We introduce ENERVERSE, a comprehensive framework for embodied future space generation specifically designed for robotic manipulation tasks. EnerVerse seamlessly integrates convolutional and bidirectional attention mechanisms for inner-chunk space modeling, thereby ensuring low-level consistency and continuity. Recognizing the inherent redundancy in video data, we propose a sparse memory context in conjunction with a chunkwise unidirectional generative paradigm to facilitate the generation of infinitely long sequences. To further augment robotic capabilities, we introduce the Free Anchor View (FAV) space, which offers flexible perspectives that enhance observation and analysis. The FAV space mitigates motion modeling ambiguity, removes physical constraints in confined environments, and significantly improves the robot's generalization and adaptability across a variety of tasks and settings. To address the prohibitive costs and labor intensity associated with acquiring multi-camera observations, we present a data engine pipeline that integrates a generative model with 4D Gaussian Splatting (4DGS). This pipeline capitalizes on the generative model's robust generalization capabilities and the spatial constraints provided by 4DGS, enabling an iterative enhancement of data quality and diversity, thus creating a data flywheel effect that effectively narrows the sim-to-real gap. Finally, our experiments demonstrate that the embodied future space generation prior substantially enhances policy predictive capabilities, resulting in improved overall performance, particularly in long-range robotic manipulation tasks.

Date: January 01, 2025 Website: <https://sites.google.com/view/enerverse>

## 1 Introduction

High-capacity foundational models have achieved remarkable success across various modalities, including language [Wang et al.](#page-15-0) [\(2024b\)](#page-15-0), images [Rombach et al.](#page-15-1) [\(2022\)](#page-15-1), and videos [Blattmann et al.](#page-13-0) [\(2023\)](#page-13-0). These models are extensively pretrained on large datasets, allowing fine-tuning for specific downstream tasks. In robotics, these foundation models offer a promising framework for addressing complex tasks by leveraging their pretrained capabilities and adapting to task-specific applications. This paradigm allows robots to handle diverse tasks based on varied input data. However, planning future actions based on real-time observations remains a core challenge in robotics. Unlike language or vision domains, robotic systems must interact with the physical world in real time, requiring precise action planning and execution. This complexity arises from two primary challenges: (1) Explicit Alignment Across Modalities: Aligning task-instructions, observations, and action spaces is inherently intricate. Earlier works [Goyal et al.](#page-13-1) [\(2024\)](#page-13-1); [Shridhar et al.](#page-15-2) [\(2022\)](#page-15-2), used pretrained models for language-visual alignment and complex algorithms to map these to actions. Recently, LLM-based methods [Liang et al.](#page-14-0) [\(2023\)](#page-14-0); [Huang et al.](#page-14-1) [\(2023,](#page-14-1) [2024\)](#page-14-2) have been introduced to generate code policies using pretrained visual models. Although simplifying alignment, these approaches are limited by the representational capacity of plain language, making them unsuitable for complex tasks. (2) **Data Scarcity:** 

<span id="page-1-0"></span>

Figure 1 The overview of our proposed ENERVERSE model, consisting of three key components. First, Initial Reconstruction uses observation images from cameras mounted on the robot to build an initial 3D point cloud, with anchor views set to adapt to the environment and meet task-specific requirements. Second, Free Anchor View Renders generates rendered images from these anchor perspectives to provide comprehensive scene representations. Finally, Chunk-wise Autoregressive Generation employs a multi-view video diffusion to produce image sequences in chunks based on task instructions. When integrated with a policy head, this module can generate robotic actions to execute the given task.

The lack of large-scale task-observation-action datasets hinders implicit learning of mapping relationships. Although large-scale datasets [O'Neill et al.](#page-15-3) [\(2023\)](#page-15-3); [Khazatsky et al.](#page-14-3) [\(2024\)](#page-14-3) have been introduced, they remain less diverse and lower in quality than those in language and vision domains. Methods [Kim et al.](#page-14-4) [\(2024\)](#page-14-4)attempt to address this limitation by combining these datasets with pretrained LLM knowledge, but they require enormous amounts of data, making them resource-intensive.

Recent studies [Wen et al.](#page-16-0) [\(2024\)](#page-16-0); [Rigter et al.](#page-15-4) [\(2024\)](#page-15-4); [Cheang et al.](#page-13-2) [\(2024\)](#page-13-2); [Guo et al.](#page-13-3) [\(2024\)](#page-13-3) have yielded promising results by integrating video generation with policy planning, utilizing large-scale video datasets without action labels. However, many of these methods [Rigter et al.](#page-15-4) [\(2024\)](#page-15-4) simply adapt general-purpose video generation models to embodied tasks, overlooking the distinct requirements inherent to robotics. It is crucial to emphasize that video generation is not synonymous with generating embodied future spaces. Robotic tasks are characterized by specific demands, including causal logic that delineates the initiation and completion of a task, the capability to achieve precise outcomes, and context-memory capabilities. Furthermore, robots operate within real-world three-dimensional environments, whereas video generation is constrained to 2D projection sequence that inadequately capture the complexities of embodied future spaces. Consequently, the relationship between video representations and three-dimensional spatial actions remains ambiguous.

For high-information-density language tasks, causal modeling paradigms [Vaswani](#page-15-5) [\(2017\)](#page-15-5); [Achiam et al.](#page-13-4) [\(2023\)](#page-13-4), which leverage unidirectional attention, have exhibited exceptional performance. However, identifying the optimal modeling paradigm for visual tasks, characterized by significant information redundancy, remains an unresolved research challenge. In contrast to language tasks, visual generation tasks often benefit from bidirectional computational mechanisms, such as bidirectional attention and convolution, which have proven highly effective across various domains, including image generation [Chi et al.](#page-13-5) [\(2023\)](#page-13-5); [Li et al.](#page-14-5) [\(2024b\)](#page-14-5); [Chang](#page-13-6) [et al.](#page-13-6) [\(2022\)](#page-13-6), general video generation [Xing et al.](#page-16-1) [\(2025\)](#page-16-1); [Ho et al.](#page-14-6) [\(2022\)](#page-14-6), and 3D generation [Gao et al.](#page-13-7) [\(2024b\)](#page-13-7); [Wu et al.](#page-16-2) [\(2024b\)](#page-16-2). Building on these insights, EnerVerse adopts a hybrid framework for modeling the embodied future space. First, to model a minimal unit of future space, defined as chunk space, we employ a combination of convolution and bidirectional attention to ensure low-level consistency and continuity. Second, for long-range spatiotemporal sequences, we utilize a chunk-wise unidirectional generative paradigm to encapsulate task execution logic, thereby enhancing the model's reasoning capabilities. Moreover, we

observe that consecutive memory can often lead to unexpected model collapse during robotic manipulations. In such instances, future space generation is more reliant on logical execution than merely extending a single scene. This indicates that fewer redundant context frames are critical for inducing a coherent sequential understanding. To address this challenge, we design a sparse context memory mechanism that preserves prior content throughout the generation process in a non-redundant manner, leading to theoretical capability to generate sequences of indefinite length. By integrating bidirectional mechanisms for local modeling with unidirectional paradigms for long-range reasoning, the proposed framework effectively resolves the unique challenges associated with embodied future space generation.

We further introduce the concept of the Free Anchor View (FAV) space. In robotics, camera observations are typically obtained using hardware-mounted cameras, which provide fixed perspectives associated with the robotic setup. In contrast, anchor views can be configured arbitrarily and can be adjusted according to task requirements or environmental conditions. Defined relative to the robot's base system, FAVs remain consistent as long as the robot's base position is fixed. As illustrated in Figure [1,](#page-1-0) anchor views are not physically affixed but exist freely in space, offering flexible perspectives that enhance observation and analysis. This "free anchor view" characteristic is particularly advantageous for robotic tasks due to the following reasons: (1) most robotic tasks benefit from multi-view observations, which strongly reduces metric ambiguity and deepens environmental understanding; (2) in complex robotic tasks involving whole-body motion, bodymounted cameras experience extrinsic changes as the robot moves, introducing motion modeling ambiguity and significantly complicating policy learning; (3) in certain task environments, such as narrow kitchens, body-mounted cameras can impose physical constraints, as the camera or its mounting apparatus may collide with walls during operation; and (4) although static, workspace-mounted cameras can mitigate some of these challenges, they simultaneously reduce the robot's generalization and flexibility across diverse tasks and environments. Furthermore, multiple FAVs provide richer visual information thus implicitly construct a 3D spatial representation, which significantly enhances the policy's performance [Goyal et al.](#page-13-1) [\(2024\)](#page-13-1).

However, acquiring meticulously calibrated multi-camera observations, mounted not only on the robot hardware but also in the surrounding environment, alongside robotic actions is both costly and labor-intensive in realworld scenarios. This limitation prevents the FAV system from obtaining sufficient training data in physical environments. In contrast, simulators can readily address this challenge by generating diverse and abundant synthetic data. Nevertheless, the sim-to-real gap, the disparity between simulated and real-world environments, remains a significant obstacle that cannot be overlooked. To address this issue, we propose a data engine pipeline that integrates a generative model with 4D Gaussian Splatting (4DGS). This pipeline capitalizes on the generative model's robust generalization capabilities and the spatial constraints and optimization strengths implied by 4DGS. Together, these two components synergistically establish a data flywheel effect, a self-reinforcing process that continuously enhances data quality and diversity, ultimately diminishing the sim-to-real gap and augmenting the effectiveness of the FAV system.

The contributions of this work are as follows.

- We develop an innovative chunk-wise autoregressive diffusion model architecture capable of logically reasoning for future space generation, benefiting from a sparse contextual memory mechanism.
- We propose a novel FAV-based 4D future space generation method associated with policy planning, significantly enhancing spatial understanding.
- We are the first to construct a data flywheel in the robotics domain that integrates 4D Gaussian Splatting optimization and multi-view video generation, enabling iterative improvements in data quality and model performance.
- The diffusion generator, combined with a naive policy head, achieves state-of-the-art (SOTA) performance, particularly in long-range manipulation tasks, demonstrating the effectiveness of future space generation prior.

#### 2.1 Video Generation Models.

Diffusion-based video generation models have achieved significant progress in recent years [Blattmann et al.](#page-13-0) [\(2023\)](#page-13-0); [Ho et al.](#page-14-7) [\(2020\)](#page-14-7); [Song et al.](#page-15-6) [\(2020\)](#page-15-6), particularly in the domain of text-to-video (T2V) generation. Early T2V models [Zhang et al.](#page-16-3) [\(2023\)](#page-16-3); [Chen et al.](#page-13-8) [\(2023\)](#page-13-8); [Ren et al.](#page-15-7) [\(2024\)](#page-15-7); [Zhang et al.](#page-16-4) [\(2024\)](#page-16-4) leverage the strong priors established by text-to-image (T2I) models, incorporating temporal modules trained on video data to enable video generation. For instance, AnimateDiff [Guo et al.](#page-13-9) [\(2023\)](#page-13-9) introduces a plug-and-play motion module that seamlessly integrates into existing personalized T2I diffusion models, effectively animating static images. Similarly, DynamicCrafter [Xing et al.](#page-16-1) [\(2025\)](#page-16-1) adapts motion priors from text-to-video diffusion models to the image-to-video (I2V) setting, generating animated clips by conditioning noise on input still images. Recent advancements [Kong et al.](#page-14-8) [\(2024\)](#page-14-8); [Zheng et al.](#page-16-5) [\(2024\)](#page-16-5); [Bao et al.](#page-13-10) [\(2024\)](#page-13-10) have explored replacing the traditional U-Net with Diffusion Transformer architectures in the denoising process, inspired by the recent success of diffusion transformer in image generation [Peebles and Xie](#page-15-8) [\(2023a\)](#page-15-8); [Liu et al.](#page-14-9) [\(2024b\)](#page-14-9); [Zhuo](#page-16-6) [et al.](#page-16-6) [\(2024\)](#page-16-6). Additionally, some works [Gao et al.](#page-13-11) [\(2024a\)](#page-13-11) extend the original video diffusion paradigm by incorporating causal mechanisms, enabling the generation of long-sequence videos. Furthermore, other studies [Hu et al.](#page-14-10) [\(2023\)](#page-14-10); [Wang et al.](#page-15-9) [\(2023\)](#page-15-9); [Zhao et al.](#page-16-7) [\(2024\)](#page-16-7) expand video generation models into the realm of world modeling, where future states are predicted. In this paper, we adopt DynamicCrafter as our base model for the image-to-video task, as it is a widely-used and open-sourced I2V framework in the research community. Our implementation is also compatible with modern Transformer-based Diffusion models (DiT), which is not our current focus for this paper.

#### 2.2 Video Pretraining for Robotics.

The concurrent work GR-2 [Cheang et al.](#page-13-2) [\(2024\)](#page-13-2) introduces a versatile and generalizable robot manipulation framework that relies on pretraining with a large collection of videos sourced from the internet. GR-2 is fine-tuned for both video generation and action prediction using robotic trajectories. LAPA [Ye et al.](#page-16-8) ([2024\)](#page-16-8) also leverages internet-scale videos to learn pretraining representations from non-robot action videos. It first learns discrete latent actions between image frames using VQ-VAE, then pretrains a latent Vision-Language Action (VLA) model to predict these latent actions from observations and task descriptions. Finally, the VLA is fine-tuned on small-scale robot manipulation datasets to map latent actions to robotic actions. SEER [Tian](#page-15-10) [et al.](#page-15-10) [\(2024\)](#page-15-10) expands on LAPA by incorporating additional inverse dynamics pretraining to further improve performance. AVID [Rigter et al.](#page-15-4) [\(2024\)](#page-15-4) utilizes DynamicCrafter [Xing et al.](#page-16-1) [\(2025\)](#page-16-1) as its base video generation model and employs an adapter to transfer the original model to the robotics domain. VidMan [Wen et al.](#page-16-0) [\(2024\)](#page-16-0), built upon OpenSora [Zheng et al.](#page-16-5) [\(2024\)](#page-16-5), leverages the environment prediction capabilities of video diffusion models prior to action generation but remains limited to the 2D image space. In contrast to the aforementioned pretraining schemes, our approach focuses on generating long-sequence future spaces using a novel data generation engine. Long-sequence data inherently captures motion information, making it particularly suitable for robotic tasks.

#### 2.3 4D Reconstruction and Generation.

There has been substantial progress [Chen and Wang](#page-13-12) [\(2024\)](#page-13-12) in reconstructing dynamic scenes from 2D videos using techniques such as 3D Gaussian Splatting (GS) [Kerbl et al.](#page-14-11) [\(2023\)](#page-14-11) and Neural Radiance Fields (NeRF) [Mildenhall et al.](#page-14-12) [\(2021\)](#page-14-12). Previous works have formulated this task by approximating a scene's underlying spatio-temporal 4D volume using a set of 4D Gaussians [Yang et al.](#page-16-9) [\(2023\)](#page-16-9). Wu et al. [Wu et al.](#page-16-10) [\(2024a\)](#page-16-10) proposed modeling the geometry and dynamics of scenes through the joint optimization of Gaussians in canonical space and a deformation field. More recent advancements in 4D generation have focused on crafting sampling schemes for diffusion models that generate multi-view videos [Li et al.](#page-14-13) [\(2024a\)](#page-14-13), primarily targeting the modeling of single dynamic objects. DimensionX [Sun et al.](#page-15-11) [\(2024\)](#page-15-11) employed multiple LoRAs [Hu et al.](#page-14-14) [\(2021\)](#page-14-14), each designed for a specific camera motion, to generate multi-view videos, which were subsequently utilized for 4D scene reconstruction. Concurrently, Cat4D [Wu et al.](#page-16-2) [\(2024b\)](#page-16-2) used a single multi-view video diffusion model to generate multi-view videos, which were then employed to reconstruct dynamic 3D scenes as deforming 3D Gaussians. In contrast, our approach generates videos from the Free Anchor View, specifically

tailored for robotic manipulation tasks. Additionally, Gaussian Splatting in our framework is primarily involved in the offline data flywheel stage, where the video generation model and GS model complement each other to reduce the Sim2Real gap.

## 3 Methods

Our ENERVERSE model is designed with several components tailored for future space generation, incorporating a Gaussian Splatting (GS) data factory pipeline. First, we employ a chunk-wise autoregressive strategy integrated with video diffusion models, enabling the prediction of future frames by analyzing preceding sequences in manageable chunks and leveraging the capabilities of video diffusion models. Second, we propose a free anchor view-based 4D generation method, where the ray direction map of each anchor is provided as prior knowledge to facilitate the efficient generation of target novel-view videos. Finally, we implement a data engine pipeline comprising a generative model and 4DGS, which produces diverse novel view video sequences with specified camera poses. These generated video sequences are then utilized to drive Sim2Real adaptation.

<span id="page-4-0"></span>

#### 3.1 Next Chunk Diffusion

Figure 2 The architecture of our proposed next-chunk diffusion model. As shown in Figure (a), a sequence of observational frames, captured by camera i and accompanied by the corresponding ray direction map, is utilized as observation priors. Leveraging these camera observations, an initial 3D reconstruction is obtained through depth wrapping and rendering [Lassner and Zollhofer](#page-14-15) [\(2021\)](#page-14-15), then several Free Anchor Views are established accordingly. In addition to camera observational frames, a render frame from the FAV is also employed as context priors for the subsequent chunk diffusion models. To synthesize the anchor view  $i + 1$  sequence, the respective ray direction map is concatenated with the video latent. Notably, the observational image from the camera is optional and used only when the camera is static. If all sensors are in motion, the rendered image alone can serve as the context prior. In the context of the chunk-wise autoregressive training process, as depicted in Figure (b), clean frames selected at random from consecutive sequences are concatenated with noisy frames to forecast denoised latents. During the inference phase, once denoised frames are produced, they are utilized as the new set of clean frames for the following inference step. This iterative process persists until the predefined End-Of-Sequence (EOS) frame is encountered. Notably, we visualize only one view in Figure (b) to simplify the demonstration of the autoregressive generation process, but multi-view generation is fully supported by the model.

Chunk-wise Autoregressive Generation: As shown in Figure [2,](#page-4-0) the observed latent sequence is represented as  $\boldsymbol{o}_0^{1:K} = [\boldsymbol{o}_0^1, \dots, \boldsymbol{o}_0^K] \in \mathbb{R}^{K \times H \times W \times C}$ , encoded using a pre-trained Variational Autoencoder (VAE). Here, K denotes the number of observed frames,  $H \times W$  represents the downsampled spatial resolution, and C indicates the number of color channels. Similarly, the latent representation of the rendered image is denoted as  $r_0 \in \mathbb{R}^{1 \times H \times W \times C}$ . The predicted latent sequence is expressed as  $z_0^{1:N} = [z_0^1, \ldots, z_0^N] \in \mathbb{R}^{N \times H \times W \times C}$ . The objective is to develop a video diffusion model that generates predicted latents conditioned on observed latents, rendered latents, and textual input, following the conditional probability distribution  $p\theta(z_0^{1:N}|c, o_0^{1:N}, r_0)$ .

Here, c denotes the textual condition, and  $\theta$  are the parameters of the denoising network, represented as  $\epsilon\theta(z_t^{1:N}, c, o_0^{1:K}, r_0, t)$ . For consistency, we refer to both observed and rendered frames as the clean frame context. The denoising network is trained to predict the ground truth noise  $\epsilon$  from the noisy frame targets, optimized with the objective:

$$
\min_{\theta} \mathbb{E}_{t, \mathbf{z} \sim z_{\text{data}}, \epsilon \sim \mathcal{N}(\mathbf{0}, \mathbf{I})} \|\epsilon - \epsilon_{\theta}\left(\mathbf{z}_{t}^{1:N}, \mathbf{o}_{0}^{1:K}, \mathbf{r}_{0}, t\right)\|_{2}^{2},
$$

where  $\epsilon$  is the sampled ground truth noise and  $\theta$  denotes the learnable network parameters. In pratice, we predict  $v$  following previous work [Salimans and Ho](#page-15-12) [\(2022\)](#page-15-12). Upon completion of model training, denoised data  $z_0$  can be derived from random noise  $z_T$  through iterative denoising.

During inference, clean frames, combined with noisy frames, are input into the diffusion generator to produce N noisy frames. The most recently generated frames are then used as the new clean frames for the next iteration of inference. This iterative process continues until the predefined End-Of-Sequence (EOS) frame is detected. Since our diffusion generation operates on consecutive latent representation frames, we calculate the generated result of each frame and its L1 distance to the EOS during the inference process. A predefined threshold is applied to determine when to terminate the process. In practice, this threshold-based method for detecting the EOS has proven to be highly accurate.

**Context Frame Mechanism.** Instead of the conventional approach of using consecutive frames as the clean frame context for chunk prediction during training, we propose an alternative method that involves sparse sampled frames as the clean frames. For video data, which often contains significant redundant information, our method can drop approximately 80% of the frames while still retaining sufficient information for effective training. Furthermore, dropping frames at a high ratio improves the model's robustness, enabling it to better handle out-of-distribution (OOD) scenarios, particularly the covariant shift problem commonly encountered in the robot learning domain. Overall, from a representation learning perspective, this randomized selection strategy encourages a more comprehensive understanding of chunk prediction, potentially leading to improved outcomes compared to methods relying on continuous frames.

During inference, clean frames are obtained from observed or rendered frames and denoised using a sliding window approach. This method ensures a seamless transition from observed to generated frames while improving inference efficiency and reducing GPU memory usage.

#### 3.2 4D Generation

Why Choose Free Anchor View Representation? Single-view video generation methods face substantial challenges in addressing occlusion, a common and unavoidable issue in robotic manipulation tasks [Huang et al.](#page-14-2) [\(2024\)](#page-14-2). Previous approaches often adopt a single top-down perspective, such as the bird's-eye view (BEV). However, this setup is insufficient for manipulation tasks due to the complexity of occlusion relationships in 3D environments. Similarly, fixed multi-anchor view representations are overly constrained by the environment. For example, in narrow and confined spaces, such as kitchens, fixed camera positions may become physically infeasible, with pre-mounted overhead cameras potentially intersecting walls or other obstacles. In contrast, free multi-view video generation provides a more practical and flexible alternative. By enabling generative models to focus on the physical properties of objects, such as their shapes and positions, this approach enhances object-level reasoning, which is particularly important for manipulation tasks that require precise modeling of physical interactions. Another common observation setup involves relative motion, such as cameras mounted on a robot's wrist. However, this setup introduces drawbacks by coupling environmental dynamics with the robot's own motion, complicating policy learning.

Free Anchor View Video Generation Pipeline. As illustrated in Figure [2,](#page-4-0) the objective of our approach is to directly generate multi-view latents, represented as  $z_0^{1:N} \in \mathbb{R}^{N \times V \times H \times W \times C}$ , where V denotes the number of views. In a multi-camera or multi-view setting, each camera inherently captures a distinct perspective of the same scene. Without explicitly accounting for these varying perspectives, the model may struggle to produce consistent outputs. To resolve this, we enhance the embedding of the initial images,  $E_{\text{init}}$ , by appending a ray direction map along the channel dimension. The ray direction map encodes observation view information, including intrinsic and extrinsic camera parameters. Through ray casting, the generation process becomes

view-aware, conditioning the model on camera parameters. This enables the model to reflect the unique perspective of each anchor view while capturing 3D spatial relationships and occlusion properties—critical for manipulation tasks. In addition, we extend the original 2D spatial attention to 3D cross-view attention to further enhance the 3D spatial perception ability of the model. This approach ensures consistency and coherence across different views while preserving the geometric relationships among objects in the scene. By leveraging free anchor view representation, the pipeline effectively addresses occlusion, enhances spatial reasoning, and adapts seamlessly to complex 3D environments.

Figure 3 The pipeline for ENERVERSE as a data engine. Observation images captured from multiple cameras, along with rendered images from anchor views, are processed by the multi-view video generator to produce denoised multi-view videos. These videos, paired with their corresponding camera poses, are utilized in 4D Gaussian Splatting (4D GS) for 4D scene reconstruction. The reconstructed content is rendered from anchor views to generate high-precision images, which are iteratively fed back into the pipeline to enhance motion consistency and reconstruction quality. This iterative loop combines geometric consistency with generative refinement, delivering high-fidelity outputs for tasks such as robotic manipulation.

Real-World Data Flywheels with EnerVerse and 4DGS. Obtaining carefully calibrated multi-camera observations in the real world is both costly and labor-intensive. As a result, we primarily rely on data sourced from simulators. However, video data from simulated environments or academic benchmarks often suffers from domain gaps when applied to real-world scenarios. These gaps typically manifest as discrepancies in visual appearance, scale perception, and metric accuracy, which hinder direct applicability. To address these challenges, we propose a data generation engine pipeline that leverages sparse or isolated observations to generate multi-perspective views of a given scene. By utilizing Gaussian Splatting for 4D reconstruction from these multi-view observations, we ensure geometric and optical consistency, thereby improving alignment and coherence across different viewpoints.

<span id="page-6-0"></span>Our EnerVerse model serves as an advanced data engine, employing a multi-stage process to enhance video generation and reconstruction. Initially, we train a base model, EnerVerse, using data from a simulator. This model is then fine-tuned into EnerVerse-D, conditioned on complete offline observation sequences, where clean, noise-free videos are captured from multiple mounted cameras. These videos include both robotic arm motion and scene dynamics, ensuring motion consistency across views. Subsequently, these multi-view videos are used to construct a 4D Gaussian representation via Gaussian Splatting. After completing the 3D scene reconstruction, the content is rendered from the anchor views to obtain higher-precision observations. The rendered observations, which are denoised and geometrically consistent, are iteratively refined using EnerVerse-D to generate pseudo-ground truth. After collecting sufficient real-world multi-view video data with the data engine, we further fine-tune the multi-view video generator using this data. This iterative process reduces noise, improves reconstruction quality, and facilitates Sim2Real domain adaptation, ultimately producing large-scale, high-quality video datasets essential for training 4D generation models.

<span id="page-7-0"></span>

Figure 4 Visualization of FAVs generation on the LIBERO benchmark. Anchor View 1 represents the observation image captured by a mounted camera. Anchor View 2 and Anchor View 3 are generated by rendering from a point cloud reconstructed from Anchor View 1 using depth wrapping.

#### 3.3 Application

**Policy Head.** In addition to video generation, we integrate a policy head into the diffusion generator networks, enabling the simultaneous generation of videos and corresponding actions after the extensive future space generation pretraining. Specifically, we design the policy head following the architecture in [Chi et al.](#page-13-5) [\(2023\)](#page-13-5), employing a stack of multiple transformer blocks. The input latent vector to the policy head, serving as a condition, is extracted from the middle layer of the diffusion generator, as shown in Figure [1.](#page-1-0) Unlike the video generation process, where multiple denoising steps are employed to improve generation quality, we use only the noisiest step, i.e., the feature vector after the first denoising step. This design significantly improves the speed of action output, meeting the frequency requirements of robotic control. Notably, during policy prediction, the sparse memory stores visual images that are either observed or reconstructed FAVs under a multi-view setup, rather than relying on generated information as shown in Figure [4.](#page-7-0) Furthermore, during the first-step action prediction, although the policy model explicitly relies only on historical observation data, extensive pretraining on future space generation ensures that information about future spatial dynamics is implicitly embedded. This enables the model to plan actions with a forward-looking perspective, aligning with the overarching goal of envisioning future spaces. Additionally, actions are predicted in chunks, allowing the model to generate multiple future action steps simultaneously. This chunk-based prediction approach further improves efficiency, making it well-suited for real-time robotic control tasks.

## 4 Experiments

#### 4.1 Experiment Settings

To demonstrate the effectiveness of proposed method, we evaluate EnerVerse in two different domains, e.g. video generation quality and robotic policy performance.

#### 4.1.1 Implementation Details

**Training Data.** We selected several publicly available datasets characterized by well-defined task logic, including RT-1 [Brohan et al.](#page-13-13) [\(2022\)](#page-13-13), Taco-Play [Rosete-Beas et al.](#page-15-13) [\(2022\)](#page-15-13), ManiSkill [Gu et al.](#page-13-14) [\(2023\)](#page-13-14), BridgeV1 [Walke](#page-15-14) [et al.](#page-15-14) [\(2023\)](#page-15-14), LanguageTable [Lynch et al.](#page-14-16) [\(2023\)](#page-14-16) and RoboTurk [Mandlekar et al.](#page-14-17) [\(2019\)](#page-14-17), for the purpose of pretraining. During this pretraining phase, only video frames were utilized for video generation training. Furthermore, we constructed a dataset containing multi-anchor view video ground truths using the Isaac Sim simulator [Mittal et al.](#page-15-15) [\(2023\)](#page-15-15). The FAV generation model was trained by leveraging the weights derived from the single-view video generation model. For the policy planning task, fine-tuning with a limited quantity of demonstration data from specific scenarios proved sufficient to attain state-of-the-art performance. To mitigate domain gaps encountered when training with heterogeneous data, we employed domain embeddings inspired by [Wang et al.](#page-15-16) [\(2024a\)](#page-15-16). Specifically, distinct domain embeddings were allocated to each sub-dataset. In subsequent space generation and policy planning, these embeddings were integrated with the diffusion timestep embeddings prior to input into the diffusion model. This methodology effectively alleviated conflicts arising from discrepancies in entities, task types, and visual styles.

Training Details. Our model is conducted based on UNet-based Video Diffusion Models (VDM) [Xing et al.](#page-16-1) [\(2025\)](#page-16-1), and can be easily adapted to DiT [Peebles and Xie](#page-15-17) [\(2023b\)](#page-15-17) architectures. In our experiments on generating embodied future spaces, we identified that chunk size significantly influences model performance. Comparative analyses utilizing chunk sizes of 1, 4, 8, and 16 revealed that the model exhibited optimal robustness when employing a chunk size of 8 (further details regarding these experiments can be found in the supplementary material). Following the methodology outlined in [Bruce et al.](#page-13-15) [\(2024\)](#page-13-15), we introduced corruptive noise to the frames within the memory context. To alleviate degradation in autoregressive generation, the intensity of this noise was modulated in a cosine-related manner relative to the distance from the current moment. In the policy prediction experiment, the action head adopts the Diffusion Policy (DP) architecture [Chi](#page-13-5) [et al.](#page-13-5) [\(2023\)](#page-13-5), with a total of 190M parameters. For the condition of the DP head, we utilize the feature before middle block of the UNet in the first denoise step, and calculate the mean value over spatial dimension, resulting in a final shape of  $T \times C$ , where T is the length of video and C is the number of channels before middle block. The rendered FAV images are with  $512 \times 320$  image sizes and the action header predicts the delta pose.

#### <span id="page-8-1"></span>4.2 Comparison Results

**Embodied Future Space Generation.** Following the approach established in AVID [Rigter et al.](#page-15-4) [\(2024\)](#page-15-4), we assess video generation quality utilizing the RT-1 [Brohan et al.](#page-13-13) [\(2022\)](#page-13-13) dataset. To create a comparable baseline, we fine-tune DynamicCrafter on the RT-1 dataset and run inference iteratively with FreeNoise [Qiu et al.](#page-15-18) [\(2023\)](#page-15-18) to enable long video generation(DC-FN). For evaluation, we generate 200 synthetic videos with varied lengths by conditioning the models on the initial frame and task instructions, subsequently comparing the generated videos against the ground truth using standard metrics such as PSNR and FVD. However, while these metrics primarily evaluate visual quality, embodied tasks necessitate additional considerations, including semantic alignment with instructions, workspace consistency across frames, and motion continuity. To address these higher-order aspects, we execute a user study involving robotics experts, who assess the generated videos based on semantic accuracy, frame consistency, and motion continuity.

<span id="page-8-0"></span>

Table 1 Performance comparison between DynamiCrafter (FN) and our proposed approach across Atomic Task metrics (Quantitative Comparison and User Study) and Long Task ability. The proposed method outperforms DynamiCrafter (FN) in most metrics, demonstrating its effectiveness in video generation and task performance.

Table [1](#page-8-0) illustrates that our method substantially outperforms DynamicCrafter (FN) in both quantitative and qualitative evaluations. In terms of quantitative metrics, our approach achieves a higher PSNR and a lower FVD. These findings indicate that our method produces videos of superior visual quality and enhanced temporal dynamics. In the user study, our method secures a higher quality score and exceeds DynamicCrafter in motion continuity, which is essential for robotic manipulation tasks. Although both methods attain equivalent semantic accuracy, this suggests that our approach effectively preserves instruction alignment while delivering superior overall performance. Moreover, our method uniquely accommodates long tasks, as evidenced by its successful execution of long-range manipulation scenarios, whereas DynamicCrafter falters in this domain. We also provide a qualitative comparison in Figure [5.](#page-9-0)

Multi-View Consistency. In this section, we qualitatively demonstrate the capability of ENERVERSE to generate multi-view videos of the same scene while ensuring consistency across anchor views. Furthermore, each view attains high-quality image generation, thereby highlighting the robustness of our approach. As shown in Figure [6,](#page-10-0) ENERVERSE could generate high-quality multi anchor view videos in both simulator and real-world settings.

Robotic Policy Evaluation Following the methodology in OpenVLA [Kim et al.](#page-14-4) [\(2024\)](#page-14-4), we evaluate robotic policies

<span id="page-9-0"></span>

Figure 5 Qualitative comparison for single view video generation between ENERVERSE and DynamiCrafter(FN) on RT-1 dataset. Since EnerVerse predict EOS frame at 42th frame for this task, we visualize 8th, 16th, 24th and 41th frame sampled from both generated sequence. The sequences generated by DynamiCrafter(FN) did not maintain the logic of the long-range task, producing many hallucinations as the sequence grew. In contrast, the sequence generated by EnerVerse was logically coherent, continuously and completely generating the future space of the entire task, and accurately predicting the EOS (End of Sequence) frame.

using the LIBERO [Liu et al.](#page-14-18) [\(2024a\)](#page-14-18) benchmark, which consists of four distinct task suites: LIBERO-Spatial, LIBERO-Object, LIBERO-Goal, and LIBERO-Long. Each suite contains 10 tasks, each with 50 human demonstrations, designed to evaluate various aspects of robotic learning. For each task suite, a separate policy model is fine-tuned. We compare our method against five baselines:

- Diffusion Policy [Chi et al.](#page-13-5) [\(2023\)](#page-13-5), a direct action learning policy trained from scratch;
- Octo [Team et al.](#page-15-19) [\(2024\)](#page-15-19), a transformer-based policy model fine-tuned on the target dataset;
- OpenVLA [Kim et al.](#page-14-4) [\(2024\)](#page-14-4), a 7B vision-language-action model fine-tuned on the target dataset;
- MDT [Reuss et al.](#page-15-20) [\(2024\)](#page-15-20), a diffusion transformer-based policy with an auxiliary MAE loss;
- MAIL [Jia et al.](#page-14-19) [\(2024\)](#page-14-19), a policy model with Mamba [Gu and Dao](#page-13-16) [\(2023\)](#page-13-16) in an encoder-decoder structure.

For evaluation, all models are tested across tasks using 50 rollouts per task, with results averaged over three random seeds. Experiments with EnerVerse are conducted under two setups: a single static-camera configuration, consistent with OpenVLA, and a three-static-camera configuration (e.g., three FAVs as shown in Figure [4\)](#page-7-0), as our method supports multiple visual inputs.

<span id="page-9-1"></span>

Table 2 Evaluation results on the LIBERO benchmark across four task suites. Our method achieves superior performance in both single and multi-visual input settings.

As shown in Table [2,](#page-9-1) ENERVERSE achieves state-of-the-art performance across the LIBERO benchmark, significantly surpassing all baselines. With a One Third View input, it achieves an average score of 84.0, outperforming strong baselines like MAIL (83.5) and OpenVLA (76.5). The Three Third View configuration further enhances performance, achieving the highest average score of 88.5, demonstrating the value of richer

<span id="page-10-0"></span>

Figure 6 Qualitative results for multi anchor view generation on LIBERO benchmark (left) and real-world manipulation data (right), collected from AgiBot World [AgiBot](#page-13-17) [\(2024\)](#page-13-17). One view is overlapped with a fixed RGB sensor and other views are manully set. Visualized Frames are uniformly sampled from generated sequence. We emphasize the consistency of objects across views by highlighting them with a red rectangle.

visual input. Task-specific results highlight the model's strengths, achieving top scores in Spatial (92.1 and 91.2 for One and Three Third View, respectively), Object (93.2 and 97.7), and Long (73.0 and 80.0). The model's balanced performance across all tasks, particularly excelling in Object and Goal tasks, underscores its robustness and adaptability. These results validate the effectiveness of the proposed architecture and its ability to leverage multi-view input for enhanced understanding and task performance.

#### 4.3 Further Studies

In this section, we explore several key design choices for EnerVerse. First, we examine the significance of the proposed sparse memory mechanism, which plays a critical role in both policy learning and video generation. Second, we discuss the training strategy utilized in EnerVerse. Third, we analyze the alignment between the predicted action spaces and visual spaces through attention map analysis. Finally, we introduce the real-world experiment setup.

**Sparse Memory Mechanism.** We evaluate the effectiveness of our sparse memory mechanism in both policy learning and video generation. The evaluation is conducted on the LIBERO-Long task suite, as this suite involves significantly longer task execution steps, requiring the policy to exhibit strong long-range memory and task reasoning capabilities. The evaluation is performed with a single visual input. As shown in Table [3,](#page-11-0) the absence of the sparse memory results in significant performance degradation, with the policy achieving only 30.8 compared to 73 when the sparse memory mechanism is applied. Similarly, Figure [7](#page-11-1) demonstrates that when the video generator operates without sparse memory, the model experiences unexpected collapse and fails to recover in out-of-distribution (OOD) scenarios. In contrast, the sparse memory mechanism ensures

<span id="page-11-0"></span>robust performance while also saving computational resources.

Table 3 Performance comparison on the LIBERO-Long task with and without Sparse Memory.

<span id="page-11-1"></span>

**EnerVerse Generated w/ sparse memory**

Figure 7 Ablation results for context memory mechanism in video generation. Providing history information to the generation model with consecutive context (first line) often leads to unexpected model collapse while the model with sparse memory (second line) shows robust performance and save mush computing resources.

Training Strategy Analysis. To analyze the impact of different training strategies on robotic policy learning, we trained four robotic policies on the LIBERO-Spatial task suite using the following approaches: (1) training the entire EnerVerse from scratch using only policy loss optimization; (2) training the entire EnerVerse as in (1) but initialized with pretrained weights from a general video generator, e.g. DynamiCrafter(DC) [Xing](#page-16-1) [et al.](#page-16-1) [\(2025\)](#page-16-1), which is trained with the general natural videos; (3) co-training EnerVerse by optimizing both the robotic policy action loss and the video generation loss simultaneously; and (4) the default two-stage training strategy, where the video generator is pretrained first, followed by fine-tuning EnerVerse using only robotic policy loss optimization.

<span id="page-11-2"></span>

Table 4 Performance comparison of different training strategies on the LIBERO-Spatial task suite. The metrics are the task success rates.

As shown in Table [4,](#page-11-2) training ENERVERSE from scratch without loading pretrained weights failed to converge, underscoring the importance of robust initialization. Another possible reason for this failure could be the relatively limited training data compared to the number of network parameters. Initializing with pretrained weights improved performance (79), while jointly optimizing the policy loss and video generation loss in a one-stage co-training setup further increased performance to 86.3. This demonstrates that the video generation task enhances policy learning. Our default Two-Stage Fine-tuning strategy, which involves pretraining the video generator followed by fine-tuning EnerVerse with policy loss optimization, achieved the best performance overall.

Attention Map Analysis. To further analyze the alignment between the predicted action space and the visual space, including the visual observations cached by our Sparse Memory Mechanism and the generated future space, we calculated and visualized the attention maps from the first several layers of the Cross-Attention Block in our policy head, as described in Section [3.3.](#page-6-0)

Figure [8](#page-12-0) illustrates attention maps from different heads and layers, showcasing the model's hierarchical focus and the impact of our proposed embodied future space generation in facilitating robust action prediction. In

Figure [8\(](#page-12-0)a), attention is distributed almost entirely across the future space, reflecting the model's ability to leverage sparse memory conditions and generated predictions from the outset. In contrast, Figure [8\(](#page-12-0)d) shows the attention sharply focused on the sparse memory space, with minimal reliance on the generated future space, indicating that the model has transitioned to memory-based reasoning. Interestingly, Figures  $8(c,e)$  $8(c,e)$ demonstrate that the model effectively integrates information from both the sparse memory space and the predicted future space. Moreover, these attention maps reveal that earlier decision steps tend to prioritize sparse memory, while later action steps shift focus to the generated future space. These results validate that our generative pretraining effectively enhances the model's ability to integrate temporal information, align predicted actions with future visual contexts, and make robust decisions.

<span id="page-12-0"></span>

Figure 8 Attention maps from different attention heads and layers of the model. The y-axis represents the predicted action space (the Query), spanning 8 steps, while the x-axis represents the Key-Value space. The first 4 columns in the KV space correspond to information from the Sparse Memory space, while the last 8 columns correspond to the predicted future space. These maps highlight how the model attends to sparse memory conditions (left) and future space conditions (right) when predicting actions. The bright yellow indicates a higher attention score while dark red indicates a lower one.

Real-World Experiments. To evaluate the manipulation capabilities of EnerVerse, we conducted real-world experiments using AgiBot-A2W and AgiBot-A2D robotics in two challenging industrial scenarios. Unlike the evaluation tasks described in Section [4.2,](#page-8-1) these scenarios required precise manipulation and robust decision-making. In the first task, the robot placed blocks into designated compartments of a foam worktable, demanding accuracy due to the tight fit and visual similarity between the foam and table. In the second task, the robot sorted several transparent plastic objects, including a measuring cup and plate, where the transparency added complexity to object recognition and manipulation. For detailed task descriptions and additional visualizations, please refer to our project page.

# 5 Conclusion

In conclusion, we present EnerVerse, a pioneering framework that addresses the challenges of multi-view video generation and long-range policy execution for robotic manipulation by modeling embodied future spaces. Leveraging sparse contextual memory and the novel Free Anchor View space, EnerVerse enhances spatial reasoning and provides flexible perspectives critical for complex tasks. Our data engine pipeline, combining generative modeling with 4D Gaussian Splatting, bridges the Sim2Real gap by producing high-quality synthetic data, reducing reliance on costly real-world data collection, and enabling seamless transitions to real-world scenarios. The diffusion generator, integrated with a naive policy head, achieves state-of-the-art performance in long-range manipulation tasks, highlighting the effectiveness of future space generation prior. Overall, EnerVerse delivers a scalable, generalizable solution for robotics, paving the way for robust advancements across diverse applications.
