

METANOIA: A Lifelong Intrusion Detection and Investigation System for Mitigating Concept Drift

Jie Ying, Tiantian Zhu*, Aohan Zheng, Tieming Chen*, Mingqi Lv, Yan Chen, *Fellow, IEEE*

Abstract—As Advanced Persistent Threat (APT) complexity increases, provenance data is increasingly used for detection. Anomaly-based systems are gaining attention due to their attack-knowledge-agnostic nature and ability to counter zero-day vulnerabilities. However, traditional detection paradigms, which train on offline, limited-size data, often overlook concept drift - unpredictable changes in streaming data distribution over time. This leads to high false positive rates. We propose incremental learning as a new paradigm to mitigate this issue.

However, we identify FOUR CHALLENGES while integrating incremental learning as a new paradigm. First, the long-running incremental system must combat catastrophic forgetting (C1) and avoid learning malicious behaviors (C2). Then, the system needs to achieve precise alerts (C3) and reconstruct attack scenarios (C4). We present METANOIA, the first lifelong detection system that mitigates the high false positives due to concept drift. It connects pseudo edges to combat catastrophic forgetting, transfers suspicious states to avoid learning malicious behaviors, filters nodes at the path-level to achieve precise alerts, and constructs mini-graphs to reconstruct attack scenarios. Using state-of-the-art benchmarks, we demonstrate that METANOIA improves precision performance at the window-level, graph-level, and node-level by 30%, 54%, and 29%, respectively, compared to previous approaches.

Index Terms—Advanced Persistent Threat, Concept Drift, Intrusion Detection, Incremental Learning

I. INTRODUCTION

IN comparison to raw audit logs, provenance graphs offer a novel perspective for identifying threats and investigating traces, facilitating the differentiation between prolonged normal behavior and malicious activities [1–3]. Presently, there is a growing trend in leveraging the rich contextual information provided by provenance graphs to perform host-based intrusion detection, referred to as *provenance-based intrusion detection systems* (PIDSes) [1, 4–18].

Among them, anomaly-based work defines a model of benign system behavior based on historical log data [1, 10–18], triggering an alert when the execution significantly deviates from this model. Since it is attack-knowledge-agnostic, counteracts zero-day vulnerabilities, and possesses meticulous detection capabilities, many researchers focus on anomaly-based detection works. Compared to the high latency and expenses associated with offline systems [12, 16–18], PIDSes capable of processing dynamic evolving provenance graphs in a streaming fashion [1, 8, 13–15] are better suited for the real-time and cost-effective requirements of current host-based detection.

However, most current anomaly-based PIDSes seem to evade a critical issue: **concept drift**. Concept drift describes unforeseeable changes in the underlying distribution of streaming data over time [19–21]. In this work, concept drift is represented as a variation in the benign behavior of a user on the host over time, e.g., switching work environments. This variation can lead to a decline in model performance since the features and patterns learned during training are no longer applicable during testing. In practical scenarios, this common phenomenon corresponds to changes in user behavior at the endpoint, such as switching to different production environments or deploying new software. This change (i.e., **concept drift**) can result in an unacceptable false-positive rate for existing PIDSes [3, 22, 23].

We observe that current PIDSes adhere to the *traditional anomaly detection paradigm*: training on offline-collected, limited-size data to identify anomalies (behaviors different from the training data) on test data. However, this paradigm does not work well as host behaviors exhibit infinite states and unknown variability. This uncertainty can lead to significant differences in the distribution of training and test data, i.e., **concept drift**. This situation causes the current anomaly-based PIDSes to have many false positives because they do not realize that the decision boundary at the current moment is different from the training time. Limitlessly expanding training data or strictly constraining user behaviors are two approaches to combat concept drift within this traditional paradigm, but these are not feasible.

To feasibly mitigate concept drift (**Goal**), we introduce incremental learning [24, 25] as a new anomaly detection paradigm (**Baseline**). Incremental learning refers to the model's ability to continuously assimilate dynamic data, enabling it to evolve and adapt within an ever-changing environment. Similarly, the system-level streaming logs are dynamic, with their distribution changing over time and continually introducing new entities and interactions. The correspondence

between the continuous learning capability of incremental learning and the distribution variability of streaming logs prompts us to *consider adopting incremental learning as a new anomaly detection paradigm to mitigate concept drift*.

However, directly integrating incremental learning with anomaly-based PIDSEs would diminish their intrusion detection capabilities. After thorough research analysis, we identified **FOUR CHALLENGES** that need to be overcome to integrate incremental learning to mitigate concept drift. First, long-running incremental PIDSEs must combat catastrophic forgetting (C1) [26]. Furthermore, the PIDSEs should endeavor to avoid high false negatives introduced by learning malicious behaviors (C2) [27]. Lastly, the PIDSEs must achieve precise alerts (C3) and reconstruct attack scenario (C4) [3, 14, 15]. It is important to emphasize that these interconnected challenges were progressively uncovered as we attempted to mitigate concept drift. Subsequently, we will elaborate on these challenges.

C1 Combat Catastrophic Forgetting. Some existing studies [12, 14, 15] have adopted the concept of incremental learning, retraining models through *oracles* (human guidance). However, this approach is plagued by *catastrophic forgetting*, a phenomenon where models, upon learning new tasks, gradually discard or forget how to perform previous tasks. We argue that anomaly-based PIDSEs should be capable of combating catastrophic forgetting, retaining memory of old tasks to reduce redundant training costs and minimize disruptive false alarms.

C2 Avoid Discrimination Paradox. The Rehearsal Approach is a widely acknowledged and effective strategy for mitigating catastrophic forgetting [26]. It fundamentally aids models in retaining the memory of prior learning by revisiting old knowledge. Nonetheless, a specific challenge arises when directly implementing the Rehearsal Approach within endpoint detection: a *discrimination paradox*. In detail, if the detection system can determine the maliciousness of data selected for replay, subsequent steps (detecting malicious behavior) become redundant. If it fails in this determination, the replay of malicious data might degrade detection performance. Consequently, PIDSEs must navigate away from the discrimination paradox.

C3 Achieve Precise Alerts. During prolonged deployment, PIDS often generates a significant number of false alarms due to the change in execution environment, the introduction of new applications, and the occurrence of low-frequency operations. It is imperative to recognize that these alarms typically reflect anomalous, yet not necessarily malicious, behaviors within the system. Therefore, we contend that PIDSEs should strive to minimize such false positives caused by concept drift, ensuring precise alerts and reducing the additional workload on security practitioners.

C4 Reconstruct Attack Scenario. Provenance data can assist in investigating the attack chains leading to intrusions and the potential damage caused by intrusions to the system [2, 28, 29]. However, manually investigating the entire graph is not feasible due to the substantial size of a typical provenance graph and its rapid expansion rate over time [30]. Practical PIDSEs need to reconstruct attack scenarios through dependencies among kernel objects, significantly reducing

manual work and enabling system administrators to quickly understand intrusions and timely design responses.

To this end, we introduce METANOIA, the first lifelong anomaly detection and investigation system that utilizes incremental learning as a new paradigm to address the high false positive problem caused by concept drift. Where lifelong refers to METANOIA's ability to continuously process streaming data to detect anomalies over a long period. METANOIA connects pseudo edges to combat catastrophic forgetting, transfers suspicious states to avoid the discrimination paradox, filters at the path-level to achieve precise alerts, and constructs mini-graphs to reconstruct attack scenarios. In summary, this paper makes the following contributions:

- We conduct an in-depth analysis of the concept drift problem in current anomaly-based PIDSEs, present shortcomings of the traditional anomaly detection paradigm, and finally propose a novel anomaly detection paradigm.
- We introduce METANOIA, a lifelong intrusion detection and investigation system for mitigating concept drift. METANOIA identifies, analyzes, and addresses four challenges inherent in adopting a new anomaly detection paradigm. We believe that METANOIA effectively minimizes false positives stemming from concept drift. To our best knowledge, METANOIA is the first system to address concept drift through the adoption of a novel anomaly detection paradigm.
- We evaluate METANOIA on publicly available benchmark datasets from DARPA [31] that simulate APT campaigns, as well as datasets that allow us to fairly compare METANOIA with state-of-the-art PIDSEs, UNICORN [1], KAIROS [15], PROGRAPHER [14] and ThreaTrace [13]. Experimental results show that the precision performance of METANOIA on window-level, graph-level, and node-level outperforms existing approaches by 30%, 54%, and 29% respectively.

II. MOTIVATION

To motivate this work, we first describe a specific scenario for PIDSEs and then present prior approaches with their limitations.

A. Scenario

As shown in Figure 1, the entire lifecycle of PIDSEs can be divided into two stages: the training phase (including Behavior A) and the testing phase (including Behavior B and C). During the training stage, PIDSEs model itself based on collected normal behaviors and establishes specific decision boundaries. And according to these boundaries, PIDSEs identify any anomalies deviating from them and raise an alert in the testing phase.

Behavior A and Behavior B are both non-malicious behaviors of the system, and Behavior C is a large-scale APT campaign simulated by DARPA [32]. Since Behavior B and Behavior C are contextually and semantically different from Behavior A, PIDSEs recognize them as anomalies and repeat threat alerts.

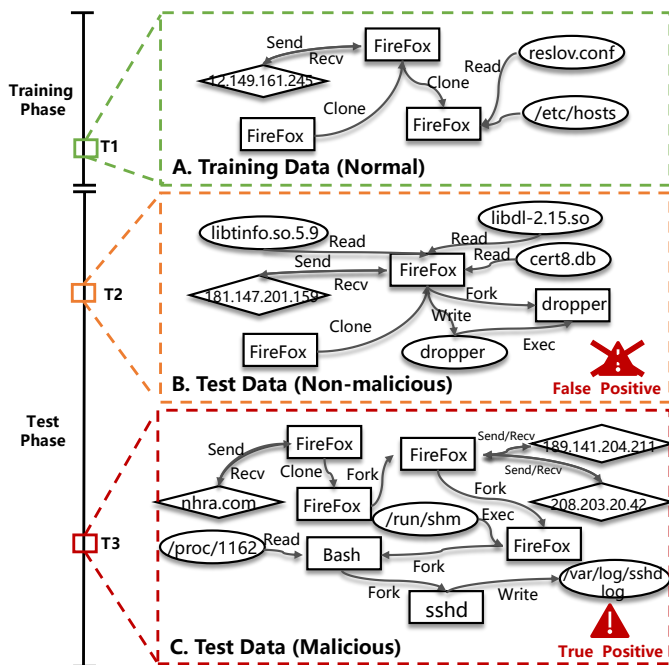

Fig. 1: Motivating Example.

Behavior A (at time T1): The Firefox process first clones itself, then connects to 12.149.161.245, and subsequently reads the `resolv.conf` and `/etc/hosts` files.

Behavior B (at time T2): The Firefox process first clones itself, then connects to 181.147.201.159, and proceeds to read the `cert8.db` and `libdl-2.15.so` files. Finally, it writes and executes the `dropper`.

Behavior C (at time T3): The attack begins with the compromise of a once-reliable website (`nhra.com`), where the attacker lies in wait for an individual using a vulnerable Firefox browser to establish a link with a malicious server. When the individual accesses the site, the attacker proceeds to run a Drakon exploit in the memory of Firefox. Consequently, Firefox is forced to establish a connection with an attacker-controlled server at the IP addresses: 189.141.204.211 and 208.203.20.42. By exploiting a driver previously installed, named `"/run/shm"`, the attacker escalates privileges on the Firefox process and achieves root access to create a new process `Bash` with access to process list. In the final stage, the attacker employs the Inject2 Process injection method to introduce shellcode into the `sshd`, resulting in the creation of a file named `sshdlog` on the disk. This action paves the way for the attacker to reach out to additional harmful web servers causing data exfiltration.

B. Prior Approaches & Limitations

Traditional supervised methods, such as ATLAS [33] and APT-KGL [34], require the use of attack samples as training data for manipulation. However, in practice, acquiring such data is extremely challenging. To address this issue, recent PIDSEs have adopted unsupervised or semi-supervised detection pipelines. These pipelines model benign data and identify abnormal behaviors as indications of malicious activities. Among state-of-the-art PIDSEs, Unicorn [1] and

StreamSpot [10] provide graph-level detection (representing the current state of the entire system), ThreaTrace [13] and MAGIC [35] offer entity-level detection, while KAIROS [15] and ShadeWatcher [12] focus on event-level detection.

We observe that current PIDSEs follow the same paradigm, as shown in Figure 1: training on offline-collected, limited-size data to identify anomalies (behaviors different from the training data) on test data. Unfortunately, this paradigm are not suitable for endpoint anomaly detection, as host behaviors exhibit infinite states and unknown variability. This uncertainty can lead to significant differences in the distribution of training and test data, i.e., **concept drift**. It is the situation that brings about a large number of false positives for current PIDSEs because they fail to realize that the decision boundary has changed after the training stage.

As shown in Figure 2, PIDSEs only modeled the Behavior A of Firefox during the training phase. In the testing phase, Firefox exhibited Behavior B, which was deemed anomalous by PIDSEs (as it crossed the decision boundary). We believe this phenomenon is quite common, such as when users deploy new software or change their production environment. PIDSEs triggered an alert (false positive), even though the Behavior B of the Firefox process at time T2 was non-malicious. This discrepancy arises from the fact that existing PIDSEs decision boundaries did not adapt to changes in data distribution.

To sum up, we believe that the traditional paradigm is limited by high false positive rates in anomaly detection scenarios with concept drift. Therefore, METANOIA employs a novel anomaly detection paradigm to mitigate false positives induced by concept drift.

III. THREAT MODEL

We make the following assumptions about the target system. The Trusted Computing Base (TCB) of the system consists of the operating system and audit framework. We assume these components are operating correctly and cannot be manipulated by attackers. We also assume that attackers cannot directly modify the contents of audit logs, which can be achieved through tamper-evident logging techniques [36–39] beyond the scope of this paper. Finally, we do not consider hardware-level, side-channel, or covert-channel attacks, since kernel-level audit systems do not explicitly capture their behaviors.

It is worth emphasizing that we do not assume the absence of concept drift, which distinguishes our approach from the majority of studies [12–15, 40–43]. These studies typically assume that system behaviors remain static over time, i.e., no concept drift exists. However, host behaviors evolve in real-world scenarios with changing user activities and requirements. Therefore, we refrain from making such unrealistic assumptions and instead, METANOIA can serve as an intrusion detection and investigation system for concept drift mitigation using system-level provenance.

IV. FRAMEWORK

In this section, we first introduce four critical node types involved in METANOIA and then provide an overview of METANOIA.

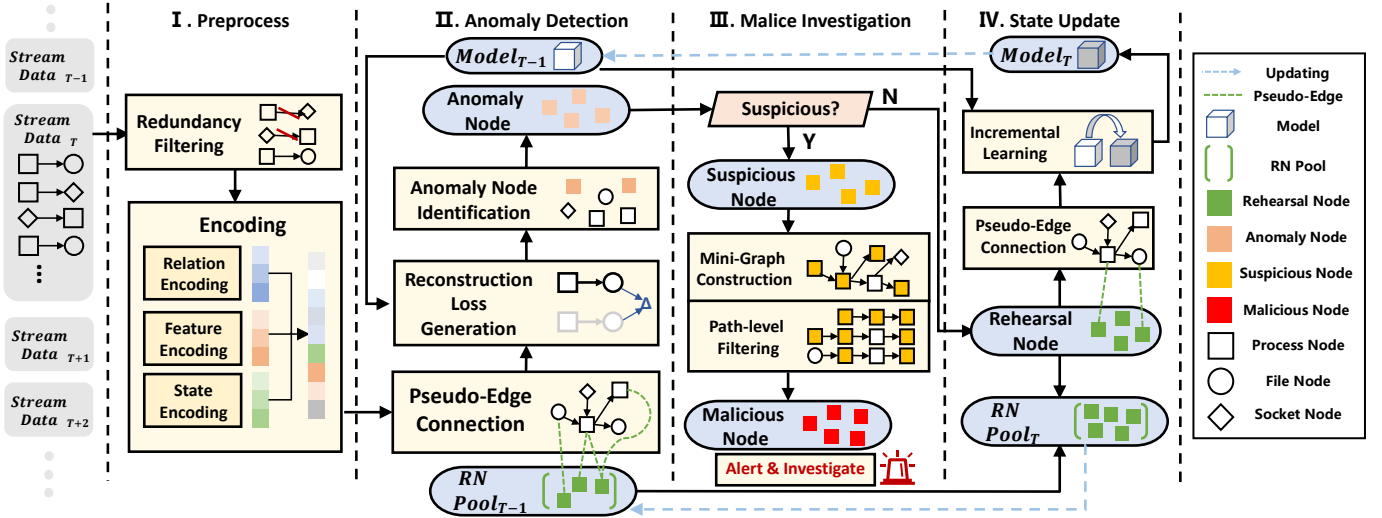

Fig. 2: Overview of METANOIA's architecture.

A. Critical Node Types

METANOIA considers that process nodes to exhibit the richest behavioral characteristics and hold the highest identification status during intrusion detection. Additionally, given the long-term nature of APT attack detection, the four types of nodes defined by METANOIA are all process nodes.

Anomalous Nodes (AN) refer to nodes that exhibit new behavior compared to the past. METANOIA believes that anomalous nodes typically consist of two distinctive behaviors: (1) nodes exhibiting behavior inconsistent with their past experiences, such as a user who predominantly uses a browser for work suddenly engaging in leisure activities, and (2) newly initiated nodes, such as users installing new applications to accomplish production goals. AN occur in large numbers when the host switches working environments or runs new applications.

Suspicious Nodes (SN) refer to anomalous nodes with suspicious state, while **Rehearsal Nodes (RN)** refer to anomalous nodes without suspicious state. In other words, the union of suspicious and rehearsal nodes constitutes anomalous nodes. METANOIA believes that rehearsal nodes serve to help the model memorize scenarios that are anomalous rather than malicious, thereby reducing false positives caused by concept drift. Consequently, METANOIA selects anomalous nodes without suspicious states as rehearsal nodes.

Malicious Nodes (MN) refer to nodes associated with attacks. METANOIA obtains malicious nodes by filtering suspicious nodes, which means that malicious nodes must be a subset of suspicious nodes. METANOIA initiates an alert when a malicious node is recognized and connects these nodes to provide a concise attack scenario graph.

B. Overview

METANOIA is an unsupervised online PIDS that effectively detects intrusion while mitigating the high false positives caused by concept drift. METANOIA adopts a novel anomaly detection paradigm by incorporating incremental learning, i.e., learning changing data distributions and updating model parameters as time windows on streaming data.

The basic architecture of METANOIA is shown in Figure 2, which can be divided into four phases: (I) Preprocess, (II) Anomaly Detection, (III) Malice Investigation, and (IV) State Update. It is important to note that METANOIA iteratively loops the above four phases as the time window progresses. For clarity, we will only describe the overview of METANOIA within a specific time window (denoted as time window T in Figure 2). Details of system design for each phase are given in Section V.

Preprocess (§ V-A). METANOIA processes streaming data at the level of time windows, which is very common in existing work [14, 15, 44]. METANOIA will perform redundancy filtering of events in the window and encode the events in terms of relation, feature, and state to achieve embedding.

Anomaly Detection (§ V-B). When a new edge emerges, METANOIA connects pseudo-edges based on the reachability between rehearsal nodes in the RN Pool and the subject and object of the new edge. Next, METANOIA generates embedding containing the information on rehearsal nodes, the neighborhood structure around the edge, and the states of nodes in the neighborhood. Then, METANOIA reconstructs the edge based on this embedding and generates reconstruction loss with the original edge. Finally, METANOIA identifies AN in this time window by utilizing the reconstruction losses. Finally, these reconstruction losses are utilized by METANOIA to identify the AN in this window.

Malice Investigation (§ V-C). METANOIA selects AN with suspicious state (i.e., the results of encoded states in preprocess) as suspicious nodes. Next, METANOIA constructs a mini-graph of suspicious nodes for the current window based on the Steiner Tree algorithm [45, 46] and merges it with the global mini-graph, which is called mini-graph construction. Afterward, METANOIA scores and filters suspicious nodes at the path level to reduce false positives caused by concept drift as much as possible. Finally, METANOIA treats the retained suspicious nodes as malicious nodes, triggers an alert, and reconstructs the attack scenario graph associated with these malicious nodes.

State Update (§ V-D). METANOIA merges rehearsal

nodes into the previous $RN Pool_{T-1}$ to get a new $RN Pool_T$ for pseudo-edge connections. Following that, METANOIA employs the current $Stream Data_T$ for training the previous $Model_{T-1}$ in order to obtain a $Model_T$ with revised parameters. $Model_T$ is then used to generate reconstruction losses (Phase I) and support incremental learning (Phase IV) for the next $Window_{T+1}$.

V. SYSTEM DESIGN

We will explain the implementation details of each phase of METANOIA in this section.

A. Preprocess

METANOIA constructs a whole-system provenance graph from streaming data collected by logging infrastructures, such as Windows ETW [47], Linux Audit [48], and CamFlow [49]. METANOIA considers three types of kernel objects and eight types of interactions. METANOIA transforms each event into a directed, time-stamped edge, in which the source node represents the event's subject and the destination node represents the object being acted upon. For any event $e \in E$, METANOIA represents it as a quintuple $\langle U_s, U_o, O, T_i \rangle$. U_s and U_o are unique identifiers for the subject and object of e , respectively. O denotes the type of e , and T_i denotes the time when e occurred. Table I shows the events between subjects and objects and the node attributes we consider. As shown in Figure 2 (Phase I), METANOIA will perform redundancy filtering and encoding in preprocessing, as described in more detail below.

1) *Redundancy Filtering*: In order to reduce redundant audit records when detecting and investigating cyber threats, we employed several redundancy filtering techniques from previous works in processing streaming data. Firstly, we implemented the Causality Preserved Reduction (CPR) [50] to aggregate audit records with the same impact scope. For instance, in Figure 1.C, FireFox receives network packets from `nhra.com` up to 198 times in a single data transmission operation. This is because the operating system typically distributes data among multiple system calls proportionally when performing tasks such as file read/write events. We believe that merging such redundant events does not alter the transmission of information. Another type of redundancy [51] that needs filtering involves events between processes and read-only libraries during initialization. To address this, we established a whitelist of trusted libraries (e.g., "libc.so", "libm.so") and removed them without compromising the correctness of causal analysis.

2) *Encoding*: METANOIA primarily encodes events from three perspectives: relation, feature, and state. Firstly, it is necessary to clarify that relation refers to the type of event, feature denotes the attribute of node (e.g., process/file name), and state indicates the semantic states of node.

For any event $e \in E$, METANOIA conducts feature encoding and state encoding for U_s and U_o separately (FE(U_s), SE(U_s), FE(U_o), SE(U_o)), and encodes O as its type (RE(O)). Subsequently, these five encoded results will be concatenated

TABLE I: Entities, their attributes, and event types.

Subject	Object	Events	Entity Attributes
Process	Process	Fork, Clone	Process Name
	File	Read, Write, Mmap, Exec	File Name
	Socket	Sendto, Recvfrom	Src/Dst IP/Port

TABLE II: Suspicious State Transfer Rule. In the second column, S denotes the subject and O denotes the object. In the third column, $S.ss$ and $O.ss$ denote the subject's and object's suspicious state, and β denotes the decay factor.

Event	Direction	Suspicious Delivery
Recvfrom	$O \rightarrow S$	$\beta \cdot \max(O.ss, S.ss) \Rightarrow S.ss$
Read/Mmap/Exec	$O \rightarrow S$	$\beta \cdot \max(O.ss, S.ss) \Rightarrow S.ss$
Write	$S \rightarrow O$	$\beta \cdot \max(O.ss, S.ss) \Rightarrow O.ss$
Fork/Clone	$S \rightarrow O$	$\beta \cdot \max(O.ss, S.ss) \Rightarrow O.ss$

to serve as the final encoding of this event for future use in Section V-B.

Relation Encoding: METANOIA utilizes one-hot encoding to embed events, similar to most PIDSeS [12, 14, 15, 17]. We consider this one-hot encoding approach to be sufficiently simple and effective in assisting the model to differentiate between different types of relations in a flat label space.

Feature Encoding: METANOIA utilizes hierarchical feature hashing [52] to encode node features. Hierarchical feature hashing employs a hash function to map original features into a fixed-size hash space, thereby transforming high-dimensional features into low-dimensional ones. This encoding method is naturally suitable for file paths with hierarchical structures, making it more likely for file names with similar semantics to be mapped to proximate positions in the hash space. For example, the distance between `/usr/local/share` and `/usr/local/lib` in feature space will be less than the distance to `/usr/ports/shells`.

State Encoding: METANOIA encodes the state of nodes from the perspective of information/control flow. METANOIA defines the suspicious node (possibly related to attacks) using a suspicious state SS , a real number ranging from 0 to 1. The closer value to 1 the higher level of suspicion. METANOIA initializes processes and files as benign ($SS = 0$). Given that METANOIA assumes attackers intrude from external sources by default, all sockets are initialized as suspicious ($SS = 1$).

In addition, METANOIA devises **Suspicious State Transfer Rules** to convey the states of streaming data, as illustrated in Table II. For example, if a freshly started benign process like `nginx` ($SS = 0$) reads a file with a suspicious state ($SS = 1$), such as `/tmp/mal.sh`, then `nginx` will inherit the suspicious state.

Finally, due to the issue of dependency explosion, the over-spreading of states may render the node states meaningless. Hence, METANOIA introduces a decay factor β to ensure that the node states decay with the increase in propagation distance. The specific setting of the β is discussed in detail in Section VI.

B. Anomaly Detection

In this section, we sequentially describe the process of Phase II in Figure 2, i.e., pseudo-edge connection, reconstruction

loss generation, and anomalous node identification. In short, METANOIA connects pseudo-edges to introduce anomalous scenario information associated with rehearsal nodes, generates reconstruction loss to determine the abnormality level of the current event, and identifies anomalous nodes in preparation for Phase III.

1) *Pseudo-Edge Connection*: When METANOIA adopts the incremental learning paradigm to address concept drift, it encounters the issue of *catastrophic forgetting*. This situation leads the model to forget the previously learned knowledge as it learns new one. This problem can result in high false positives and significant retraining costs for anomaly detection systems in long-term operation.

Inspired by the classic network architecture ResNet [53], METANOIA attempts to solve the problem by connecting pseudo-edges for scene replay. There are two key insights of METANOIA: (1) *Rehearsal nodes are anomalous yet benign, containing critical information about anomalous scenes*, and (2) *Pseudo-edge connection assist the model in revisiting anomalous scenes and expanding the scope of recollection*. For any event e , METANOIA assesses whether a reachable relationship exists between its entity (U_s or U_o) and the rehearsal nodes in the RN Pool. If so, METANOIA establishes a pseudo-edge between them to replay crucial scene information. METANOIA considers that this method helps the model combat catastrophic forgetting through scene recall and prevent the inclusion of malicious scenes. It should be noted that pseudo-edges are only temporarily constructed during the generation of event embedding and do not affect the original components of the provenance graph.

This subsection presents the principle and method of pseudo-edge construction. The details on how to utilize pseudo-edge information and select rehearsal nodes will be discussed in Sections V-B2 and V-D, respectively.

2) *Reconstruction Loss Generation*: We believe that only by considering all causally related events and their temporal order can one determine whether a node is anomalous. METANOIA employs Temporal Graph Networks (TGN) [54] to reconstruct event types, and generate reconstruction loss (the difference between reconstructed types and actual types).

For each node i seen so far, METANOIA maintains a memory vector s_i representing the node's history in a compressed format. For each event involving node i , a message is computed to update i 's memory. In the case of an interaction event $e_{ij}(t)$ between source node i and target node j at time t , the message $m_i(t)$ can be computed by:

$$m_i(t) = msg_s(s_i(t^-), s_j(t^-), \Delta t, e_{ij}(t)) \quad (1)$$

where $s_i(t^-)$ is the memory of node i just before time t and msg_s is the concatenation operation. The Δt refers to the difference between t^- and t , which METANOIA uses to introduce temporal information. For interaction events involving two nodes i and j , the memories of both nodes are updated after the event. METANOIA updates the node's memory for each event involving the node itself:

$$s_i(t) = mem(m_i(t), s_i(t^-)) \quad (2)$$

where mem is a learnable function and METANOIA uses the GRU [55]. Then, METANOIA generates the final embedding

$z_{ij}(t)$ for edge e_t at any given time t :

$$z_{ij}(t) = \sum_{j \in N(i)} h(s_i(t), s_j(t), e_{ij}(t), v_i(t), v_j(t)) \quad (3)$$

where h is a learnable function, and METANOIA chooses an attention-based Graph Neural Network (GNN) [56]. $N(i)$ refers to all neighboring nodes of node i . e_{ij} refers to the encoding of event e by METANOIA, which is described in detail in Section V-A2. $v_i(t)$ refers to the temporal feature of node i at time t , which is generated after METANOIA processes the timestamp using a simple linear mapping. In summary, METANOIA embeds the events from node historical information ($m_i(t)$), event encoding ($e_{ij}(t)$), and neighborhood structures ($N(i)$).

Finally, METANOIA employs a Multi-Layer Perceptron (MLP) to transform the embedding vector $z_{ij}(t)$ into vector $P(e_t)$. Then METANOIA utilizes cross-entropy to compute the loss between $P(e_t)$ and the observed event type (in one-hot form) as the Reconstruction Loss (RL).

3) *Anomaly Node Identification*: METANOIA identifies anomalous nodes based on the reconstruction loss. Specifically, METANOIA calculates a threshold σ_t in each time window t , which is the mean of all reconstruction losses within that window plus two standard deviations. METANOIA will consider the relevant subjects and objects of all events with reconstruction losses exceeding this threshold σ_t to be anomalous nodes.

C. Malice Investigation

Unlike other existing approaches [1, 12, 14], METANOIA does not directly equate anomaly with maliciousness and issue an alert upon detecting AN but enters a secondary investigation. As shown in Figure 2 (Phase III), METANOIA firstly combines the information of state encoding (Section V-A) to select AN (the output of Phase II) with suspicious states higher than the suspicion threshold γ as suspicious nodes. In other words, suspicious nodes are those nodes that simultaneously exhibit suspicious semantics and anomalous behavior. Next, METANOIA obtains the final malicious nodes through mini-graph construction and path-level filtering oriented towards suspicious nodes. The detailed design is as follows:

1) *Mini-Graph Construction*: Typically, there are multiple suspicious nodes in each time window, and METANOIA posits that these suspicious nodes are not independent of each other. The key insight behind mini-graph construction: *there are the most anomalous and shortest reachable relationships among suspicious nodes*. Based on this insight, METANOIA will construct a mini-tree MT_t for all suspicious nodes within the current window t by the Steiner Tree algorithm [45, 46] combined with reconstruction loss. The Steiner Tree algorithm's primary objective is to locate a tree that encompasses a designated set of specific nodes (i.e., suspicious nodes) in the graph (i.e., provenance graph G_t in time window t) while minimizing the total weight of the tree as much as possible. Due to the interchangeability between maximum and minimum, METANOIA can utilize this algorithm to find the mini-tree MT_t , which contains all suspicious nodes within the time window t and has the largest reconstruction loss sum. For

a new MT_t , METANOIA either merges it into the existing mini-graph MG or creates a new mini-graph containing only MT_t . That is, MT_t is merged into the existing MG :

$$MG = MG \cup MT_t, \text{ if } MG \cap MT_t \neq \emptyset \quad (4)$$

If the new MT_t has no intersection with any MG , then the MT_t is preserved as a new MG .

2) *Path-level Filtering.*: The goal of METANOIA is to achieve precise intrusion detection while mitigating the high false positives problem caused by concept drift. Through observation, METANOIA has identified two typical false positives: (1) New process initiation. Since METANOIA is an anomaly-based detection model, it inevitably identifies unseen processes as suspicious nodes, leading to false alarms. (2) Long-running suspicious processes. Legitimate processes that frequently interact with the external environment may carry a suspicious label for an extended period. METANOIA does not consider them as rehearsal nodes, thus unable to memorize their behavioral characteristics over the long term, resulting in false alarms.

Based on the observation, METANOIA designs a path-level filtering algorithm based on feature scoring to eliminate these two types of false positives, as shown in Algorithm 1. Firstly, for any suspicious node sn_i under time window t , METANOIA employs random walks on its corresponding MG to generate multiple paths (lines 1-3). Each path is comprised of traversed nodes and events, including information such as node indexes, event reconstruction losses, and elapsed time windows. Subsequently, METANOIA scores all paths from four perspectives: volatility, periodicity, heterogeneity, and persistence (lines 7-11). METANOIA considers the path with high volatility (significant reconstruction loss discrepancies), weak periodicity (erratic node behavior), strong heterogeneity (a multitude of non-repeating nodes in the path), and high persistence (long duration) to be more likely traces left by a malicious node. Specifically, METANOIA employs Standard Deviation to measure volatility (line 8), Discrete Fourier Transform to calculate periodicity (line 9), the de-duplicated set of node names divided by the path length as heterogeneity (line 10), and path length as persistence (line 11). As these four features are not on the same scale, METANOIA normalizes each separately (line 12). Finally, METANOIA generates the final path score based on these four features and identifies the suspicious node sn_i with the presence of a path score above the threshold δ (malicious path) as a malicious node (lines 13-15).

3) *Alert & Investigate.*: After identifying a malicious node within a window, METANOIA reconstructs the corresponding attack scenario of that malicious node. Considering the persistence of APT attacks, for those suspicious nodes that are not identified as malicious, METANOIA considers the possibility that they may contain latent malicious semantics (for example, if attackers are still in the discovery phase). To avoid false negatives resulting from learning malicious behavior, METANOIA discards these nodes instead of placing them into the RN Pool.

Typically, attacks span multiple windows, requiring METANOIA to identify correlations between different win-

dows to reconstruct the complete attack scenario. To begin with, METANOIA designates the current window as a malicious window. Next, it traverses preceding windows iteratively to determine if the malicious paths in the preceding windows intersect with those in the malicious window. If so, the preceding windows are also considered malicious. Then, METANOIA merges all malicious paths along with suspicious events (exceeding the reconstruction loss threshold σ in Section V-B2) related to the malicious paths as the reconstructed attack scenario. Lastly, METANOIA triggers an alert and returns the attack scenario reconstructed with the malicious node.

D. State Update

METANOIA integrates incremental learning as a novel paradigm for anomaly detection and therefore requires state update over time, as shown in Figure 2 (Phase IV). Initially, METANOIA identifies anomalous nodes with suspicion below the threshold γ (Section V-C) as rehearsal nodes, merging them with the old $RN\ Pool_{t-1}$ to form the new $RN\ Pool_t$. Subsequently, METANOIA follows the procedure in Section V-B1 to utilize the $RN\ Pool_t$ for pseudo-edge connection. Finally, METANOIA trains the old $Model_{t-1}$ and updates it to the new model $Model_t$ using streaming data from time window t .

If no rehearsal nodes are detected, it indicates that METANOIA ($Model_{T-1}$) is familiar with the data from the time window t or that all anomalous behaviors originate from suspicious nodes. And, METANOIA updates $Model_{T-1}$ only after detecting rehearsal nodes.

VI. EVALUATION

METANOIA is an intrusion detection system designed to address the high false positive problem caused by concept drift. Therefore, we focus on addressing the following questions:

- **RQ 1:** Can METANOIA achieve better detection performance than SOTA methods?
- **RQ 2:** How important are the components we designed for mitigating concept drift?
- **RQ 3:** Can METANOIA effectively reconstruct attack scenarios?
- **RQ 4:** How do hyperparameters affect the performance of METANOIA?
- **RQ 5:** Is METANOIA fast enough to perform realtime detection and investigation?

A. Experiment Protocol

We implemented a METANOIA prototype in Python. We utilized PyG [57] to generate reconstruction losses, Networkx [58] to construct the minimum graph, and GraphViz [59] to visualize the reconstructed attack scenario graph. METANOIA leverages the agents to collect data from monitored hosts. The collected data have the same format as other detection systems [1, 12, 14, 15].

We selected three representative anomaly-based APT online detection systems, namely UNICORN [1], PROGRAPHER [14], and KAIROS [15], as baselines for comparison. And we will compare the window-level detection accuracy with these three and node-level detection accuracy with the latter two. It is noteworthy that PROGRAPHER and KAIROS did not directly evaluate their node-level detection capabilities in the original paper. However, we observed that both reconstruct attack scenarios, aligning with METANOIA’s functionality. Therefore, we considered the nodes involved in reconstructed attack scenarios as the basis for evaluating node-level detection accuracy. We directly used the source code released by UNICORN and KAIROS and employed their default parameters to avoid possible biases. As for PROGRAPHER, since it is not open source, we reproduce it and will release its code. Our experiments were carried out on a server running Ubuntu 18.04 64-bit OS with Intel(R) Xeon(R) Silver 4214R CPU @ 2.40GHz, 256GB memory.

B. Metrics

We define window-level precision as: $\frac{W_{TP}}{W_{TP}+W_{FP}}$, where W_{TP} and W_{FP} are window-level true positives and false positives, respectively. We consider a provenance graph (time window) to be W_{TP} if it contains attack steps and is reported as an alert. Otherwise, we consider it as W_{FP} . We define window-level recall as $\frac{W_{TP}}{W_{TP}+W_{FN}}$, where W_{FN} is the number of window-level false negatives, which contain attack steps but are not identified as alerts. We define window-level accuracy as $Accuracy = \frac{W_{TP}+W_{TN}}{W_{TP}+W_{FP}+W_{TN}+W_{FN}}$ and window-level F1 as $F1 = 2 * \frac{Precision * Recall}{Precision + Recall}$. We consider the definitions of window-level, graph-level, and node-level metrics to be similar, and to save space, we will not repeat the latter two.

C. Datasets

The purpose of METANOIA is to help long-running online detection systems combat the problem of false positives caused by concept drift that requires long-term datasets for evaluation. Given that there are multiple adversarial scenarios designed to mimic real-world Advanced Persistent Threats (APTs) on enterprise networks within the Transparent Computing (TC) program, we choose to employ datasets from DARPA’s TC. Specifically, multiple red teams (e.g., CADETS, ClearScope, and THEIA) launched a series of attacks toward critical services such as web, email, and SSH servers, while engaging in benign activities such as browsing websites, checking emails, and SSH log-ins. The datasets from the third (E3) and fifth (E5) engagements of DARPA TC are publicly accessible [32, 60].

Table III details the statistics from the different datasets, including duration time (specific dates and hours), the number of nodes and edges, the specific attack time and their proportions, as well as the number of attack-related nodes. The open-source report for DARPA TC E3 [60] and E5 [32] show an attack for E3-CLEARSCOPE on April 12, 2018 from 15:19 to 15:24, an attack for E5-CLEARSCOPE on May 17, 2019 from 15:42 to 16:00. However, we couldn’t find any relevant attack records (including file downloading and process creating) in the corresponding log files for this period. Therefore, we do not label it as attack time.

Ground Truth Labeling. In TC, attack activities occurred only in a subset of time windows within a specific day, as shown in Table III. For instance, in our motivating example of Section II, attackers executed `loaderDrakon` in the Firefox memory and escalated privileges for performing memory injection into the `sshd` to write file `sshdlog` between 14:58 and 15:07 on May 15, 2019. DARPA provides ground truth reports to aid us in quickly labeling. For Window-level, METANOIA partitions the streaming provenance logs into time windows and labels windows containing attack behaviors as **attack-related windows** while those lacking such behaviors as **benign windows**. For node-level, we manually identify all crucial nodes involved in attack behaviors as **attack-related nodes**, while labeling other nodes as **benign nodes**.

D. RQ 1: The detection performance of METANOIA

KAIROS [15] is a window-level detection system, THREATTRACE [13] is a node-level detection system, while UNICORN [1] and PROGRAPHER [14] are graph-level detection systems. To ensure fairness, we will compare METANOIA with three baselines at their respective levels to demonstrate the detection performance of METANOIA.

1) *Window-level:* KAIROS detects anomalous windows based on the anomalousness and rareness of nodes. To ensure a fair comparison, we adopted the same time window size (15 minutes) and DARPA dataset for evaluating both KAIROS and METANOIA by calculating precision and recall at the window-level.

According to statistics shown in Table IV, METANOIA outperforms KAIROS comprehensively in both precision and

TABLE III: Summary of the experimental datasets. Columns 1 and 2 indicate the name and duration time of the corresponding dataset. Columns 3 and 4 indicate the number of nodes and edges. Columns 5 and 6 indicate the specific time of attack occurrence and the percentage of the attack time for the whole time. Column 7 indicates the number of attack nodes involved in the attack window.

Dataset	Duration Time	# N	# E	Specific Attack Time	% of Attack Time	# of AN
E3-CADETS	2018/4/2-13 (247h)	613,713	31,573,565	4.6 11:21-12:08 + 4.12 14:00-14:38 + 4.13 9:04-9:30	0.901%	49
E3-ClearScope	2018/2-13 (168h)	369,021	22,254,213	4.11 13:55-14:47	0.892%	23
E3-THEIA	2018/4/3-13 (142h)	1,258,362	44,366,117	4.10 13:41-14:55 + 4.12 12:44-13:26	1.585%	97
E5-CADETS	2019/5/8-17 (240h)	12,893,578	1,003,492,271	5:16 9:32-10:08 + 5.17 10:16-10:55	0.625%	65
E5-ClearScope	2019/5/8-17 (240h)	172,699	151,104,106	5.15 15:39-16:18	0.521%	81
E5-THEIA	2019/5/8-15 (192h)	2,286,124	140,994,662	5.15 14:48-15:07	0.260%	36
Avg	/	2,932,249	232,297,489	/	0.797%	58.5

recall at the window-level. For KAIROS, we replicated and evaluated its performance while **keeping its code and parameters unchanged**. However, its results were worse than those in the paper, which we attribute to three reasons after a detailed investigation. (1) We relabeled the datasets. For instance, in E3-CADETS, attacks occurred on three days, April 6, April 12, and April 13, involving a total of nine time windows. However, KAIROS only considered April 6 and ignored the attacks that occurred during the two days (April 12, and April 13). We relabeled the dataset and evaluated both METANOIA and KAIROS based on this. (2) KAIROS does not distinguish between nodes with the same name. For example, in E5-THEIA, there were a total of 6,647 unique IDs for the Firefox process, but KAIROS grouped them all under one single Firefox process. This causes KAIROS to convey node features incorrectly, which affects the judgment of anomalies. (3) KAIROS relies excessively on training data. KAIROS constructs an anomalous window queue by determining whether there are nodes with anomalousness (high reconstruction error) and rareness (high inverse document frequency, IDF) between different windows. The combination of the latter two factors results in KAIROS being unable to construct an anomalous window queue when attackers employ living-off-the-land attacks (involving no writing of files with special names to the disk). It is important to note that we only evaluated based on the new dataset labeling and did not modify the output of KAIROS.

In terms of precision, METANOIA outperforms KAIROS by 30%. As shown in Table IV, METANOIA generates an average of 6.7 false positives (FPs), which accounts for only 0.9% of the average window count of 691 in the dataset. We believe this demonstrates METANOIA’s ability to efficiently mitigate alarm fatigue issues, allowing analysts to manage alerts more effectively. However, it is important to emphasize that **METANOIA only mitigates false positives caused by concept drift and does not eliminate all false alarms**. When the host’s operating environment changes (such as switching work environments), METANOIA inevitably generates false alarms in the initial stages. As shown in Section IV-B, we use a new anomaly detection paradigm to ensure that METANOIA ceases to generate alerts once the environment stabilizes after switching. But METANOIA will trigger alerts when users engage in rare behaviors (such as suddenly accessing unknown websites and downloading files). Given that such behaviors inherently share similarities with attack behaviors in terms of anomalousness and rareness, METANOIA does not consider handling such false positives

TABLE IV: Experiment results for METANOIA and KAIROS at Window-level.

Dataset	KAIROS			METANOIA		
	TP/FP/FN	Precision	Recall	TP/FP/FN	Precision	Recall
E3-CADETS	7/9/2	0.44	0.88	11/4/0	0.73	1.00
E3-ClearScope	0/0/3	0.00	0.00	2/6/1	0.25	0.67
E3-THEIA	7/6/2	0.54	0.79	9/3/0	0.75	1.00
E5-CADETS	6/10/0	0.38	1.00	6/9/0	0.4	1.00
E5-ClearScope	3/18/0	0.14	1.00	3/13/0	0.18	1.00
E5-THEIA	1/1/1	0.50	0.50	2/5/0	0.29	1.00
Avg	4/7.3/1.3	0.33	0.66	5.5/6.7/0.2	0.43	0.95

to avoid false negatives. This is precisely why false alarms still exist in METANOIA. In Section VI-E, we discuss in detail the importance of METANOIA’s components in mitigating false positives caused by concept drift.

In terms of Recall, METANOIA outperforms KAIROS by 41%. Both METANOIA and KAIROS exhibit poor recall performance on the E3-CLEARSCOPE dataset (0 and 0.67, respectively). E3-ClearScope represents a vulnerability exploitation attack that occurred on the Android platform. On April 11th, the attacker gained control of Firefox by browsing the malicious website `www.mit.gov.jo`. Following that, the attacker downloaded a payload (`shared_files`) and executed it with root privileges. Finally, several attempts were made to load modules and inject processes, but both failed. For unknown reasons, there is no associated process creation behavior (CLONE/FORK/EXECUTE) in ClearScope, which prevents the transmission of inter-process information, significantly impacting METANOIA’s recall performance. However, on the other datasets, METANOIA maintains a recall of 1. Therefore, we believe that METANOIA can detect attack-related windows when supported by a good auditing system (as described in Section III).

2) *Graph-level*: UNICORN transforms streaming data into fixed-size, updatable graph sketches that preserve Jaccard similarity [61] to model a system’s behavior. Each sketch represents a snapshot, depicting an overall summary of the system’s state from the beginning of execution to the time of snapshot capture. PROGRAMMER [14], on the other hand, converts snapshots into fixed-size vectors using graph neural networks `graph2vec` [62] and leverages recurrent neural networks `TextRCNN` [63] to learn benign system behavior changes.

Considering both the above studies are graph-level detection systems, we employed the same evaluation protocol as theirs to guarantee fairness, i.e., determining whether the entire graph is benign or malicious. We classify a graph to be malicious if the time window of the METANOIA alert is a subset of the corresponding time window of the graph. Since

TABLE V: Experiment results for METANOIA, UNICORN and PROGRAPHER at Graph-level.

Dataset	System	Precision	Recall	Accuracy	F1
E3-CADETS	UNICORN	0.31	1.00	0.44	0.47
	PROGRAPHER	0.50	1.00	0.96	0.67
	METANOIA	0.80	1.00	1.00	0.88
E3-ClearScope	UNICORN	1.0	0.75	0.93	0.89
	PROGRAPHER	0.60	1.00	0.98	0.86
	METANOIA	1.00	1.00	1.00	1.00
E3-THEIA	UNICORN	0.67	0.67	0.8	0.67
	PROGRAPHER	0.60	1.00	0.97	0.75
	METANOIA	1.00	1.00	1.00	1.00

UNICORN and PROGRAPHER were evaluated only on the E3 dataset (CADETS, ClearScope, THEIA), METANOIA was also compared on the same dataset to avoid the bias introduced by hyper-parameters tuning.

The experiment results for METANOIA and the other two baselines at graph-level are reported in Table V. METANOIA detects all attacks in three datasets (1.0 recall) and only identified one benign graph in E3-CADETS as malicious, indicating its effectiveness in capturing attack traces while avoiding alert fatigue issues. Further investigation revealed that for the E3-CADETS dataset, METANOIA incorrectly identified the window between 13:45 and 14:15 on 2018.4.13 as a malicious window. This was due to an `imapd` process being identified as a suspicious node during this period, and both the `imapd` process and `sshd` (parent process of malicious process `pEja72ma`) interacted with the same sensitive file, `/etc/spwd.db`, creating a suspicious path, as shown in Figure 3. Additionally, this period is a subset of the period corresponding to a graph, leading to a graph-level false positive. However, in real-world scenarios, attackers may use an injected `sshd` to accomplish multiple tasks across periods. Therefore, this case requires security analysts' intervention to determine whether it is a false positive.

For comparison, UNICORN and PROGRAPHER all perform worse than METANOIA in nearly every metric. We learned that there are two reasons why UNICORN's performance is worse than reported in the original paper: (1) UNICORN was trained using benign datasets under DARPA TC that were not publicly available, leading to bias in the model. (2) UNICORN did not enforce that the testing graphs occur after training and validation, which is a typical Data Snooping [64]. While PROGRAPHER was not open-sourced, we replicated it based on the description of the paper. Keeping the hyper-parameters and necessary components unchanged, we believe the main reason for PROGRAPHER's poorer performance compared to the original paper is that the encoder (Graph2Vec) cannot generate suitable embedding vectors. We primarily used Doc2Vec [65] provided by Gensim [66] in combination with RSG mentioned in PROGRAPHER to generate embedding vectors for snapshots, but the performance was unsatisfactory. We attribute the result to our lack of expertise rather than the original authors, and we intend to open-source the reproduction code of PROGRAPHER.

3) *Node-level:* THREATTRACE is a detection system that assesses the anomalousness of nodes using a multi-model framework. While METANOIA generates a reconstruction graph of the attack scenario corresponding to the mali-

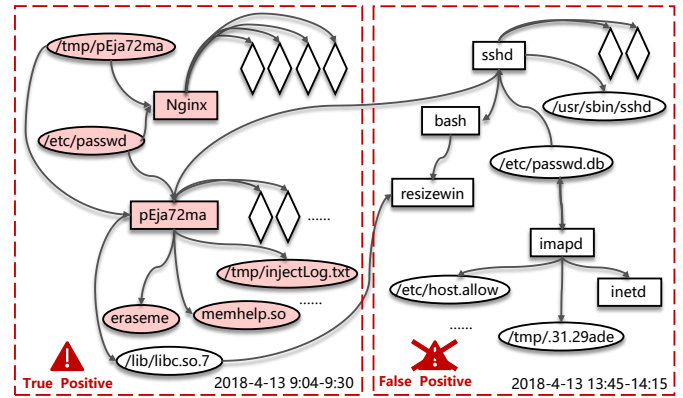

Fig. 3: Reconstructed Attack Scenario. The red dashed box indicates the window-level alerts generated by METANOIA, with the specific time shown in the bottom right corner. On the left are the true positive, and on the right are the false positive. Red nodes represent attack-related nodes, while white nodes represent non-attack-related nodes.

cious windows, allowing for evaluation at the node level for both. THREATTRACE [13] is an open-source system, enabling us to run it directly for comparison. To maintain fairness, we adopted THREATTRACE's way of computing metrics and selected a subset of the DARPA TC dataset used by THREATTRACE.

As shown in Table VI, METANOIA significantly outperforms THREATTRACE in precision (improved by 29%), while slightly lagging in recall (decreased by 4%). Through our further investigation, we identified two main reasons for this discrepancy. Firstly, THREATTRACE employs heuristic extensions to the node-level GroundTruth. Specifically, *THREATTRACE labels malicious nodes and their neighbors within two hops as GroundTruth, even if the neighbor nodes are not directly involved in the attack.* For instance, in E5-THEIA, the number of malicious nodes labeled by THREATTRACE (162,714) is 4,519 times higher than that labeled by METANOIA (36). This GroundTruth leads to poorer recall performance for METANOIA. Secondly, THREATTRACE discretely assesses node anomalies. This results in malicious nodes being identified across various windows without establishing their relationships. In contrast, METANOIA delineates malicious windows, merges malicious paths, identifies malicious nodes, and ultimately generates a reconstructed graph representing malicious behavior. This superior approach contributes to the higher precision of METANOIA, as all the malicious nodes it identifies (positives) are around real malicious nodes (true positives).

In addition, THREATTRACE cannot to reconstruct a complete attack scenario. Node-level information can indeed assist analysts in understanding attack behavior relative to graph-level data. However, when the number of false positive nodes is large, such as the 63,137 false positives in E5-THEIA for THREATTRACE (under such lenient labeling conditions), security analysts are still inundated with alerts, making them difficult to take countmeasures timely.

TABLE VI: Experiment results for METANOIA and THREATTRACE at Node-level.

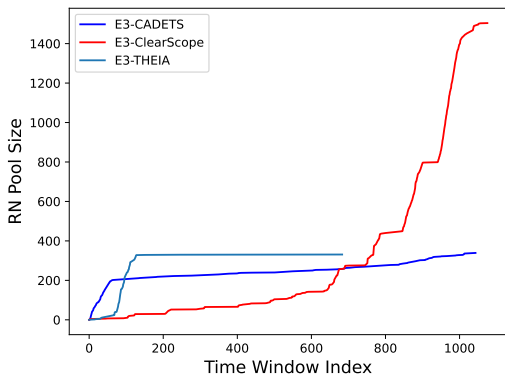

Dataset	System	Precision	Recall	Accuracy
E3-CADETS	THREATTRACE	0.90	0.99	0.99
	METANOIA	1.00	0.92	0.98
E3-THEIA	THREATTRACE	0.87	0.99	0.99
	METANOIA	1.00	0.94	0.99
E5-CADETS	THREATTRACE	0.63	0.86	0.97
	METANOIA	1.00	0.84	0.98
E5-THEIA	THREATTRACE	0.70	0.92	0.99
	METANOIA	1.00	0.90	0.98

E. RQ2: The Importance of METANOIA's Components

The goal of METANOIA is to mitigate the high false positives caused by concept drift in long-running anomaly detection systems. In other words, **METANOIA focuses on reducing false positives caused by concept drift rather than addressing all false positives.** Currently, METANOIA attempts to mitigate high false positives by introducing incremental learning as a new anomaly detection paradigm. However, there are some challenges, as described in Section I, for which we have designed specific components in METANOIA to address them. In this section, we focus on showing the performance and effectiveness of these components and answer questions step-by-step.

How does the size of the RN Pool change over time?

Figure 4 shows the variation trend of the RN Pool size in the corresponding dataset. It can be observed that the RN Pool corresponding to E3-ClearScope exhibits an abnormal growth rate, attributed to the absence of process creation-related events (FORK/CLONE). This results in METANOIA initializing all processes as benign without suspiciousness, and identifying numerous anomaly nodes as rehearsal nodes. In both E3-CADETS and E3-ClearScope, the RN Pool experiences rapid growth in the initial stages, with many nodes being identified as anomalies but benign, effectively aiding METANOIA in building a memory bank to swiftly reduce false alarms. Subsequently, the RN Pool experiences a slow increase as suspicious information propagates rapidly through event interactions, to avoid METANOIA memorizing malicious behaviors.

**Fig. 4:** Growth Trend of RN Pool size over time.

Can the RN Pool be contaminated? From Table VII, we can observe that the constructed RN Pool has no intersection with the attack nodes across almost all datasets. This is attributed to METANOIA's stringent suspicious state

TABLE VII: Contamination analysis of RN Pool.

Dataset	RN Pool Size	# of Attack Nodes (%)
E3-CADETS	339	0 (0%)
E3-ClearScope	1504	12 (0.8%)
E3-THEIA	616	0 (0%)
E5-CADETS	832	0 (0%)
E5-ClearScope	292	0 (0%)
E5-THEIA	331	0 (0%)

TABLE VIII: Impact of fine-tuning the benchmark set for building IDF on KAIROS. In the second column, 4.3-5 refers to the selection of CADETS corresponding to data from April 3 to April 5, 2018, to construct IDF benchmark set.

Dataset	Selected Days	TP/FP/FN	Precision	Recall	Accuracy	F1
E3-CADETS	IDF 4.3-5	4/1/0	0.80	1.0	0.99	0.89
	IDF 4.2-4	4/95/80	0.04	1.0	0.47	0.08
	IDF 4.3-4	4/95/80	0.04	1.0	0.47	0.08

transfer rules in constructing the RN Pool, thereby enabling METANOIA to avoid learning malicious behaviors and introducing false negatives. Prior work [9, 28] suggests that suspicious state transfer captures the essence of intrusion attacks, and METANOIA utilizes this rule to inversely identify rehearsal nodes that can provide replay information of critical scenarios. Additionally, in the case of E3-ClearScope, due to the same reason (absence of events related to process creation), the suspicious state can't transfer effectively, resulting in all attack-related nodes being included in the RN Pool. We attribute this to issues with the auditing system.

Why is KAIROS able to achieve similar precision with METANOIA at the window level? We have evaluated METANOIA and KAIROS at the window level in Section VI-D1. While both exhibit similar precision, their mechanisms for achieving this are different. KAIROS directly determines whether there is an intersection of nodes between different windows that exhibit both anomaly (high reconstruction loss) and rareness (high IDF), thereby constructing an anomalous window queue. We believe that KAIROS can accurately identify these nodes for two reasons: (1) KAIROS aggregates all nodes with the same name into one node, and (2) KAIROS carefully selects the benchmark set for constructing IDF. Upon detailed analysis, we found that all nodes supporting the construction of the anomalous window queue in KAIROS are not present in the benchmark set for constructing IDF. We consider this method relies too heavily on the benchmark set and is overly sensitive. For E3-CADETS, KAIROS used the benchmark set (4.3, 4.4, and 4.5) to build the IDF and tested it on the test set (4.6 and 4.7). As shown in Table VIII, when we fine-tuned the days of the IDF benchmark set, KAIROS produced a significant number of false positives, leading to a substantial decrease in precision. In contrast, METANOIA employs a new anomaly detection paradigm and does not suffer similar effects.

Can pseudo-edge connections, state transfer, and path-level filtering effectively reduce false positives? As mentioned in Section I, we believe that introducing incremental

TABLE IX: Ablation experiments on the effectiveness of METANOIA. 'Incremental Learning' only uses incremental learning as an anomaly detection paradigm. 'w/o Pseudo Edges' disables pseudo-edge connection. 'w/o State Transfer' disables state encoding and suspicious state judgment. 'w/o Path-level Filtering' disables path-leveling filtering.

Dataset	Incremental Learning		METANOIA (w/o Pseudo Edges)		METANOIA (w/o State Transfer)		METANOIA (w/o Path Filtering)		METANOIA	
	Precision	Recall	Precision	Recall	Precision	Recall	Precision	Recall	Precision	Recall
E3-CADETS	0.025	1.00	0.09	1.00	0.16	1.00	0.11	1.00	0.73	1.00
E3-ClearScope	0.011	1.00	0.05	1.00	0.08	1.00	0.07	1.00	0.25	0.67
E3-THEIA	0.039	1.00	0.11	1.00	0.17	1.00	0.10	1.00	0.75	1.00

E5-THEIA	0.008	1.00	0.06	1.00	0.10	1.00	0.12	1.00	0.29	1.00
Avg	0.018	1.00	0.06	1.00	0.10	1.00	0.09	1.00	0.43	0.95

learning as a new paradigm for anomaly detection can mitigate the high false positives problem caused by concept drift. METANOIA combats catastrophic forgetting through pseudo-edge connections (Section V-B1), avoids discrimination paradox through state transfer (Section V-A2), and reduces typical false positives through path-level filtering (Section V-C2). As described in Table IX, we designed corresponding ablation experiments to demonstrate the effectiveness of these three components. It can be seen that incremental learning without any component is the most ineffective, with an average false positive count reaching 340 and an average precision of 0.018. Besides, the ablation of any component results in a significant deterioration in METANOIA's performance, with an average decrease in precision rate of 81% and an average increase of 81 false positives. This is because each component represents a critical solution proposed to address the significant challenges encountered in moving to a new paradigm of anomaly detection. These components do not operate independently, and only by complementing each other can achieve optimal results.

F. RQ3: The Effectiveness of Reconstructing Attack Scenarios

Previous researches [15, 33, 67] indicate that reconstructing attack scenarios is an essential capability for existing detection systems. Unlike rule-based detection methods, anomaly-based detection systems focus more on this ability. The reason for this is that anomaly-based detection systems inherently have a certain amount of false positives, requiring involvement from security analysts. Reconstructing a complete and concise attack scenario can effectively assist security analysts in eliminating false positives and reducing time overhead.

METANOIA has the capability to reconstruct real APT attack scenarios. Due to the operating system's use of multiple cloned subprocesses to collaboratively accomplish tasks, the attack scenario graph often contains numerous nodes with the same name. Therefore, to streamline the graph structure and facilitate better understanding by analysts, METANOIA merges nodes with the same name in the attack scenario graph to achieve optimal presentation. Table X illustrates the sizes of the attack scenario graphs reconstructed by METANOIA from each dataset. We observe that the number of events identified as malicious windows is 18,041 times larger than the merged attack scenario graph. This demonstrates METANOIA's ability to assist security analysts in rapidly comprehending attack scenarios, effectively filtering out false positives, and reducing the workload in "man in the loop".

TABLE X: Statistics of reconstructed attack scenario graphs. The second column is the total number of events in the window identified by METANOIA as malicious. The third column is the initial attack scenario graph. The fourth column is the attack scenario graph of merged nodes with the same name.

Dataset	# of Edges in Windows	Attack Graph		Attack Graph (Merged)	
		Nodes	Edges	Nodes	Edges
E3-CADETS	1,179,901	426	489	101	119
E3-ClearScope	275,209	217	256	41	47
E3-THEIA	1,485,706	193	241	89	104
E5-CADETS	1,763,829	504	560	106	122
E5-ClearScope	3,772,183	698	727	143	159
E5-THEIA	1,128,869	184	213	52	69
Avg	1,600,949	370	414	87	103

G. RQ4: The Influence of Hyper-parameters

We now analyze the impact of four key parameters on the effectiveness of METANOIA. Considering efficiency, we select only day 4.6 of the E3-CADETS dataset as the evaluation dataset. We independently vary the parameters to examine the influence of each parameter and the experimental results are shown in Figure 5.

The decay factor β refers to the decay rate of node suspicion. A smaller decay factor leads to a faster decrease in node suspicion, causing METANOIA to select more nodes. Besides, METANOIA determines if an event is anomalous through the event anomaly threshold σ , which is composed of the window's mean value of reconstruction loss plus variance. A higher abnormal threshold results in METANOIA retaining more anomaly events. Simultaneously, METANOIA determines if a path is anomalous through the path-level scoring threshold δ . A higher δ leads to METANOIA retaining less anomalous paths. As illustrated in Figures 5(a), 5(b), and 5(c), with the increase of the decay factor, event anomaly threshold, and path-level scoring threshold, the precision of METANOIA increases while the recall decreases. At last, METANOIA determines if a node is suspicious through the node suspicion threshold γ . A higher γ leads to METANOIA retaining more suspicious nodes. As shown in Figure 5(d), with the increase of the node suspicion threshold, the precision of METANOIA decreases while the recall increases.

In the end, we choose the decay factor β as 0.95, the event anomaly threshold σ as mean reconstruction loss plus 2 standard deviations, the path-level scoring threshold δ as 0.7 and the node suspicion threshold γ as 0.5.

Fig. 5: Impact of decay factor β , event anomaly threshold σ , path-level scoring threshold δ and node suspicion threshold γ . The four metrics corresponding to each parameter are, from left to right, Precision, Recall, Accuracy, and F1-Score.

TABLE XI: Overhead of each component.

Component	Mean Duration	Max Duration
Preprocess	16.71s	93.37s
Anomaly Detection	12.65s	135.91s
Malice Investigation	42.93s	107.12s
State Update	62.34s	509.03s
Total	134.63s	745.43s

H. RQ5: The Overhead of METANOIA

In this section, we evaluate the overhead of METANOIA, an online anomaly detection system that applies incremental learning. In this section, we set the time window to 15 minutes and measure the runtime overhead of each component, as shown in Table XI. When processing streaming logs, METANOIA requires an average of only 144.58 seconds (excluding state updates) to detect malicious windows and generate attack scenario graphs. This is significantly smaller than the duration of the window (15 minutes), demonstrating that METANOIA is a real-time anomaly detection system. Furthermore, considering extreme scenarios, we also evaluate the time overhead of METANOIA under the window with the most events. We selected the time window of 2019/5/15 23:41-23:56 under E5-CADETS, which contains 1,549,130 events, and METANOIA can complete the detection and investigation tasks within the corresponding time window, as shown in Table XI.

VII. DISCUSSION

Evasion Attack. Evasion attack refers to the actions taken by the attacker to mimic benign behavior to deceive detection systems during an attack. While evasion attacks pose a threat to all PIDSes, evading anomaly-based PIDSes is not straightforward. Therefore, to mimic benign behavior, attackers need to carefully orchestrate their attack actions, ensuring that malicious behavior exhibits benign features at the log level while maintaining their attack objectives. This requires attackers to have a deep understanding of both the target system’s benign behavior and the mechanics of running PIDSes. Previous work [17] has demonstrated that existing graph-based adversarial attacks cannot evade the detection of PIDSes because the provenance graphs have more structural features and time constraints. A recent robustness study [68] has indicated that evasion attacks can be achieved by automatically modifying system logs to evade existing PIDSes and have released evasion datasets based on DARPA E3-THEIA.

However, KAIROS pointed out that this dataset only includes a small portion of the attack activities described in the DARPA ground truth, rather than the complete attack traces included in the original DARPA dataset. Further investigation confirmed this, and we did not proceed with further evaluation.

Poisoning Attack. If an attacker can poison the training data to contain malicious activity for model learning, then future attacks will go undetected. To the best of our knowledge, SIGL [17] is the only PIDS that evaluates its robustness against data poisoning in-depth, but only for the software installation scenario. ShadeWatcher [12] inserts attack data from one day during training and demonstrates that it can still detect the corresponding attack. We performed a similar evaluation and also obtained good detection results. METANOIA adopts a new anomaly detection paradigm that requires replaying scenarios to combat catastrophic forgetting and is therefore more sensitive to poisoning attacks. METANOIA starts from the opposite side of the suspicious information flow to avoid the discrimination paradox and thus combat the poisoning attack.

VIII. RELATED WORK

In terms of detection methods, existing PIDSes can be categorized as heuristic-based and anomaly-based. Heuristic-based PIDSes [2, 7, 8, 28, 69] use empirical knowledge to construct matching rules to find known attacks in the provenance graph. However, they have difficulties in detecting unknown attacks and extending scale. Anomaly-based PIDSes detect intrusions by identifying deviations from normal behavior. Besides, offline PIDSes [12, 17, 18], due to their high operational overhead, fail to achieve efficient real-time intrusion detection. Online PIDSes [1, 13, 14] relies on a fixed-size training set and cannot effectively address the problem of concept drift. UNICORN [1] combats concept drift by gradual forgetting but causes key information to decay with duration. KAIROS [15] relies on the intervention of analysts to re-train the model to combat concept drift, resulting in breaking attack-agnostic and high training costs. Although KAIROS acknowledges this issue in the paper, it does not provide a targeted solution, leaving it for future work.

Moreover, previous PIDSes [1, 10, 11, 30] required manual investigation of large-scale provenance graphs, rendering them impractical for real-world use. Recently, THREATTRACE [13] and SHADEWATCHER [12] began identifying anomalies at the node level, but they cannot reconstruct complete attack

scenarios like METANOIA. SIGL [17] attempts to generate graphs for software installation, but it struggles to scale to full-system intrusion detection. PROGRAPHER [14], on the other hand, sorts the root subgraphs (RSGs) in snapshots by anomaly severity to help narrow down the scope of the investigation but loses the connection between multiple snapshots. Meanwhile, KAIROS [15] attempts to reconstruct attack scenarios in anomaly queues using community discovery algorithms but can only generate multiple star-shaped small attack scenarios (according to its open-source results).

In conclusion, METANOIA is the first intrusion detection system for concept drift mitigation adapting a new anomaly detection paradigm with the ability to reconstruct concise and effective attack scenario graphs.

IX. CONCLUSION

METANOIA is the first lifelong anomaly detection and investigation system that utilizes incremental learning as a new paradigm to address the high false positive problem caused by concept drift. Our evaluations demonstrate that METANOIA can monitor systems over long periods and achieve optimal performance.
