0), market inverse demand functions [\(11\)](#page-4-1), and welfare function [\(12\)](#page-4-2):

(i) the best response of the market maker to the actions x in X of the producers is

$$
\mathcal{B}_0(x) = \operatorname*{arg\,max}_{y \in \mathcal{Y}} u_0(y, x);
$$

(ii) the best response of a producer i in N to the actions x_{-i} in \mathcal{X}_{-i} of the other producers and the action y in Y of the market maker is

$$
\mathcal{B}_i(x_{-i}, y) = \underset{x_i \in \mathcal{A}_i}{\arg \max} u_i(x_i, x_{-i}, y);
$$

(iii) a configuration (x^*, y^*) in $\mathcal{X} \times \mathcal{Y}$ is a (pure-strategy) Nash equilibrium if

$$
y^* \in \mathcal{B}_0(x^*)\,, \qquad x_i^* \in \mathcal{B}_i(x_{-i}^*,y^*)\,, \quad \forall i \in \mathcal{N}\,.
$$

Fig. 2: On the left: the market network of Example [3.](#page-4-3) On the right: an equivalent network for the special case (b) of Example [3.](#page-4-3)

Remark 3: The utility functions of both the market maker [\(13\)](#page-4-4) and the producers [\(14\)](#page-4-5) depend on the action y of the market maker only through the vector $By²$ $By²$ $By²$. Notice that the market-link incidence matrix typically has $rank(B) < l$, so that there may exist several actions y in Y with the same image By. Clearly, $y \in \mathcal{B}_0(x)$ is a best response of the market maker to some to some action x in $\mathcal X$ of the producers if and only if every \tilde{y} in $\mathcal Y$ such that $B\tilde{y} = By$ is also a best response, i.e., $\tilde{y} \in \mathcal{B}_0(x)$ (see, e.g., Figure [3\)](#page-5-0). Symmetrically, $x_i \in \mathcal{B}_i(x_{-i}, y)$ is a best response of producer i to (x_{-i}, y) if and only if $x_i \in \mathcal{B}_i(x_{-i}, \tilde{y})$ for every \tilde{y} in \mathcal{Y} such that $B\tilde{y} = By$. It follows that (x^*, y^*) is a Nash equilibrium for a NCGMM if and only if (x^*, \tilde{y}^*) is also a Nash equilibrium for every $\tilde{y} \in \mathcal{Y}$ such that $B\tilde{y} = By$.

Example 3: Consider a single producer $\mathcal{N} = \{1\}$ selling on two distinct markets $\mathcal{M} = \{1, 2\}$ that are connected by an undirected link with the same capacity $\chi \geq 0$ in both directions, so that

$$
A = \begin{pmatrix} 1 & 1 \end{pmatrix} \qquad B = \begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix} \qquad c = (\chi, \chi).
$$

The market network is shown on the left of Figure [2.](#page-4-7) Let both inverse demand functions of the two markets be affine:

$$
\Phi_1(z_1) = 1 - z_1, \qquad \Phi_2(z_2) = 2 - 2z_2. \tag{15}
$$

Following [\(6\)](#page-3-4), let

$$
z = diag(A^{T}x) + By = (x_{11} - \Delta, x_{12} + \Delta),
$$

where

$$
\Delta = y_1 - y_2.
$$

The market maker's utility is

$$
u_0(y,x) = \omega(x,z)
$$

= $z_1 + 2z_2 - z_1^2/2 - z_2^2 - \Psi_1(x_{11}, x_{12})$
= $x_{11} + 2x_{12} - \frac{1}{2}x_{11}^2 - x_{12}^2 - \Psi_1(x_{11}, x_{12})$
+ $(1 + x_{11} - 2x_{12})\Delta - \frac{3}{2}\Delta^2$,

and its best response function is

$$
\mathcal{B}_0(x) = \{ y \in [0, \chi]^2 : y_1 - y_2 = \Delta^*(x) \},\qquad(16)
$$

²On the other hand, observe that the capacity constraints affect directly the action y and not simply By , so that one cannot simply rewrite the problem using the variable $r = By$.

Fig. 3: The best response set [\(16\)](#page-4-8) for the market maker in the NCGMM of Example [3](#page-4-3) in four special cases: (i) for x_{11} – $2x_{12}+1 \leq -3\chi$, $\mathcal{B}_0(x)$ is the grey bullet point; (ii) for -3χ $x_{11} - 2x_{12} + 1 \le 0$, $\mathcal{B}_0(x)$ is the grey segment; (iii) for $0 < \chi < x_{11} - 2x_{12} + 1 \leq 3\chi$, $\mathcal{B}_0(x)$ is the black segment; (iv) for $x_{11} - 2x_{12} + 1 \ge 3\chi$, $\mathcal{B}_0(x)$ is the black bullet point.

where (see Figure [3\)](#page-5-0)

$$
\Delta^*(x) = \begin{cases}\n\chi & \text{if } 1 + x_{11} \ge 2x_{12} + 3\chi \\
(1 + x_{11} - 2x_{12})/3 & \text{if } |1 + x_{11} - 2x_{12}| < 3\chi \\
-\chi & \text{if } 1 + x_{11} \le 2x_{12} - 3\chi.\n\end{cases}
$$

We now consider two special cases, differing in the choice of the production costs.

(a) Assume the production cost function to be quadratic as in [\(8\)](#page-3-5) with $\Theta^{(1)} = 11'$ and $\gamma^{(1)} = 0$, so that

$$
\Psi_1(x_{11}, x_{12}) = (x_{11} + x_{12})^2. \tag{17}
$$

The producer's utility is then

$$
u_1(x,y) = x_{11}\Phi_1(z_1) + x_{12}\Phi_2(z_2) - \Psi(x_1)
$$

= $x_{11} - 2x_{11}^2 + 2x_{12} - 3x_{12}^2 - 2x_{11}x_{12}$
+ $(x_{11} - 2x_{12})\Delta$,

and its best response is

$$
\mathcal{B}_1(y) = \begin{cases} \left\{ \left(\frac{1+\Delta}{4}, 0 \right) \right\} & \text{if } \Delta \geq \frac{3}{5} \\ \left\{ \left(\frac{1+5\Delta}{10}, \frac{3-5\Delta}{10} \right) \right\} & \text{if } -\frac{1}{5} < \Delta < \frac{3}{5} \\ \left\{ \left(0, \frac{1-\Delta}{3} \right) \right\} & \text{if } \Delta \leq -\frac{1}{5}. \end{cases}
$$

It follows that, on the one hand, for every $\chi > 1/3$, the set of Nash equilibria is the segment $\{(x^*, y^*)\}$, where

$$
x^* = \left(\frac{4}{15}, \frac{2}{15}\right), \quad y^* \in \left\{y \in [0, \chi]^2 : y_1 - y_2 = \frac{1}{3}\right\},\
$$

on the other hand, for every $0 < \chi \leq 1/3$, there exists a unique Nash equilibrium (x^*, y^*) , where

$$
x^* = \left(\frac{1+5\chi}{10}, \frac{3-5\chi}{10}\right), \qquad y^* = (\chi, 0).
$$

Thus, in every Nash equilibrium there is a positive net flow $\Delta^* = \min\{\chi, 1/3\}$ from market 1 to market 2. Indeed, the demand is higher in market 2 than it is in market 1, hence, when the quantity of good sold on the two markets is the same, the unitary price is higher in market 2 than it is in market 1. The best response of the market maker aims at reducing the gap between these two prices by moving the net quantity Δ^*

from the market with the lowest price to the one with the highest price. When the link capacity $\chi \geq 1/3$ is sufficiently high, the market maker is able to move an optimal quantity $\Delta^* = 1/3$ from market 1 to market 2, in this way succeeding in equating the unit prices

$$
\Phi_1(z_1^*) = \Phi_1\left(\frac{4}{15} - \frac{1}{3}\right) = \frac{16}{15} = \Phi_2\left(\frac{2}{15} + \frac{1}{3}\right) = \Phi_1(z_2^*)\,.
$$

In contrast, when the link capacity χ < 1/3 is not large enough to allow the market maker to move the desired quantity of good, the link from market 1 to market 2 saturates and

$$
\Phi_1(z_1^*) = \Phi_1 \left(\frac{1+5\chi}{10} - \chi \right) = \frac{9}{10} + \frac{\chi}{2},
$$

$$
\Phi_1(z_2^*) = \Phi_2 \left(\frac{3-5\chi}{10} + \chi \right) = \frac{7}{5} - \chi > \Phi_1(z_1^*),
$$

so that a price difference persists between the two markets for every $0 < \chi < 1/3$. Finally, observe that, while

$$
z_2^* = \min\{(3+5\chi)/10, 7/15\} > 0,
$$

for every value of $\chi > 0$, we have that

$$
z_1^* = \max\{(1-5\chi)/10, -1/15\}\,,
$$

that is nonnegative if and only if $\chi \leq 1/5$. Hence, for every $\chi > 1/5$, we have $z_1^* < 0$, i.e., the consumption in market 1 at equilibrium is negative (c.f. Remark [1\)](#page-3-6).

(b) Consider now separable quadratic cost functions as in [\(8\)](#page-3-5) with $\Theta^{(1)} = I$ and $\gamma^{(1)} = 0$, so that

$$
\Psi_1(x_{11}, x_{12}) = x_{11}^2 + x_{12}^2. \tag{18}
$$

In this case, the producer's utility is

$$
u_1(x,y) = x_{11} - 2x_{11}^2 + 2x_{12} - 3x_{12}^2 + (x_{11} - 2x_{12})\Delta,
$$

and its best response is

$$
\mathcal{B}_1(y) = \left\{ \left(\frac{1+\Delta}{4}, \frac{1-\Delta}{3} \right) \right\} .
$$

It follows that, on the one hand, for every $\chi > 7/25$, the set of Nash equilibria is the segment $\{(x^*, y^*)\}$, where

$$
x^* = \left(\frac{8}{25}, \frac{6}{25}\right), \quad y^* \in \left\{y \in [0, \chi]^2 : y_1 - y_2 = \frac{7}{25}\right\},\,
$$

on the other hand, for every $0 < \chi \leq 7/25$, there exists a unique Nash equilibrium (x^*, y^*) , where

$$
x^* = \left(\frac{1+\chi}{4}, \frac{1-\chi}{3}\right), \qquad y^* = (\chi, 0).
$$

Thus, in every Nash equilibrium there is a positive net flow $\Delta^* = \min\{\chi, 7/25\}$ from market 1 to market 2. Observe that, when $\chi \geq 7/25$, we have

$$
\Phi_1(z_1^*) = \Phi_1\left(\frac{8}{25} - \frac{7}{25}\right) = \frac{24}{25} = \Phi_2\left(\frac{6}{25} + \frac{7}{25}\right) = \Phi_1(z_2^*),
$$

i.e., the equilibrium prices are the same in the two markets. In contrast, when χ <7/25, so that link from market 1 to market 2 saturates and

$$
\Phi_1(z_1^*) = \Phi_1\left(\frac{1+\chi}{4} - \chi\right) = \frac{3}{4}(1+\chi),
$$

$$
\Phi_1(z_2^*) = \Phi_2\left(\frac{1-\chi}{3} + \chi\right) = \frac{4}{3}(1-\chi) > \Phi_1(z_1^*),
$$

so that a price difference persists between the two markets for every $0 < \chi < 7/25$. Notice that, in this case, we have that

$$
z_1^* = \max\left\{\frac{1-3\chi}{4}, \frac{1}{25}\right\} > 0, \quad z_2^* = \min\left\{\frac{1+2\chi}{3}, \frac{13}{25}\right\} > 0,
$$

so that, at equilibrium, the consumption in both markets is positive for every value of χ . Finally, observe that, since in this case the cost [\(18\)](#page-5-1) of the producer is a separable function of the quantities sold in the two markets, the Nash equilibria of this game coincide with the Nash equilibria of a game with two producers with cost functions, respectively, $\Psi_1(x_{11}) = x_{11}^2$ and $\Psi_2(x_{22}) = x_{22}^2$, each one selling on a different market (see the graph in the right side of Figure [2\)](#page-4-7).

III. EXISTENCE OF EQUILIBRIA AND POTENTIAL

In this section, we consider NCGMMs satisfying the following assumption and prove that they always admit a Nash equilibrium. We shall then consider a subclass of NCGMMs that satisfy additional assumptions and prove that they are exact potential games.

- *Assumption 1:* (i) The production cost functions [\(10\)](#page-4-0) are continuous, strictly increasing, convex, and such that $\Psi_i(0) = 0;$
- (ii) the markets' inverse demand functions [\(11\)](#page-4-1) are continuous, strictly decreasing, concave, and such that

$$
\Phi_j(\overline{z}_j) = 0\,,\tag{19}
$$

for some finite $\overline{z}_j > 0$;

(iii) the welfare function [\(12\)](#page-4-2) is continuous and such that $\omega(z, x)$ is concave in z in \mathbb{R}^m for every x in $\mathbb{R}^{n \times m}_+$.

Notice that Example [3](#page-4-3) satisfies Assumption [1.](#page-6-1)

A. Existence of Nash equilibria

Definition 3: In a NCGMM on a network (A, B, c) , with production cost functions [\(10\)](#page-4-0), market inverse demand func-tions [\(11\)](#page-4-1), and welfare function [\(12\)](#page-4-2), an action x_i in \mathbb{R}^m_+ is *strictly dominated* for a producer i in N if there exists another action \tilde{x}_i in \mathbb{R}^m_+ such that

$$
u_i(x_i, x_{-i}, y) < u_i(\tilde{x}_i, x_{-i}, y),
$$

for every action profile x_{-i} in $\mathbb{R}^{(n-1)\times m}_{+}$ of the other producers and action y in Y of the market maker.

Lemma 1: Every vector x_i in \mathbb{R}^m_+ such that

$$
A_{ij} = 1, \t x_{ij} > \overline{z}_j + \sum_{\substack{k \in \mathcal{L}: \\ B_{kj} = -1}} c_k, \t (20)
$$

for some market i in M is a strictly dominated action for a producer i in N .

Proof: Let j in M be a market such that [\(20\)](#page-6-2) holds true, and let \tilde{x}_i in \mathcal{A}_i be an action of producer i with entries $\tilde{x}_{ij} = 0$ and $\tilde{x}_{ig} = x_{ig}$ for every g in $\mathcal{M} \setminus \{j\}$. For every x_{-i} in $\mathcal{R}_+^{\mathcal{N}\setminus\{i\}}$ and y in \mathcal{Y} , we have that

$$
z_j = \sum_{h \in \mathcal{N}} A_{hj} x_{hj} + \sum_{k \in \mathcal{L}} B_{jk} y_k \geq x_{ij} - \sum_{\substack{k \in \mathcal{L}: \\B_{kj} = -1}} c_k > \overline{z}_j,
$$

so that Assumption [1\(](#page-6-1)ii) implies that

$$
\Phi_j(z_j) < \Phi_j(\overline{z}_j) = 0 \, .
$$

It then follows from Assumption $1(i)$ and (14) that

$$
0 < \Psi_i(x_i) - \Psi_i(\tilde{x}_i) - x_{ij}\Phi_j(z_j)
$$

=
$$
u_i(\tilde{x}_i, x_{-i}, y) - u_i(x_i, x_{-i}, y),
$$

for every x_{-i} in $\mathcal{R}_+^{\mathcal{N}\setminus\{i\}}$ and y in \mathcal{Y} , so that action \tilde{x}_i strictly dominates x_i .

We are now in a position to prove the first main result of the paper, guaranteeing existence of a Nash equilibrium for NCGMMs satisfying Assumption [1.](#page-6-1)

Theorem 1: Consider a NCGMM on a network (A, B, c) , with production cost functions [\(10\)](#page-4-0), inverse demand functions [\(11\)](#page-4-1), and welfare function [\(12\)](#page-4-2) satisfying Assumption [1.](#page-6-1) Then, a Nash equilibrium exists.

Proof: Thanks to Lemma [1,](#page-6-3) we may remove the strictly dominated actions and consider the restricted game where the action space of the producers is the hyper-rectangle

$$
\overline{\mathcal{A}}_i = \left\{ v \in \mathcal{A}_i : v_j \le A_{ij} \overline{z}_j + \sum_{\substack{k \in \mathcal{L} : \\ B_{kj} = -1}} c_k, \ \forall j \in \mathcal{M} \right\},\
$$

for every i in N , while the actions space of the market maker remains the hyper-rectangle Y . Notice that the action spaces Y and \overline{A}_i , for i in N are non-empty, convex, and compact. Moreover, Assumption [1](#page-6-1) ensures that the utility functions u_i , for i in $\{0\} \cup \mathcal{N}$, are continuous, that $y \mapsto$ $u_0(y, x) = \omega(x, \text{diag}(A'x) + By)$ is concave for every x and so is $x_i \mapsto u_i(x_i, x_{x_{-i}}, y)$ for every producer i in N, x_{-i} in $\mathbb{R}^{(n-1)\times m}_{+}$, and y in \mathcal{Y} . Hence, existence of a Nash equilibrium follows from a classical result in game theory [37, Theorem 1.2].

B. Sufficient conditions for exact potential game

In this subsection, we determine sufficient conditions for a NCGMM to be an exact potential game. We start with the following definition (c.f. [38]).

Definition 4: A NCGMM is an exact potential game if there exists a function

$$
P(x,y)
$$

to be referred to as the potential function, such that

$$
P(\tilde{x}, y) - P(x, y) = u_i(\tilde{x}, y) - u_i(x, y), \qquad (21)
$$

for every x and \tilde{x} in $\mathbb{R}^{n \times m}_+$ such that $\tilde{x}_{-i} = x_{-i}$ and y and \tilde{y} in Y, and

$$
P(x, \tilde{y}) - P(x, y) = u_0(x, \tilde{y}) - u_i(x, y), \qquad (22)
$$

for every x in $\mathbb{R}_+^{n \times m}$ and y and \tilde{y} in \mathcal{Y} .

Theorem 2: Every NCGMM on a network (A, B, c) , with production cost functions [\(10\)](#page-4-0) satisfying Assumption [1\(](#page-6-1)i), affine inverse demand functions [\(11\)](#page-4-1) with $\Phi'_j = -\beta_j < 0$ for every market j in M , and Walrasian welfare function [\(7\)](#page-3-7) is an exact potential game with potential function

$$
P(x,y) = \omega(x, \text{diag}(A'x) + By) - \sum_{i \in \mathcal{N}} \sum_{j \in \mathcal{M}} \frac{A_{ij} \beta_j}{2} x_{ij}^2, (23)
$$

and the set of its Nash equilibria coincides with

$$
\underset{x \in \mathcal{X}, y \in \mathcal{Y}}{\arg \max} P(x, y). \tag{24}
$$

Moreover, for every two Nash equilibria (x^*, y^*) and $(\tilde{x}^*, \tilde{y}^*)$, we have that $x^* = \tilde{x}^*$ and $By^* = B\tilde{y}^*$.

Proof: To prove relations [\(21\)](#page-6-4) and [\(22\)](#page-6-5), we can equivalently prove that, for every producer i in N , the difference $u_i(x, y) - P(x, y)$ is constant in the vector variable x_i , and that the difference $u_0(x, y) - P(x, y)$ is constant in the vector variable y. For every producer i in N , we have

$$
u_i(x,y) = \sum_{j \in \mathcal{M}} A_{ij} x_{ij} (\alpha_j - \beta_j z_j) - \Psi_i (x_i)
$$

=
$$
\sum_{j \in \mathcal{M}} A_{ij} \alpha_j x_{ij} - \sum_{j \in \mathcal{M}} A_{ij} \beta_j x_{ij}^2 - \Psi_i (x_i)
$$

-
$$
\sum_{j \in \mathcal{M}} A_{ij} \beta_j x_{ij} \left(\sum_{\substack{h \in \mathcal{N} \\ h \neq i}} A_{hj} x_{hj} + \sum_{k \in \mathcal{L}} B_{jk} y_k \right).
$$

On the other hand, the candidate potential function $P(x, y)$ can be equivalently expressed as

$$
P(x,y) = \sum_{j \in \mathcal{M}} \alpha_j \left(\sum_{h \in \mathcal{N}} A_{hj} x_{hj} + \sum_{k \in \mathcal{L}} B_{jk} y_k \right)
$$

\n
$$
- \sum_{j \in \mathcal{M}} \frac{\beta_j}{2} \left(\sum_{h \in \mathcal{N}} A_{hj} x_{hj} + \sum_{k \in \mathcal{L}} B_{jk} y_k \right)^2
$$

\n
$$
- \Psi_i (x_i) - \sum_{h \in \mathcal{N}} \sum_{j \in \mathcal{M}} \frac{A_{hj} \beta_j}{2} x_{hj}^2
$$

\n
$$
= \sum_{j \in \mathcal{M}} \alpha_j A_{ij} x_{ij} - \sum_{j \in \mathcal{M}} \frac{\beta_j}{2} A_{ij} x_{ij}^2 - \Psi_i (x_i)
$$

\n
$$
- \sum_{j \in \mathcal{M}} A_{ij} \beta_j x_{ij} \left(\sum_{\substack{h \in \mathcal{N} \\ h \neq i}} A_{hj} x_{hj} + \sum_{k \in \mathcal{L}} B_{jk} y_k \right)
$$

\n
$$
- \sum_{j \in \mathcal{M}} \frac{\beta_j}{2} \left(\sum_{\substack{h \in \mathcal{N} \\ h \neq i}} A_{hj} x_{hj} + \sum_{k \in \mathcal{L}} B_{jk} y_k \right)^2
$$

\n
$$
- \sum_{j \in \mathcal{M}} \frac{\beta_j}{2} A_{ij} x_{ij}^2 - \sum_{\substack{h \in \mathcal{N} \\ h \neq i}} \sum_{j \in \mathcal{M}} \frac{A_{hj} \beta_j}{2} x_{hj}^2.
$$

Therefore, the difference

$$
u_i(x, y) - P(x, y) = \sum_{j \in \mathcal{M}} \frac{\beta_j}{2} \left(\sum_{\substack{h \in \mathcal{N} \\ h \neq i}} A_{hj} x_{hj} + \sum_{k \in \mathcal{L}} B_{jk} y_k \right)^2
$$

$$
+ \sum_{\substack{h \in \mathcal{N} \\ h \neq i}} \sum_{j \in \mathcal{M}} \frac{A_{hj} \beta_j}{2} x_{hj}^2,
$$

does not depend on any of the variables in the vector x_i . Concerning the market maker, notice that both $u_0(x, y)$ and $P(x, y)$ depend on y through the same addend $\omega(x, z)$ and thus also $u_0(x, y) - P(x, y)$ is constant y. This proves that the game is exact potential with potential P .

Equations [\(21\)](#page-6-4) and [\(22\)](#page-6-5) imply that every Nash equilibrium of the NCGMM satisfies the first-order optimality conditions for the potential function $P(x, y)$ on the domain $\mathcal{X} \times \mathcal{Y}$. Finally, observe that the assumptions that the production costs $\Psi_i(x_i)$ are strictly increasing and that the inverse demand functions $\Phi_j(z_j)$ are strictly decreasing imply that if (x^*, y^*) and $(\tilde{x}^*, \tilde{y}^*)$ both satisfy the first-order optimality conditions for the the potential function $P(x, y)$ on $\mathcal{X} \times \mathcal{Y}$, then necessarily $x^* = \tilde{x}^*$ and $By^* = B\tilde{y}^*$. This proves the last point of the claim.

Example 4: Consider the same setting as in Example [3](#page-4-3) (a), that is, one producer with the quadratic cost in [\(17\)](#page-5-2) that sells on two markets with inverse demand functions as in [\(15\)](#page-4-9). If we consider the Walsarian welfare, then the assumptions of Theorem [2](#page-6-6) are satisfied. Starting from the computations in Example [3,](#page-4-3) we obtain that the potential function in [\(23\)](#page-6-7) takes the form

$$
P(x,y) = u_0(y,x) - \frac{1}{2}x_{12}^2 - x_{12}^2
$$

= $x_{11} + 2x_{12} - 2x_{11}^2 - 3x_{12}^2 - 2x_{11}x_{12}$
+ $(1 + x_{11} - 2x_{12})(y_1 - y_2) - 3(y_1 - y_2)^2/2$.

IV. PRICE DIFFERENCES, LINK SATURATION, AND NON-NEGATIVITY OF THE DEMAND

In this section, we investigate the relationship between price differences and link saturations, and explore their consequences on the sign of the consumption in the different markets.

A. Market maker's best response and link saturation

We start by with the following general result establishing a key connection between the optimal flow chosen by the market maker and the capacity constraint.

Theorem 3: Consider a NCGMM on a network (A, B, c) , with production cost functions [\(10\)](#page-4-0), inverse demand functions [\(11\)](#page-4-1), and welfare function $\omega(x, z)$ that is differentiable in the variable z in \mathbb{R}^m . For x in $\mathbb{R}^{n \times m}_+$ and

$$
y \in \mathcal{B}_0(x) \,, \tag{25}
$$

let $z = diag(A'x) + By$. Then,

$$
\frac{\partial \omega}{\partial z_{\sigma_k}}(x,z) < \frac{\partial \omega}{\partial z_{\tau_k}}(x,z) \qquad \Longrightarrow \qquad y_k = c_k \,, \qquad (26)
$$

and

$$
\frac{\partial \omega}{\partial z_{\sigma_k}}(x, z) > \frac{\partial \omega}{\partial z_{\tau_k}}(x, z) \qquad \Longrightarrow \qquad y_k = 0. \tag{27}
$$

for every link k in \mathcal{L} .

Proof: Consider a link k in $\mathcal L$ such that

$$
\frac{\partial \omega}{\partial z_{\sigma_k}}(x,z) < \frac{\partial \omega}{\partial z_{\tau_k}}(x,z) \,, \tag{28}
$$

and assume by contradiction that $y_k < c_k$. Then, there would exist a value $\bar{\varepsilon} > 0$ such that $y + \varepsilon \delta^{(k)} \leq c$ for every ε such that $0 \leq \varepsilon \leq \overline{\varepsilon}$, so that d $\frac{\mathrm{d}}{\mathrm{d}\varepsilon}u_0\left(y+\varepsilon\delta^{(k)},x\right)\Big|_{\varepsilon=0}$ $=\frac{d}{1}$ $\frac{\mathrm{d}}{\mathrm{d}\varepsilon}\omega\left(x,z+\varepsilon B\delta^{(k)}\right)\bigg|_{\varepsilon=0}$ $=\frac{d}{1}$ $\frac{\mathrm{d}}{\mathrm{d}\varepsilon}\omega\left(x,z+\varepsilon\delta^{(\tau_k)}-\varepsilon\delta^{(\sigma_k)}\right)\Big|_{\varepsilon=0}$ $=\frac{\partial \omega}{\partial \omega}$ $\frac{\partial \omega}{\partial z_{\tau_k}} \left(x, z \right) - \frac{\partial \omega}{\partial z_{\sigma_j}}$ $\frac{\partial \boldsymbol{\omega}}{\partial z_{\sigma_k}}(x,z)$ $> 0,$ (29)

where the first equality follows from [\(13\)](#page-4-4), the second one from [\(2\)](#page-2-4), and the last inequality from [\(28\)](#page-7-1). Inequality [\(29\)](#page-8-0) implies that we can find $\varepsilon^* > 0$ such that $u_0(y, x) < u_0(y + \varepsilon^* \delta^{(k)}, x)$ while still satisfying the capacity constraint $y_k + \varepsilon^* \leq c_k$, thus contradicting assumption [\(25\)](#page-7-2). This proves [\(26\)](#page-7-3).

Arguing similarly, we find that, for a link k in $\mathcal L$ such that

$$
\frac{\partial \omega}{\partial z_{\sigma_k}}(x, z) > \frac{\partial \omega}{\partial z_{\tau_k}}(x, z), \tag{30}
$$

if by contradiction $y_k > 0$, then we would have

$$
\frac{\mathrm{d}}{\mathrm{d}\varepsilon}u_0\left(y+\varepsilon\delta^{(k)},x\right)\bigg|_{\varepsilon=0}<0\,,
$$

which implies that we can find $\varepsilon^* > 0$ such that $u_0(y, x) <$ $u_0(y - \varepsilon^* \delta^{(k)}, x)$ while still satisfying the nonnegativity constraint $y_k - \varepsilon^* \geq c_k$, thus contradicting assumption [\(25\)](#page-7-2). This proves [\(27\)](#page-7-4), thus concluding the proof.

Theorem [3](#page-7-5) can be used to prove the existence of critical cuts with mono-directional saturated flow, as stated below. For a subset of markets $U \subseteq M$ define the in- and out-boundaries (c.f. Figure [4\)](#page-8-1)

$$
\partial_{\mathcal{U}}^{+} = \{ k \in \mathcal{L} : \sigma_k \in \mathcal{M} \setminus \mathcal{U}, \ \tau_k \in \mathcal{U} \},
$$

$$
\partial_{\mathcal{U}}^{-} = \{ k \in \mathcal{L} : \sigma_k \in \mathcal{U}, \ \tau_k \in \mathcal{M} \setminus \mathcal{U} \}.
$$

Corollary 1: Consider a NCGMM on a network (A, B, c) , with production cost functions [\(10\)](#page-4-0), inverse demand functions [\(11\)](#page-4-1), and welfare function $\omega(x, z)$ that is differentiable in the variable z. Let x in $\mathbb{R}^{n \times m}_+$, y in $\mathcal{B}_0(x)$, and $z = \text{diag}(A'x) +$ By. Then, for every nonempty proper subset of markets $\mathcal{U} \subseteq$ M such that

$$
\max_{j \in \mathcal{U}} \frac{\partial \omega}{\partial z_j}(x, z) < \min_{j \in \mathcal{M} \setminus \mathcal{U}} \frac{\partial \omega}{\partial z_j}(x, z) \,, \tag{31}
$$

we have that

$$
y_k = c_k, \quad \forall k \in \partial_{\mathcal{U}}^+, \tag{32}
$$

$$
y_k = 0, \quad \forall k \in \partial_{\mathcal{U}}^-.
$$
 (33)

Proof: The result follows directly from Theorem [3.](#page-7-5)

We notice that conditions [\(30\)](#page-8-2) and [\(31\)](#page-8-3) have a natural interpretation in terms of a price mismatch when w is the Walrasian welfare. We show it in the following Corollary that particularizes Theorem [3](#page-7-5) and Corollary [1](#page-8-4) to that specific case.

Corollary 2: Consider a NCGMM on a network (A, B, c) , with production cost functions [\(10\)](#page-4-0), inverse demand functions [\(11\)](#page-4-1), and Walrasian welfare function [\(7\)](#page-3-7). Let x in $\mathbb{R}^{n \times m}_+$, y in $\mathcal{B}_0(x)$, and $z = \text{diag}(A'x) + By$. Then:

(i) for every link k in $\mathcal L$

$$
\Phi_{\sigma_k}(z_k) < \Phi_{\tau_k}(z_k) \qquad \Longrightarrow \qquad y_k = c_k \,, \qquad (34)
$$

Fig. 4: A cut in a network.

and

$$
\Phi_{\sigma_k}(z_k) > \Phi_{\tau_k}(z_k) \qquad \Longrightarrow \qquad y_k = 0 \,. \tag{35}
$$

(ii) for every nonempty proper subset of markets $U \subseteq M$ such that

$$
\max_{j \in \mathcal{U}} \Phi_j(z_j) < \min_{j \in \mathcal{M} \setminus \mathcal{U}} \Phi_j(z_j) \,, \tag{36}
$$

we have that [\(32\)](#page-8-5) and [\(33\)](#page-8-6) hold true.

Proof: Observe that for the Walrasian welfare [\(7\)](#page-3-7), we have

$$
\frac{\partial}{\partial z_j}\omega(x,z) = \Phi_j(z_j)\,, \qquad \forall j \in \mathcal{M}\,.
$$

Then, point (i) immediately follows from Theorem [3](#page-7-5) and point (ii) from Corollary [1.](#page-8-4)

Corollary [2](#page-8-7) rigorously establishes a connection between capacity bottlenecks and price differences, a phenomenon widely observed in real-world power networks. More precisely, when flows are determined according to the market maker's best response, a price discrepancy between two markets connected by a link implies that the link is saturated. In this scenario, the flow will move from the node with the lower price to the node with the higher price. We remark that this holds true for any value of x and does not require that producers maximize their best responses. Readily, this result applies to Nash equilibria, whenever they exist. We will illustrate this effect in Example [6](#page-9-1) and in the case study presented in Section [V.](#page-9-0)

B. Non-negativity of the demand

As mentioned in Remark [1,](#page-3-6) the demand vector z can have negative entries in general. Enforcing the constraint $z \geq 0$ while computing the market maker's best response comes at the cost of complicating the model, requiring the analysis of the resulting generalized Nash equilibria of the game. With the following result, we provide a sufficient condition for the non-negativity of z .

Theorem 4: Consider a NCGMM on a network (A, B, c) , with production cost functions [\(10\)](#page-4-0), inverse demand functions [\(11\)](#page-4-1), and welfare function [\(12\)](#page-4-2) satisfying Assumption [1.](#page-6-1) If

$$
\Phi_j(0) = a \,, \qquad \forall \, j \in \mathcal{M} \,, \tag{37}
$$

for some constant $a > 0$, then

$$
z = \text{diag}(A'x) + By \ge 0,\tag{38}
$$

for every x in $\mathbb{R}^{n \times m}_+$ and y in $\mathcal{B}_0(x)$.

Proof: Consider the subset of markets

$$
\mathcal{U} = \{j \in \mathcal{M} \,:\, z_j \geq 0\} \,.
$$

First, observe that, if U were empty, then we would have

$$
0 > \sum_{j \in \mathcal{M}} z_j = 1'z = 1' \operatorname{diag}(A'x) + 1'By
$$

$$
= \sum_{i \in \mathcal{N}} \sum_{j \in \mathcal{M}} x_{ij} \ge 0,
$$

which is a contradiction. Hence, necessarily U is nonempty.

Observe that by Assumption [1\(](#page-6-1)ii) the inverse demand functions are all strictly decreasing so that

$$
\Phi_j(z_j) > \Phi_j(0) = a \,, \qquad \forall j \in \mathcal{M} \setminus \mathcal{U} \,, \tag{39}
$$

$$
\Phi_j(z_j) \le \Phi_j(0) = a \,, \qquad \forall j \in \mathcal{U} \,, \tag{40}
$$

Now, assume by contradiction that $\mathcal{U} \neq \mathcal{M}$. Then [\(39\)](#page-9-2) and [\(40\)](#page-9-3) imply that [\(36\)](#page-8-8) is satisfied so that Corollary [2\(](#page-8-7)ii) would imply that [\(32\)](#page-8-5) and [\(33\)](#page-8-6) hold true. In turn, this would imply that

$$
\sum_{j \in \mathcal{M} \setminus \mathcal{U}} (By)_j = \sum_{k \in \partial_{\mathcal{U}}} y_k - \sum_{k \in \partial \mathcal{U}^+} y_k = \sum_{k \in \partial_{\mathcal{U}}} c_k,
$$

so that

$$
0 > \sum_{j \in \mathcal{M} \setminus \mathcal{U}} z_j = \sum_{j \in \mathcal{M} \setminus \mathcal{U}} (By)_j
$$

+
$$
\sum_{j \in \mathcal{M} \setminus \mathcal{U}} \sum_{i \in \mathcal{N}} A_{ij} x_{ij} \ge \sum_{k \in \partial_{\mathcal{U}}} c_k \ge 0,
$$

which is a contradiction. Therefore, it must be $U = M$, thus proving the claim.

Example 5: Let us now consider the same setting as in Example [3,](#page-4-3) except for the inverse demand functions of the two markets that we now set to be affine as in [\(9\)](#page-3-8) with $\alpha_1 = \alpha_2 = 1, \beta_1 = 1, \text{ and } \beta_2 = 2, \text{ so that}$

$$
\Phi_1(z_1) = 1 - z_1, \qquad \Phi_2(z_2) = 1 - 2z_2.
$$

Observe that $\Phi_1(0) = \Phi_2(0) = 1$ and therefore condition [\(37\)](#page-8-9) is satisfied. Let

$$
z = diag(A'x) + By = (x_{11} - \Delta, x_{12} + \Delta),
$$

where $\Delta = y_1 - y_2$. The market maker's utility is then given by

$$
u_0(y, x) = \omega(x, z)
$$

= $z_1 + z_2 - z_1^2/2 - z_2^2 - (x_{11} + x_{12})^2$
= $x_{11} + x_{12} - \frac{3}{2}x_{11}^2 - 2x_{12}^2 - 2x_{11}x_{12}$
+ $(x_{11} - 2x_{12})\Delta - \frac{3}{2}\Delta^2$,

and its best response function is

$$
\mathcal{B}_0(x) = \{ y \in [0, 1]^2 : y_1 - y_2 = \Delta^*(x) \}
$$

where

$$
\Delta^*(x) = \begin{cases}\n\chi & \text{if } x_{11} - 2x_{12} \ge 3\chi \\
(x_{11} - 2x_{12})/3 & \text{if } |x_{11} - 2x_{12}| < 3\chi \\
-\chi & \text{if } x_{11} - 2x_{12} \le -3\chi.\n\end{cases}
$$

Observe that for every x in $\mathcal X$ we have

$$
z_1^* = x_{11} - \Delta^*(x) = \begin{cases} x_{11} - \chi & \text{if } x_{11} - 2x_{12} \ge 3\chi \\ \frac{2}{3}(x_{11} + x_{12}) & \text{if } |x_{11} - 2x_{12}| < 3\chi \\ x_{11} + \chi & \text{if } x_{11} - 2x_{12} \le -3\chi. \end{cases}
$$

$$
z_2^* = x_{12} + \Delta^*(x) = \begin{cases} x_{12} + \chi & \text{if } x_{11} - 2x_{12} \ge 3\chi \\ \frac{1}{3}(x_{11} + x_{12}) & \text{if } |x_{11} - 2x_{12}| < 3\chi \\ x_{12} - \chi & \text{if } x_{11} - 2x_{12} \le -3\chi, \end{cases}
$$

so that both $z_1^* \ge 0$ and $z_2^* \ge 0$, as predicted by Theorem [4.](#page-8-10)

Remark 4: In contrast to Example [5,](#page-9-4) note that, in Example [3](#page-4-3) we had $\Phi_1(0) = 1 \neq \Phi_2(0) = 2$ and therefore [\(37\)](#page-8-9) was not satisfied. We noticed need that the equilibrium demand z_1^* can be negative in that case. Observe that Theorem [4](#page-8-10) gives a sufficient condition, and indeed there are some cases where z ∗ is nonnegative even if the condition is not satisfied (see Example [3](#page-4-3) (b), for instance).

Example 6: Let us consider the network (A, B, c) of Example [1.](#page-2-1) We consider the same affine inverse demand function for all markets and the same quadratic cost function for all producers: $\Phi_j(z_j) = 14 - 3z_j$ for $1 \le j \le 4$ and $\Psi_i(q_i) =$ $0.3q_i + 0.7q_i^2$ for $1 \le i \le 3$. Moreover, we set the market maker utility w equal to the Walrasian welfare (7) . Notice that the assumptions of Theorem [2](#page-6-6) are satisfied, this means that the game is potential with a unique Nash equilibrium that can be found solving [\(24\)](#page-7-6).

Fig. [5](#page-10-0) describes the variables at a Nash equilibrium. We notice the emergence of two different prices at equilibrium: markets 1, 2, and 3 achieve an equilibrium price of 7.64 while in market 4 the price is 8. By Theorem [3,](#page-7-5) this implies the existence of a critical cut between markets 4 and 3. In particular, we can see that the link going from market 3 to market 4 is saturated while the link in the opposite direction has no flow. This is coherent with what we expected from the Theorem as market 4 has a higher price than market 3 at equilibrium. Finally, notice that since $\Phi_i(0) = \alpha = 14$ for $j = 1, 2, 3, 4$ $j = 1, 2, 3, 4$, we know from Theorem 4 that the demand will be positive in each market and this is confirmed once again by the simulation: we find $z_i = 2.11$ for $j = 1, 2, 3$ and $z_4 = 2$.

V. A CASE STUDY

In this section, we study the prediction accuracy of the proposed model starting from real data from the Italian electricity market [39]. The Italian electricity market, liberalized in 1999, is divided in a spot market (Mercato elettrico a pronti) and a futures market (Mercato elettrico a termine). The Italian electricity spot market is again articulated in a series of branches: the day ahead market (Mercato del giorno prima - MGP), several intraday markets (Mercato infragiornaliero - MI), the ancillary services market (Mercato del servizio di dispacciamento - MSD) and the balancing market (Mercato di Bilanciamento - MB). In this case study, we focus on the day-ahead electricity market, where the majority of electricity is traded. Firms take part into hourly auctions by bidding offers in which they state both the amount they are willing to buy/supply and the corresponding marginal price. The

Fig. 5: Production quantities, flows, prices and bottlenecks at equilibrium. The grey numbers represent the total production of each producer, the colored numbers next to each market are the respective equilibrium prices and the numbers close to each link are the actual flow at equilibrium. In red, we highlighted the saturated link.

offers are accepted after the market session closes, based on economic merit and taking into consideration the transit limits between zones. The offers for sale are remunerated at the zonal price, that is, the market-clearing price of the zone they belong to, while the purchase bids are cleared at the National Unique Price (PUN).

The following analysis is based on two datasets publicly available at [40]. The first dataset gathers the zones and the transit limits between them, while the second one contains records of every bid (pairs quantity/price) submitted by the participating firms at each hour of the day. In particular, we focus on the following features: the identification code for each producer/consumer participating in the market (*UNIT_REFERENCE_NO*), the binary variable that determines whether it is a demand or offer bid (*PURPOSE_CD*), the macro-zone of the bid/offer (*ZONE_CD*), the quantity offered and the quantity awarded once the market is cleared (*QUAN-TITY_NO* and *AWARDED_QUANTITY_NO*, respectively), the offered price associated with the transaction and the awarded price (*ENERGY_PRICE_NO* and *AWARDED_PRICE_NO*, respectively). Quantities are expressed in MWh, while marginal prices are expressed in \in/NWh .

From the provided data, it is possible to extract a number of statistics describing the composition of the Italian electricity production landscape. In this analysis, we focus on a specific date and time, that is, October 24th at 8 pm, 2024, and we consider only zones where production/consumption takes place and only bidders that are offering positive quantities on such hour of such day. We then obtain the Italian (and neighboring countries) power network shown in Fig. [6](#page-11-0) consisting of $m =$ 10 markets (the nodes of the network numbered from 0 to 9) and 9 links. We have a total of $n = 1444$ producers, each selling on a single market. The actual distribution of producers in each market is shown in Table [I](#page-10-1) and in Fig. [6](#page-11-0) (the red number next to each market) together with the maximum capacity for each line, measured in MWh.

In the real market, both producers and consumers participate

in the auction. Anyway, in order to apply our model, we assume that only producers are players in the game and we estimate the demand based on consumers' bids. More precisely, we consider affine inverse demand functions $\Phi_i(z_i)$ = $\alpha_j - \beta_j z_j$ for all markets $1 \leq j \leq m$ (measured in \in/MWh) and quadratic cost functions $\Psi_i(q_i) = \gamma_i q_i + \theta_i q_i^2$ for all producers $1 \leq i \leq n$ (measured in \in). We set the market maker utility w equal to the Walrasian welfare in (7) .

The value of the parameters has been tuned to fit the real data following similar ideas as in [41], [42]. The demand parameters in each zone, that is, α_j , β_j for j in M, have been estimated in the following way. Starting from all the submitted bids and their merit order, we estimate the demand curve in each zone. We then estimate the demand parameters through a standard linear regression. The resulting set of intercepts are presented in Table [I.](#page-10-1) We remark that most of the production takes place in the North (see node 5).

The estimation of the costs parameters γ_i and θ_i for each producer i in N is more challenging. The parameter γ_i represents the minimum price at which it is strategically convenient for firm i to bid a nonzero quantity to the market. Consequently, we considered the minimum offered marginal price for each production unit, scaled by a factor of 0.99 in case the bid was not truthful. The parameter θ_i , instead, was used to incorporate the capacity limits of each producer. More precisely, starting from $\Psi_i'(q_i) = \gamma_i + 2\theta_i q_i$, we derive the formula

$$
\theta_i = \frac{\hat{p} - \gamma_i}{2\hat{q}}
$$

where \hat{p} denotes the awarded price and \hat{q} denotes the awarded quantity. As a consequence, firms that produce higher quantities will result in a lower parameter θ_i , while θ_i is high and the costs grow fast when firms produce low quantities. The distributions of γ and θ among the producers are shown in Fig. [7](#page-11-1) and Fig. [8,](#page-11-2) respectively.

In this setting, assumptions of Theorem [2](#page-6-6) are satisfied, this means that the game is potential with a unique Nash equilibrium that can be found solving [\(24\)](#page-7-6). By doing that, we find the equilibrium prices as shown in Fig. [9](#page-12-1) and detailed in Tab. [I.](#page-10-1)

Market	Name	α, β	Num. Prod.	Eq. Price $\frac{\epsilon}{\text{MWh}}$	\boldsymbol{z}
Ω	Switzerland	177.34, 0.14	42	127	339.23

TABLE I: Parameters, producers, price and demand in each market at equilibrium.

We observe the emergence of four distinct price groups, each characterized by a unique equilibrium price. According to Theorem [3,](#page-7-5) and in particular Corollary [2,](#page-8-7) the power lines connecting these groups must be saturated, facilitating energy flow exclusively from lower-priced markets to higher-priced ones. This observation aligns perfectly with our numerical

Fig. 6: Italian power network with, the number of producers in each market is indicated by the red numbers. The black numbers denote the power line capacities in both directions, with the convention that the top number corresponds to the capacity of the link connecting the node with the lower label to the one with the higher label, while the bottom one is the link capacity in the opposite direction.

Fig. 7: Distribution of the cost parameter γ . The value of γ represents the marginal cost of the producer in zero, that is, the minimum price at which he is willing to produce.

Fig. 8: Distribution of the cost parameter θ . We recall that higher values of θ represent producers with lower capacities, while lower values of θ allow for higher capacities. There are few producers with very high values of θ (that is, producing very low quantities) therefore the distribution is shown for first for all producers and then only for producers with θ less than .

14₂ ≈ 179 $\Phi \approx 190$ Saturated link

ian power network at equilibrium. Different colors highlight groups of markets that have different prices at equilibrium. Dashed lines denote saturated power lines connecting these groups and the arrows indicate the actual direction of the energy flow. Links with no flow have been removed. The actual flow in both directions is represented by the black numbers next to each link, with the convention that the top number corresponds to the flow in the link connecting the node with the lower label to the one with the higher label, while the bottom one is the flow in the opposite direction.

results. Figure [9](#page-12-1) visually illustrates the groups using distinct colors, with the equilibrium prices labeled next to each node. Dashed lines represent the saturated links, while links with no flow are omitted for clarity.

By comparing our findings with the real data from the GME website we can make several interesting observations.

- In Fig. [9,](#page-12-1) [10](#page-12-2) and [11,](#page-13-0) we can see the predicted prices at Nash equilibrium and the real observed ones, respectively. As expected, we do not recover the exact real prices through our model due to the parameter estimation and some approximations made (such as affine inverse demand functions and quadratic costs). We do, however, predict increasingly higher costs as we go from the north to the south and we recover exactly the saturated link from North to Center-North, as shown in Fig. [12.](#page-13-1) In our prediction of the Nash equilibrium the link from Center-North to Center-South is also saturated, while according to the data it was not. On the other hand, one can observe that there is a consistent flow that goes from Center-North to Center-South which is near the transit limit and this is consistent with our prediction.
- The real data reveal the presence of three distinct price groups. Consistent with the predictions of Theorem [3,](#page-7-5) the links connecting these groups are saturated, facilitating flow from lower-priced markets to higher-priced ones, while no flow occurs in the opposite direction. This behavior is precisely mirrored in our simulations, albeit with the emergence of four price groups due to previously discussed approximations. Thus, Theorem [3](#page-7-5) provides a

Fig. 10: Flows, prices, and capacity bottlenecks in the Italian power network extracted from the data. Different colors highlight groups of markets that have different prices at equilibrium. Dashed lines denote saturated power lines connecting these groups and the arrows indicate the actual direction of the energy flow. Links with no flow have been removed.

formal explanation of the intrinsic relationship between price differences and capacity bottlenecks.

• The demand at equilibrium in each market is positive, even though the hypothesis of Theorem [4](#page-8-10) is not satisfied. Our conjecture is that, in this real world example, the demand and the supply in each region are sufficiently balanced to avoid anomalous behaviors.

VI. CONCLUSIONS

In this paper, we have studied a model of a networked Cournot competition involving producers and a market maker competing on multiple markets connected by links with finite capacity. This model is suited to describe energy marketplaces where the links connecting the markets represent physical power lines. We first provided conditions for existence and uniqueness of Nash equilibria. Then, we proved a very general result concerning the optimal action of the market maker and the presence of critical links and cuts in the power network where the flow is saturated and only moves following a specific direction. This result allowed us to shed light on the implications of capacity bottlenecks in the power network on the emergence of price differences between different markets. This phenomenon is often observed in real-world scenarios and our model replicates this behavior, as pointed out in the case study of the Italian day-ahead electricity market.

Ongoing research is focused on exploiting our results on critical links and cuts to develop optimal network intervention/design policies. Possible problems involve finding the critical cut and how to optimally create new links or allocate additional capacity among the lines of the power network in order to level price differences or maximize certain welfare functions. We are also interested in studying the game as a Stackelberg competition where first the producers choose the quantities and then the market maker establishes the flows, as in real-world scenarios.

Fig. 11: Zonal prices in Italy on October 24th, 2024, at 8pm. This map can be obtained through the [GME website](https://gme.mercatoelettrico.org/en-us/Home/Results/Electricity/MGP/Results/DemandSupply) by selecting the button MAP. In red, we show for comparison the predicted prices at Nash equilibrium.

Giacomo Como is a Professor at the Department of Mathematical Sciences, Politecnico di Torino, Italy, and a Senior Lecturer at the Automatic Control Department of Lund University, Sweden. He received the B.Sc., M.S., and Ph.D. degrees in Applied Mathematics from Politecnico di Torino, in 2002, 2004, and 2008, respectively. He was a Visiting Assistant in Research at Yale University in 2006–2007 and a Postdoctoral Associate at the Laboratory for Information and Decision Systems, Massachusetts Institute of

Technology, from 2008 to 2011. He currently serves as Senior Editor of the *IEEE Transactions on Control of network Systems* and Associate Editor of *Automatica*. . He has been serving as Associate Editor of the *IEEE Transactions on network Science and Engineering* and of the *IEEE Transactions on Control of network Systems* and as the chair of the IEEE-CSS Technical Committee on networks and Communications. He was the IPC chair of the IFAC Workshop NecSys'15 and a semi-plenary speaker at the International Symposium MTNS'16. He is recipient of the 2015 George S. Axelby Outstanding Paper Award. His research interests are in dynamics, information, and control in network systems with applications to cyber-physical systems, infrastructure networks, and social and economic networks.

Fabio Fagnani received the Laurea degree in Mathematics from the University of Pisa and the Scuola Normale Superiore, Pisa, Italy, in 1986. He received the PhD degree in Mathematics from the University of Groningen, Groningen, The Netherlands, in 1991. From 1991 to 1998, he was an Assistant Professor of Mathematical Analysis at the Scuola Normale Superiore. In 1997, he was a Visiting Professor at the Massachusetts Institute of Technology (MIT), Cambridge, MA. Since 1998, he has been with the

Politecnico of Torino, where since 2002 he has been a Full Professor of Mathematical Analysis. From 2006 to 2012, he has acted as Coordinator of the PhD program in Mathematics for Engineering Sciences at Politecnico di Torino. From June 2012 to September 2019, he served as the Head of the Department of Mathematical Sciences, Politecnico di Torino. His current research topics are on cooperative algorithms and dynamical systems over networks, inferential distributed algorithms, and opinion dynamics. He is an Associate Editor of the *IEEE Transactions on Automatic Control* and served in the same role for the *IEEE Transactions on network Science and Engineering* and of the *IEEE Transactions on Control of network Systems*.

Leonardo Massai is a post-doctoral scientist at at the Automatic Control Laboratory, EPFL — Lausanne, Switzerland working in the DECODE group with Prof. Giancarlo Ferrari Trecate on distributed control based on neural networks and machine learning. He obtained his bachelor's degree in Business Engineering from the University of Pisa in 2012 and his master's degree in Mathematical Engineering from Politecnico di Torino in 2015. Dr. Massai then earned his PhD from Politecnico di Torino, where he researched

graph and game theory. His research interests include optimization theory, machine learning, and financial mathematics.

Martina Vanelli received the B.Sc., M.S. (*cum laude*), and Ph.D. (*with honors*) degrees in Applied Mathematics from Politecnico di Torino, in 2017, 2019, and 2024, respectively. She is currently a postdoctoral fellow at the Institute for Information and Communication Technologies, Electronics and Applied Mathematics (ICTEAM), Université catholique de Louvain. From October 2018 to March 2019, she was a visiting student at Technion, Israel Institute of Technology. Her research interests include identification, analy-

sis, and control of multi-agent systems, with application to social and economic networks, and power markets.
