This Letter reports the precise measurement of reactor antineutrino spectrum and flux based on the full data set of 4.7 million inverse-beta-decay (IBD) candidates collected at Daya Bay near detectors. Expressed in terms of the IBD yield per fission, the antineutrino spectra from all reactor fissile isotopes and the specific  $^{235}$ U and  $^{239}$ Pu isotopes are measured with 1.3%, 3% and 8% uncertainties respectively near the 3 MeV spectrum peak in reconstructed energy, reaching the best precision in the world. The total antineutrino flux and isotopic  $^{235}$ U and  $^{239}$ Pu fluxes are precisely measured to be  $5.84 \pm 0.07$ ,  $6.16 \pm 0.12$  and  $4.16 \pm 0.21$  in units of  $10^{-43}$ cm<sup>2</sup>/fission. These measurements are compared with the Huber-Mueller (HM) model, the reevaluated conversion model based on the Kurchatov Institute (KI) measurement and the latest Summation Model (SM2023). The Daya Bay flux shows good consistency with KI and SM2023 models, but disagrees with HM model. The Daya Bay spectrum, however, disagrees with all model predictions.

Nuclear reactors produce an essentially pure flux of electron antineutrinos  $(\overline{\nu}_e)$  via β-decay processes of fission isotopes. They have been one of the most powerful tools to study neutrino properties from neutrino discovery  $[1]$  to neutrino oscillations  $[2-5]$  $[2-5]$ , and are expected to continue making significant contributions in the upcoming precision era  $[6-11]$  $[6-11]$ . Accurate knowledge of the energy spectrum and flux of reactor  $\bar{\nu}_e$  are important for precision oscillation measurements.

Despite many advances in understanding the reactor  $\overline{\nu}_e$  spectrum and flux from both experimental measurements [\[12–](#page-6-8)[21\]](#page-6-9) and theoretical calculations, including conversion models [\[22](#page-6-10)[–24\]](#page-6-11) and summation models [\[25–](#page-6-12)[27\]](#page-6-13), there remain anomalies to be resolved. The measured reactor  $\overline{\nu}_e$  flux rate has an overall 6% deficit with respect to the Huber-Mueller (HM) model [\[28\]](#page-6-14). This rate anomaly tends to vanish when confronted with the recent measurement at the Kurchatov Institute (KI) [\[24\]](#page-6-11) which claims an over-estimation of the <sup>235</sup>U contribution in the HM model as first indicated by Daya Bay in Ref. [\[16\]](#page-6-15). The measured reactor  $\overline{\nu}_e$  spectrum shape exhibits typically an excess around 5 MeV not found in both conversion and summation model predictions [\[15,](#page-6-16) [17,](#page-6-17) [19–](#page-6-18)[21\]](#page-6-9). The latest summation model [\[26\]](#page-6-19), noted as SM2023, has been improved with refined  $\beta$ -decay formalism and recent evaluated nuclear decay data compared to previous SM2018 model [\[25\]](#page-6-12), and gives the complete error budget of the summation method for the first time. An alterna-

tive summation model, noted as SM2023\*, incorporates a single empirical parameter  $\alpha$  in the  $\beta$ -transition model that corrects for the pandemonium effect and missing transitions [\[26\]](#page-6-19); and it shows good agreement with the STEREO  $\bar{\nu}_e$  spectrum with  $\alpha = 0.7$  [\[29\]](#page-6-20). These recent developments provide insight into the possible origin of the anomalies in spectrum and flux, however, definitive conclusions remain elusive due to limited precision. More precise measurements of reactor  $\overline{\nu}_e$  spectrum and flux would provide further understanding of these discrepancies. Such measurements also offer accurate data-driven inputs for other experiments aiming at high-precision neutrino oscillation studies such as JUNO [\[6–](#page-6-6)[9\]](#page-6-21), and a benchmark for future elastic neutrino-nucleus scattering experiments at low-enriched uranium (LEU) reactors [\[30\]](#page-6-22). Moreover, such measurements offer valuable inputs for sterile neutrino searches, as well as applications in nuclear science and reactor safety [\[30,](#page-6-22) [31\]](#page-6-23).

This Letter reports a comprehensive measurement of reactor  $\overline{\nu}_e$  spectrum and flux at Daya Bay, using data collected over the full experimental operation period. The Daya Bay experiment, consisting of 8 antineutrino detectors (ADs) deployed in 2 near sites (2 ADs each) and 1 far site (4 ADs), detects  $\overline{\nu}_e$  from 6 commercial reactor cores [\[32\]](#page-6-24). In commercial LEU reactors, four parent isotopes, i.e.  $^{235}$ U,  $^{238}$ U,  $^{239}$ Pu and  $^{241}$ Pu, contribute more than 99.7% of the  $\overline{\nu}_e$  flux. Utilizing the gadolinium doped liquid scintillator (Gd-LS) technology, Daya

Bay detects  $\overline{\nu}_e$  via the inverse beta decay (IBD) reaction, i.e.  $\overline{\nu}_e + p \rightarrow e^+ + n$ , with a prompt signal of positron and a delayed signal of neutron captured primarily on Gd (n-Gd). The experiment operated for 3158 days from 2011 to 2020 and accumulated about 4.7 million n-Gd IBD candidates with its near detectors. The total reactor  $\overline{\nu}_e$  spectrum and flux are measured in terms of the IBD yield aggregating all isotope contributions. The total spectrum and flux are then decomposed into <sup>235</sup>U and <sup>239</sup>Pu isotopic contributions using the fuel evolution analysis technique developed by Daya Bay [\[16,](#page-6-15) 17]. To examine the data to model consistency, the Daya Bay spectra and fluxes are compared with predictions based on the most representative models to date, including HM, KI, and SM2023. Furthermore, the spectra are unfolded from reconstructed energy to neutrino energy, where the unfolding technique is applied for multiple spectra together, for the first time, by considering their correlation. and a delayed signal of neutron captured primarily on<br>
Cd (n-Gd). The experiment operated for 3158 days from<br>
2011 to 2020 and accumulated about 4.7 million n-Gd<br>
HB candidates with its near detectors. The total race-<br>
to

The reactor  $\overline{\nu}_e$  IBD yield, denoted as  $\sigma_f$ , can be understood as the number of  $\overline{\nu}_e$  per fission multiplied by the IBD cross section. It is experimentally defined at Daya Bay for each AD as,

<span id="page-2-0"></span>
$$
\sigma_f = \frac{N_{\text{IBD}}}{\epsilon_{\text{IBD}} N_p T_{\text{eff}} \sum_{r=1}^6 \frac{W_{\text{th},r}}{4\pi L_r^2 \overline{E}}}. \tag{1}
$$

The  $N_{\rm IBD}$  stands for the number of IBD events obtained based on IBD candidates after the non-equilibrium and spent nuclear fuel corrections, background subtraction, as well as oscillation correction. The denominator of  $Eq.(1)$ represents the effective fission number, in which  $\epsilon_{IBD}$  is the IBD detection efficiency,  $N_p$  is the number of target protons,  $T_{\text{eff}}$  is the effective livetime,  $W_{\text{th},r}$  is the reactor thermal power,  $L_r$  is the distance between reactor and detector,  $\overline{E} = \sum_i f_{i,r} e_i$  is the average energy release per fission with  $f_{i,r}$  the fission fraction and  $e_i$  the energy release per fission. The subscript indices  $i$  and  $r$  stand for the isotope and reactor core respectively.

The systematic uncertainty in the IBD yield measurement arises from the detector, reactor and background effects, with the detector effects being the dominant factor. The detector uncertainty in the flux rate is 1.2%, incorporating contributions from the proton number, detection efficiency and IBD cross section [\[33\]](#page-6-25). The uncertainties of the energy scale [\[34\]](#page-6-26), energy non-linearity [\[35\]](#page-6-27) and inner acrylic vessel effect [\[32\]](#page-6-24) are further taken into account in the spectrum shape measurement. The uncertainties of the reactor power and the fission fraction are 0.5% and 5% respectively and are treated as reactor-uncorrelated. The energy release per fission and its uncertainty are taken from Ref. [\[36\]](#page-6-28). The uncertainties associated with non-equilibrium and spent nuclear fuel effects are both 30% [\[32,](#page-6-24) [34\]](#page-6-26). The uncertainties related to background and oscillation parameters are taken from Ref. [\[37\]](#page-6-29).

In this analysis, the IBD events are classified into 25 bins according to the reconstructed energy of IBD

<span id="page-2-1"></span>FIG. 1. The total IBD yield spectrum measured at Daya Bay is shown as the black points in the top left panel, in comparison with HM (red)  $[22, 23]$  $[22, 23]$  $[22, 23]$  and SM2023 (blue)  $[26]$  models. The ratio between data and HM model is shown in the bottom left panel, as well as the ratio of SM2023 to HM. The top right panel shows the flux rate comparison between Daya Bay and models, including HM  $(6.15 \pm 0.15)$ , KI  $(5.90 \pm 0.14)$  and SM2023  $(5.92 \pm 0.19)$  in units of  $10^{-43}$ cm<sup>2</sup>/fission. The error bars in the data points represent the square root of the diagonal elements of the covariance matrix for the total spectrum, incorporating both statistic and systematic uncertainties. The error bands for different models reflect the uncertainties inherent to each specific model.

prompt signals from 0.7 to 8 MeV: 1 bin in 0.7-1.25 MeV, 23 equal bins in 1.25-7 MeV and 1 bin in 7-8 MeV. According to the definition of  $Eq.(1)$  $Eq.(1)$ , Daya Bay measures the total IBD yield spectrum  $s_f$  using the data of all near ADs, as shown in Fig. [1.](#page-2-1) Its precision reaches about 1.3% at the typical reconstructed peak energy around 3 MeV, where the systematic uncertainty is dominant.

In comparison with the HM model, the measured total spectrum shows a disagreement of more than  $5\sigma$  significance with most notably a 8% deficit below 4 MeV in terms of reconstructed energy. The SM2023 prediction matches the Daya Bay spectrum better overall at  $1.2\sigma$ significance but shows a worse agreement around the 5 MeV region.

By integrating all energy bins, the total IBD yield  $\sigma_f$ is measured to be  $[5.84 \pm 0.07] \times 10^{-43}$ cm<sup>2</sup>/fission, where the systematic uncertainty is dominant and the statistic uncertainty contributes less than 5% of the total uncertainty budget. As shown in the right panel of Fig. [1,](#page-2-1) the Daya Bay flux shows 5.0% deficit with respect to HM model, while it is consistent with KI and SM2023 models.

By factorizing out the rate difference from models to Daya Bay data, a shape-only comparison is therefore per-

<span id="page-3-0"></span>FIG. 2. The extracted  $^{235}$ U (left) and  $^{239}$ Pu (right) IBD yield spectra in terms of reconstructed energy of prompt signals are shown as black points. For comparison, the HM and SM2023 predictions are drawn in red and blue respectively. The SM2023\* with the empirical parameter  $\alpha = 0.7$  is drawn in magenta. The ratios between data and the HM model are shown in the bottom panels, as well as the ratios of SM2023 and SM2023\* to HM. The error bars for the data points represent the square root of the diagonal elements of the covariance matrix, while the error band illustrates the uncertainty associated with models. The error bars in the data points represent the square root of the diagonal elements of the covariance matrix for the extracted spectra. The error bands for HM and SM2023 predictions reflect the uncertainties inherent to each model. Only central values are plotted for SM2023\*.

formed. And it turns out that the Daya Bay spectrum shape shows a clear excess around 5 MeV with respect to the HM model at more than  $5\sigma$  significance and the SM2023 model at  $3\sigma$  level.

The total IBD yield can be considered as the combination of the four major isotopic yields from  $^{235}$ U,  $^{238}$ U, <sup>239</sup>Pu and <sup>241</sup>Pu. Each nuclear isotope yields unique  $\bar{\nu}_e$ spectrum and flux due to different fission yields and beta decay branches. With the burning of reactor fuel, the fraction of isotopes evolves, inducing an evolution of the total IBD yield. The effective fission fraction  $F_i$  viewed by one AD is defined as

$$
F_i = \sum_{r=1}^{6} \frac{W_{\text{th},r} f_{i,r}}{L_r^2 \sum_i f_{i,r} e_i} / \sum_{r=1}^{6} \frac{W_{\text{th},r}}{L_r^2 \sum_i f_{i,r} e_i},\tag{2}
$$

to study the IBD yield evolution. In commercial reactors, during one fuel cycle, the <sup>235</sup>U fraction decreases monotonically, and the <sup>238</sup>U fraction remains approximately constant, while the  $^{239}$ Pu and  $^{241}$ Pu fractions both increase monotonically. Based on the data from all near ADs, the average effective fission fractions of the 4 isotopes are determined at Daya Bay to be  $\overline{F}_{235}$  :  $\overline{F}_{238}$  :  $\overline{F}_{239}$ :  $\overline{F}_{241} = 0.564$ : 0.076: 0.304: 0.056.

The  $F_{239}$  is chosen to represent the fuel evolution status. In the following analysis, the  $F_{239}$  is first calculated in a weekly basis; then 20 groups are defined based

on the weekly  $F_{239}$  values; the IBD data is then categorized into the 20 groups, leading to an evolved IBD yield with  $F_{239}$ . The evolution of the IBD yield rate can be approximated with a linear relation with respect to  $F_{239}$ , where the slope  $d\sigma_f/dF_{239}$  is determined to be  $[-1.96 \pm 0.11(stat.) \pm 0.07(syst.)] \times 10^{-43} \text{cm}^2/\text{fission}.$ 

The evolution of the total IBD yield spectrum  $s_f$  enables a decomposition of the isotopic spectra, denoted as  $s_i$ , according to the following  $\chi^2$  analysis,

<span id="page-3-1"></span>
$$
\chi^2 = \chi^2(\mathbf{s}_f, \mathbf{F}, \mathbf{s}_i, \boldsymbol{\epsilon}) + \chi^2(\mathbf{s}_{238}, \mathbf{s}_{241}). \tag{3}
$$

The  $\chi^2$  analysis constructs for each  $F_{239}$  group the difference between measured total spectrum  $(s_f)$  and corresponding prediction that is the combination of isotopic spectra  $(s_i)$  according to the effective fission fractions **F**. The  $\epsilon$  represents nuisance parameters encompassing systematic uncertainties from the reactor, detector and background [\[32,](#page-6-24) [33,](#page-6-25) [37\]](#page-6-29). The evolution of isotopic fission fractions is degenerate, because <sup>239</sup>Pu and <sup>241</sup>Pu fractions evolve in a similar manner, and <sup>238</sup>U fraction is stable during the fuel burning. In order to reduce the degeneracy and extract <sup>235</sup>U and <sup>239</sup>Pu spectra, external constraints based on HM model are introduced on  $^{238}$ U and  $^{241}$ Pu spectra through  $\chi^2(\mathbf{s}_{238}, \mathbf{s}_{241})$ , given that  $^{238}$ U and  $^{241}$ Pu are minor contributions at Daya Bay. The external constraints are loosely set by considering enlarged uncertainties with respect to HM original ones.

The shape uncertainty of <sup>238</sup>U spectrum is set to be 10- 35% in 0.7-8 MeV, and the rate uncertainty is set to be 10%, which covers the uncertainties from data and also the difference between data and model [\[38\]](#page-6-31). The uncertainty of  $241$ Pu spectrum is set to be 7-35\% for the shape, and 10% for the rate. Consistent results are obtained when the SM2023 model replaces the HM model in the  $\chi^2(\mathbf{s}_{238}, \mathbf{s}_{241})$  term.

The extracted <sup>235</sup>U and <sup>239</sup>Pu spectra, i.e.  $s_{235}$  and  $s_{239}$ , are shown in Fig.2. The <sup>235</sup>U and <sup>239</sup>Pu spectra reach unprecedented precision of 3% and 8%, respectively, in the 3 MeV region, leading to a 15% improvement compared to previous Daya Bay results [17]. The statistical uncertainty still contributes more than 50% for both spectra.

The <sup>235</sup>U spectrum measured at Daya Bay differs from HM model with a deficit below 4 MeV with more than  $4\sigma$  significance. However, it differs from SM2023 model most notably with an excess between 5 and 7 MeV which reaches about  $3\sigma$  significance. The SM2023<sup>\*</sup> model, despite showing agreement with the STEREO 235U spectrum  $[29]$ , disagrees with the Daya Bay  $^{235}$ U spectrum above 5 MeV as illustrated in Fig.2. The precision of the Daya Bay <sup>239</sup>Pu spectrum is insufficient to differentiate between models. shape, and 10% for the rate. Consistent results are obtained when the SM2023 model replaces the HM model in the  $\chi^2$ (s<sub>338</sub>, s<sub>241</sub>) term.<br>
In the  $\chi^2$ (s<sub>338</sub>, s<sub>241</sub>) term. The extracted <sup>239</sup>U and <sup>239</sup>Pu spectra, i

In terms of the shape-only comparison, the Daya Bay <sup>235</sup>U and <sup>239</sup>Pu spectra differ from both HM and SM2023 models with a bump around 5 MeV. The local shape-only discrepancy around 5 MeV for <sup>235</sup>U spectrum is quantified at  $4\sigma$  level when comparing the Daya Bay measurement with both HM and SM2023 models, while that for <sup>239</sup>Pu spectrum is less than  $2\sigma$  due to the relatively large uncertainty in the measurement.

The fission fractions of  $^{239}$ Pu and  $^{241}$ Pu exhibit an approximate proportionality. Thus, as proposed in Ref. [\[17\]](#page-6-17), the reconstructed energy spectra of <sup>239</sup>Pu and <sup>241</sup>Pu can be treated as a single combined component, named as Pu combo. This is defined as  $s_{\text{comb}} = s_{239} + k s_{241}$ , where the  $s_{\text{comb}}$  stands for the spectrum of Pu combo and the coefficient  $k = 0.185$  is derived by fitting the correlation between  $F_{239}$  and  $F_{241}$ . The Pu combo approach reduces the reliance on the model for  $s_{241}$  and the relative uncertainty in  $s_{\text{comb}}$  is 30% less than that of  $s_{239}$  with negligible impact on  $s_{235}$ . The Supplemental Material contains the  $s_{\text{comb}}$  results.

In analogy with the spectrum decomposition, the  $^{235}\rm{U}$  and  $^{239}\rm{Pu}$  flux rates, denoted as  $\sigma_{235}$  and  $\sigma_{239},$ can also be extracted through a  $\chi^2$  analysis similar to Eq. $(3)$  by replacing 25 energy bins by an integrated bin. The rate decomposition gives  $\sigma_{235}$  and  $\sigma_{239}$  respectively as  $[6.16 \pm 0.04(stat.) \pm 0.08(syst.) \pm 0.08(model)]$ and  $[4.16 \pm 0.07(stat.) \pm 0.09(svst.) \pm 0.18(model)] \times$  $10^{-43}$ cm<sup>2</sup>/fission, as shown in Fig[.3.](#page-4-0) The systematic uncertainty and the uncertainty from model constraint of <sup>238</sup>U and <sup>241</sup>Pu are equally dominant for  $\sigma_{235}$ , while the uncertainty from model constraint is dominant for  $\sigma_{239}$ .

<span id="page-4-0"></span>FIG. 3. The extracted isotopic reactor  $\bar{\nu}_e$  fluxes of <sup>235</sup>U and <sup>239</sup>Pu in terms of IBD yield are represented by the black point. The green contours indicate the  $\sigma_{235}$  and  $\sigma_{239}$  twodimensional allowed regions with 1, 2, and  $3\sigma$  significance. For comparison, the HM, KI and SM2023 model values are provided for  $\sigma_{235}$  as  $6.62 \pm 0.14$ ,  $6.27 \pm 0.13$  and  $6.16 \pm 0.20$ , and for  $\sigma_{239}$  as  $4.34 \pm 0.11$ ,  $4.33 \pm 0.11$  and  $4.41 \pm 0.15$ , in units of  $10^{-43}$ cm<sup>2</sup>/fission.

The Daya Bay <sup>235</sup>U flux shows 7.0% deficit in comparison with the HM value with about  $3\sigma$  significance, while it is only 1.8% lower to the KI prediction and well consistent with the SM2023 prediction. The Daya Bay <sup>239</sup>Pu flux shows respective 4.1%, 3.9% and 5.7% deficit to HM, KI and SM2023 model predictions in this analysis with full data set, while it was consistent with models in previous measurements using partial data [\[16,](#page-6-15) [17\]](#page-6-17). However, considering its relatively large uncertainty, this deficit has only about  $1\sigma$  significance.

spectrum point. The green contours index<br>
inferentiate the *T* compariso Thanks to the flux decomposition analysis, Daya Bay is able to examine the possible contributing isotopes responsible for the reactor antineutrino anomaly in total rate with respect to HM model. Hence, several hypothesis tests are performed. In the previous Daya Bay publication [16], only HM central values are considered in the hypothesis test, whereas a more inclusive approach is adopted here by also taking into account the uncertainties of the HM model. Compared to the case where both <sup>235</sup>U and <sup>239</sup>Pu contribute to the deficit in total rate, the hypothesis of  $^{235}$ U as the sole contributor is slightly disfavored by  $0.9\sigma$ ; the hypothesis of <sup>239</sup>Pu as the sole contributor is more significantly disfavored by 2.6 $\sigma$ ; moreover, the hypothesis of the four isotopes as the contributors is merely disfavored by  $1.4\sigma$ . Due to the deficits observed in both <sup>235</sup>U and <sup>239</sup>Pu in the final data set, Daya Bay has no strong preference for <sup>235</sup>U as the sole offending isotope in HM prediction.

The aforementioned measurements on total, <sup>235</sup>U or <sup>239</sup>Pu IBD yield spectra are achieved in terms of reconstructed energy for positron signals, which contains detector response effects, such as energy scale nonlinearity and resolution. The neutrino energy spectrum can be obtained by applying unfolding technique, such as SVD regularization [\[39\]](#page-6-32), Wiener SVD [\[40\]](#page-6-33) and Bayesian iteration [\[41\]](#page-6-34) methods. The unfolded neutrino energy spectrum facilitates a direct comparison with models or experiments, and can also serve as an input spectrum for other reactor neutrino experiments.

As Daya Bay extracts simultaneously the reconstructed energy spectra of  $^{235}$ U and  $^{239}$ Pu, where correlation exists between  $\boldsymbol{s}_{235}$  and  $\boldsymbol{s}_{239},$  the correlation should be taken into account when performing unfolding. In addition, as shown in reference [\[42\]](#page-6-35), a generic unfolded neutrino energy spectrum  $(s_g^{\nu})$  can be constructed primarily based on Daya Bay's total spectrum $(s_f^{\nu})$ , with isotopic spectra  $(s_i^{\nu})$  as corrections according to the fission fraction difference between experiments. In this context, the correlation among the Daya Bay reconstructed energy spectra of  $s_f$ ,  $s_{235}$  and  $s_{239}$  should be all included when performing unfolding. structed energy for positron signals, which contains declared energy by positron signals, which contains declared by applying unifolding technique such as SVD regularization [39], Wiener SVD [40] and Bayesian iretarion en

The Wiener-SVD method achieved a smaller Mean Squared Error (MSE) than other methods in the previous Daya Bay analysis where each spectrum was unfolded individually [\[42\]](#page-6-35). The correlation among spectra affects the Wiener filter undesirably but does not affect the traditional SVD regularization. Therefore, the SVD regularization method is adopted to unfold the  $s_f$ ,  $s_{235}$ and  $s_{239}$  together, which is achieved by minimizing the following  $\chi^2$ ,

$$
\chi^2 = \left(\mathbf{S} - \mathbf{R}\mathbf{S}^{\nu}\right)^T \mathbf{V}^{-1} \left(\mathbf{S} - \mathbf{R}\mathbf{S}^{\nu}\right) \n+ \tau \left(\mathbf{C}\mathbf{S}^{\nu}\right)^T \left(\mathbf{C}\mathbf{S}^{\nu}\right).
$$
\n(4)

S is composed of the three reconstructed energy spectra,  $s_f$ ,  $s_{235}$  and  $s_{239}$ , and  $S^{\nu}$  is composed of the corresponding neutrino energy spectra,  $s_f^{\nu}$ ,  $s_{235}^{\nu}$  and  $s_{239}^{\nu}$ . V is the covariance matrix of the three reconstructed energy spectra.  $\bf{R}$  is the response matrix, which contains the conversion relation between reconstructed energy and neutrino energy, and it contains three sub-matrices for the three spectra.  $\tau$  is the regularization strength that minimizes the MSE between data and the model.  $C$  is composed of three second-order derivative matrices arranged diagonally, through which the smoothness of each individual spectrum is imposed. The total,  $^{235}$ U and  $^{239}$ Pu spectra are unfolded together, bringing about the neutrino energy spectra as presented in Fig. [4.](#page-5-0) Consistent results are obtained when using different models for the MSE minimization. The additional smearing matrices and covariance matrices associated with the unfolded neutrino energy spectra, as well as the unfolding inputs can be found in Supplemental Materials.

<span id="page-5-0"></span>FIG. 4. Unfolded neutrino energy spectra for the overall,  $^{235}$ U and <sup>239</sup>Pu IBD yields. The unfolding imposes smoothness condition while the characteristic spectral features persist in the energy range between 5 and 7 MeV. The error bars for the data points represent the square root of the diagonal elements of the covariance matrix.

In summary, this Letter presents a comprehensive measurement of reactor  $\overline{\nu}_e$  spectrum and flux based on the full IBD data set collected with Daya Bay near detectors. The reactor antineutrino spectra and fluxes from <sup>235</sup>U and <sup>239</sup>Pu are extracted using the fuel evolution technique. In terms of the reconstructed energy of prompt signals, the total,  $^{235}$ U and  $^{239}$ Pu spectra are measured with precision 1.3%, 3% and 8% respectively, around the 3 MeV peak energy. The Daya Bay spectra are inconsistent with model predictions, exhibiting most notably a 5 MeV bump in shape. When considering the comparison in both shape and rate, the Daya Bay <sup>235</sup>U spectrum shows significant deficit below 4 MeV compared to the HM prediction. In addition, Daya Bay measures the energy-integrated overall, <sup>235</sup>U and <sup>239</sup>Pu fluxes with 1.2%, 1.9% and 5.0% precision respectively. The total and <sup>235</sup>U fluxes of Daya Bay show respectively 5.0% and 7.0% deficits compared to HM predictions at about  $3\sigma$  significance level; however, they are consistent with KI and SM2023 models. Moreover, the measured three reconstructed energy spectra are unfolded into neutrino energy spectra using the SVD regularization method with correlations among different spectra taken into account when simultaneously unfolding multiple spectra together. The world-leading precision measurement presented in this Letter enriches the knowledge about the reactor  $\bar{\nu}_e$  spectrum and flux. The discrepancies presented in this Letter reinforce the necessity of higher precision measurements and the further refinement of models in the future.

The Daya Bay experiment is supported in part by the Ministry of Science and Technology of China, the U.S. Department of Energy, the Chinese Academy of Sciences, the CAS Center for Excellence in Particle Physics, the National Natural Science Foundation of China, the New Cornerstone Science Foundation, the Guangdong provincial government, the Shenzhen municipal government, the China General Nuclear Power Group, the Research Grants Council of the Hong Kong Special Administrative Region of China, the Ministry of Education in Taiwan, the U.S. National Science Foundation, the Ministry of Education, Youth, and Sports of the Czech Republic, the Charles University Research Centre UNCE, and the Joint Institute of Nuclear Research in Dubna, Russia. We acknowledge Yellow River Engineering Consulting Co., Ltd., and China Railway 15th Bureau Group Co., Ltd., for building the underground laboratory. We are grateful for the cooperation from the China Guangdong Nuclear Power Group and China Light & Power Company.
