

LP-ICP: General Localizability-Aware Point Cloud Registration for Robust Localization in Extreme Unstructured Environments

Haosong Yue, *Member, IEEE*, Qingyuan Xu, Fei Chen, *Senior Member, IEEE*, Jia Pan, *Senior Member, IEEE*, and Weihai Chen, *Member, IEEE*

Abstract—The Iterative Closest Point (ICP) algorithm is a crucial component of LiDAR-based SLAM algorithms. However, its performance can be negatively affected in unstructured environments that lack features and geometric structures, leading to low accuracy and poor robustness in localization and mapping. It is known that degeneracy caused by the lack of geometric constraints can lead to errors in 6-DOF pose estimation along ill-conditioned directions. Therefore, there is a need for a broader and more fine-grained degeneracy detection and handling method. This paper proposes a new point cloud registration framework, LP-ICP, that combines point-to-line and point-to-plane distance metrics in the ICP algorithm, with localizability detection and handling. LP-ICP consists of a localizability detection module and an optimization module. The localizability detection module performs localizability analysis by utilizing the correspondences between edge points (with low local smoothness) to lines and planar points (with high local smoothness) to planes between the scan and the map. The localizability contribution of individual correspondence constraints can be applied to a broader range. The optimization module adds additional soft and hard constraints to the optimization equations based on the localizability category. This allows the pose to be constrained along ill-conditioned directions, with updates either tending towards the constraint value or leaving the initial estimate unchanged. This improves accuracy and reduces fluctuations. The proposed method is extensively evaluated through experiments on both simulation and real-world datasets, demonstrating higher or comparable accuracy than the state-of-the-art methods. The dataset and code of this paper will also be open-sourced at <https://github.com/xuqingyuan2000/LP-ICP>.

Note to Practitioners—This paper was motivated by addressing the challenges of Simultaneous Localization and Mapping (SLAM) that use LiDAR as one of the sensors in extreme unstructured environments such as planetary-like environments and underground tunnels. Due to the lack of features and geometric structures in these environments, the performance of pose estimation based on the Iterative Closest Point (ICP) algorithm is limited in the degenerate directions. This leads to low accuracy and poor robustness in localization and mapping. Most existing degeneracy detection methods have limited applicability,

such as those that only work with point-to-plane ICP algorithms, or are not fine-grained. This paper proposes a new point cloud registration algorithm that analyzes the localizability of point-to-line and point-to-plane correspondences to detect and handle degeneracy in pose estimation. The proposed localizability detection method has the potential to be extended to other variants of ICP or multi-sensor fusion frameworks. The optimization module incorporates both soft and hard constraints to improve accuracy and reduce fluctuations. We have demonstrated through extensive experiments that the proposed algorithm performs accurate localizability detection and robust pose estimation in challenging environments, achieving higher or comparable accuracy in localization and mapping.

Index Terms—SLAM, iterative closest point (ICP), LiDAR degeneracy, localizability, unstructured environments.

I. INTRODUCTION

SIMULTANEOUS Localization and Mapping (SLAM) provides robots with pose information and a map of the surrounding environment, serving as a key technology in robotics. Currently, sensors such as LiDAR, cameras, and inertial measurement units (IMUs) are frequently used in SLAM systems. The point clouds from LiDAR can provide accurate distance measurements. Therefore, LiDAR-based methods have become an important branch of SLAM [1]–[3].

Point cloud registration is a crucial step in LiDAR-based SLAM approaches. It aligns two sets of point clouds by finding the optimal rotation and translation [4], [5]. The Iterative Closest Point (ICP) algorithm is commonly used for scan-to-scan or scan-to-map registration to estimate the robot's pose. Common distance metrics include point-to-point [6], point-to-line [7], and point-to-plane [8], [9]. These methods have been widely adopted in many advanced SLAM systems [2], [10]–[13]. In recent years, the ICP algorithm has continued to undergo further research [14]–[16].

In typical urban or indoor environments, there are generally sufficient geometric constraints for existing point cloud registration methods. Therefore, the localization accuracy in these environments is quite satisfactory. However, extreme unstructured environments, such as planetary-like environments [17], [18] on Mars or the Moon, as well as underground tunnels [19], as shown in Fig. 1, are characterized by self-similarity and sparse geometrical structures. This results in insufficient constraints being provided for ICP optimization. The optimization is rendered degenerate in certain directions of the 6-DoF pose, leading to decrease in the accuracy of localization and mapping.

Different geometric constraint information, such as planes in various orientations or their edges, has varying impacts on the

solution of ICP optimization. The evaluation of such impacts and the handling of different levels of degeneracy should be incorporated into the framework to improve the nature of the solution. Zhang et al. [20] were the first to introduce the degeneracy factor into the optimization problem of state estimation, which can be used to detect the overall degeneracy level in each direction of the 6-DoF pose. However, it can only assess the overall degeneracy in a given direction and cannot be used to calculate the localizability contribution of individual constraints within it. Additionally, the binary judgment of degeneracy relies on threshold settings, which may lead to insufficient utilization of the constraints information. Tuna et al. [21] recently introduced localizability detection of individual constraints in point-to-plane ICP for point cloud registration and established a ternary judgment for degeneracy, referred to as X-ICP. However, their method does not utilize point-to-line localizability information, which limits the potential for further accuracy improvement. Moreover, the formula for calculating the localizability contribution of individual constraints cannot be generalized to broader ICP algorithms and their variants. Additionally, X-ICP introduces hard constraints in partially localizable optimization directions. This increases the risk of fluctuations or even significant drift in the estimated trajectory in some SLAM systems, potentially leading to localization failure.

In this paper, we propose a new localizability-aware point cloud registration framework, LP-ICP, to address the LiDAR degeneracy problem. It is designed to improve the localization and mapping accuracy of SLAM systems in extreme unstructured environments. The proposed framework is illustrated in Fig. 2. More specifically, LP-ICP is a point cloud registration framework that combines point-to-line and point-to-plane distance metrics in the ICP algorithm, with localizability detection and handling. The calculation formulas for the localizability contribution of individual correspondence constraints can be applied to other variants of ICP, or more

generally, to pose estimation problems optimized using the Gauss-Newton method, such as estimating poses by minimizing the reprojection error in vision-based methods. Therefore, it has the potential to be extended to multi-sensor fusion frameworks. It consists of two modules: the localizability detection module (LocDetect-Module) and the optimization module with soft and hard constraints (Optimization-Module). During the scan-to-map registration, the LocDetect-module utilizes the correspondences between edge points and lines, as well as between planar points and planes. It analyzes the contribution strength along the principal directions of the optimization in the eigenspace. Then, we filter out the noise and pick out high localizability contributions. Further, the localizability of each direction of the 6-DoF pose is evaluated through a ternary threshold judgment, classified as: fully localizable, partially localizable, and non-localizable.

The Optimization-Module first calculates additional constraints, utilizing localizability information from geometric constraints and correspondences with high localizability contributions. Then, based on the localizability categories from the LocDetect-Module, soft and hard constraints are added to the optimization equation. This ensures that the pose in non-localizable directions is not updated, maintaining the initial estimate unchanged. In partially localizable directions, the pose is updated under additional constraints, tending toward the constraint value rather than being strictly equal to it. This reduces the risk of large pose fluctuations and drift, which could lead to localization failure. This is one of the differences between our approach and [21]. For fully localizable directions, the pose update remains unaffected. The aim is to effectively utilize more geometric constraint information while attempting to ensure relatively stable pose updates.

Additionally, to test the algorithm’s performance in typical extreme unstructured environments, such as planetary-like environments, we collected a simulated SLAM dataset with LiDAR, IMU, and camera data from a visually realistic lunar-like environment. The dataset contains 10 sequences. The total trajectory length is 10 km. It can be used to test various components of the SLAM framework and different tasks in planetary exploration.

The proposed framework has been tested in multiple experiments on challenging simulation and real-world datasets. The experiments suggest that LP-ICP performs well in extreme unstructured environments and can improve the robot’s localization capability and mapping accuracy in degraded environments. Compared to the state-of-the-art approaches [20], [21], the proposed framework achieves higher or comparable accuracy in all experiments.

To summarize, the contributions of this work are listed as follows:

- We propose a new ICP algorithm framework with localizability detection and handling, utilizing point-to-line and point-to-plane localizability information. It is used to detect and handle degeneracy in extreme unstructured environments.
- We propose a general method for calculating the localizability contribution of individual correspondences. It can

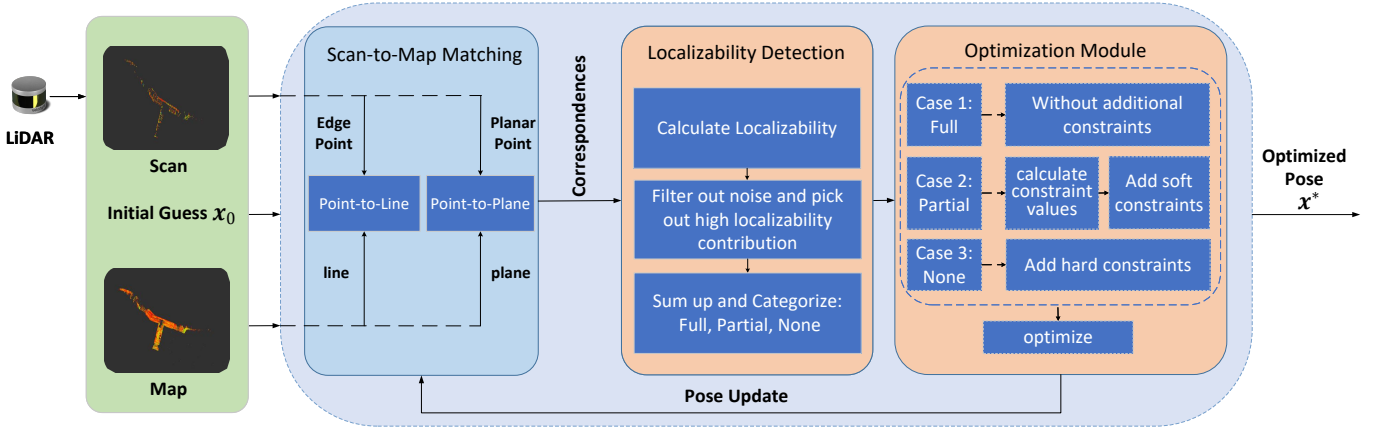

Fig. 2. Overview of the Proposed Point Cloud Registration Framework. The current scan from the LiDAR frame is transformed into the map frame using the initial estimate x_0 and enters the ICP loop together with the existing map. Next, LP-ICP, which combines point-to-line and point-to-plane distance metrics into the ICP framework, applies the proposed localizability detection and optimization modules to estimate the optimal pose.

be used for pose estimation problems optimized using the Gauss-Newton method.

- A combined soft and hard constraint ICP optimization module, which utilizes localizability information, is developed to handle degeneracy.
- We collected a multi-sensor simulated SLAM dataset from a visually realistic lunar-like environment, used for SLAM testing in typical extreme degraded environments.
- Comparing with state-of-the-art methods, a variety of experiments verify the efficacy of the proposed framework.

II. RELATED WORK

In this section, we first review the ICP method and its variants. After that, we survey studies related to degeneracy detection and handling.

A. ICP Algorithm and Its Variants

Point cloud registration aligns two or more sets of point clouds into a unified coordinate system by solving for the pose transformation between them. ICP is a commonly used method for point cloud registration. The ICP algorithm iteratively solves for the pose transformation between the source and target point clouds by minimizing a cost function, obtaining the optimal solution. Over the years, the ICP algorithm has evolved to include cost functions with different metrics, such as point-to-point [6], point-to-line [7], and point-to-plane [8], [9]. Segal et al. [22] combined point-to-point and point-to-plane ICP into a probabilistic framework. Furthermore, Billings et al. [23] introduced a noise model for further extension. Serafin and Grisetti [24] proposed NICEP, which incorporates angular errors of normal vectors into the cost function. Li et al. [25] considered both the angles and distances of local normals while introducing a point-to-surface version of ICP. Additionally, there are learning-based methods, such as [26]. Currently, the ICP algorithm combining point-to-line and point-to-plane distance metrics remains one of the preferred choices. It has been applied in many advanced SLAM systems, such as [2], [10], [11], [27].

Currently, existing algorithms already demonstrate strong performance in feature-rich environments. However, in extreme unstructured environments, such as planetary-like environments or underground tunnels, they often fail due to the lack of features and structures. The lack of geometric constraints may lead to degeneracy in certain directions of 6-DoF pose estimation. When combined with the impact of noise, this can potentially result in an incorrect global optimal solution. Therefore, detecting and handling degeneracy is essential to obtain reliable pose estimation.

B. Degeneracy Detection and Handling

In recent years, many studies on degeneracy detection and handling have emerged. Gelfand et al. [28] proposed a point selection strategy to improve the geometric stability of the point-to-plane ICP algorithm. When selecting sampling points, the condition number of the covariance matrix is used as a stability measure. By increasing the sampling points in regions with fewer geometric constraints, the ICP algorithm reduces unstable transformations caused by sliding and improves accuracy. For point selection, the normal vector information of point-to-plane correspondences is utilized. However, it cannot handle situations where there are insufficient points in degenerate directions to allow for perfect optimization convergence. Shi et al. [29] proposed a degeneration-aware correlative scan matching (CSM) algorithm, DN-CSM, for 2D LiDAR. The algorithm extracts dense normal vector features from the current point cloud. By modeling and aggregating these features, it calculates the degeneracy direction and degree. It then utilizes a motion model with dynamic weighting to account for the degeneracy and implement CSM.

Zhang et al. [20] pioneered the concept of the degeneracy factor, using the eigenvalues of the Hessian matrix to evaluate the overall degeneracy in the six directions of pose estimation. By solution remapping, they ensure that poses in degenerate directions do not update, thereby mitigating the negative impact of degeneracy. This method has been adopted in several LiDAR-based SLAM frameworks, such as [2], [11], [30]–[33]. Hinduja et al. [34] used the condition number to set

a threshold for determining degeneracy in the point-to-plane ICP algorithm. During optimization, they applied the solution remapping technique. The results were incorporated into the SLAM pose graph optimization as partial loop closure factors, ensuring that ICP and pose graph updates and optimization are performed only in well-constrained directions of the state space. Lee et al. [35], building on [20], utilized a chi-square distribution to non-heuristically set thresholds for the three most degenerate directions in LiDAR odometry. Wen et al. [36] set a threshold for binary detection of degeneracy by using the total residuals of the ICP algorithm in LiDAR odometry and the pose estimation results of the Visual-Inertial Odometry (VIO). In the degenerate direction of the LiDAR odometry, only visual measurements and IMU residuals are used for estimation. However, these methods cannot be used to evaluate the localizability contribution of individual constraints. Furthermore, the binary degeneracy detection depends on threshold settings, which may result in insufficient utilization of constraint information.

Zhen et al. [37] proposed a method that constructs an information matrix using the plane normal vectors from an existing map. They then use its eigenvalues to assess the localizability in the translational directions. However, they did not provide a detailed explanation or handling approach for the metrics. Furthermore, Zhen and Scherer [38] in the point-to-plane ICP algorithm used the sensitivity of LiDAR measurements w.r.t. the 6-DoF pose as a measure of localizability to assess the strength of the constraints. They also utilized the geometric information from the point and plane normals. To handle low localizability, they chose to incorporate measurements from other sensors for compensation. Tuna et al. [21] recently introduced localizability detection into the point-to-plane ICP algorithm, utilizing point and plane normal information, referred to as X-ICP. They pioneered a ternary degeneracy judgment mechanism for each direction of the pose solution, thereby incorporating more constraint information. The localizability calculation formula for individual constraints is explained from a geometric or force perspective. However, further mathematical derivation and explanation from the perspective of degeneracy are necessary. Furthermore, in some SLAM systems, X-ICP optimization uses hard constraints in partially localizable directions, which increases the risk of trajectory fluctuations or even significant drift, potentially leading to localization failure. Hatleskog and Alexis [39] proposed a method in the point-to-plane ICP algorithm that considers the noise in both point and plane normals. By accounting for the probabilistic characteristics of the noise entering the Hessian, their approach helps to detect degeneracy and reduces the impact of noise in degenerate directions. These studies provide more fine-grained detection of localizability and enable the evaluation of the localizability contribution of individual constraints. However, they are limited to the point-to-plane ICP algorithm and do not utilize the localizability information from point-to-line correspondences, which limits further improvements in accuracy.

Nubert et al. [40] proposed using a learning-based approach to detect the localizability of LiDAR. The method is trained with simulated data and utilizes the point-to-plane

ICP algorithm. Degeneracy detection does not require heuristic threshold adjustments, but it still relies on a binary decision. Moreover, it is only applicable to scan-to-scan point cloud registration. There are also learning-based methods such as [41], [42]. However, their reliance on labeled ground truth data and high computational demands limits their use in resource-constrained systems.

III. PROBLEM FORMULATION, PRELIMINARIES AND SYSTEM OVERVIEW

This section introduces the preliminaries of point cloud registration and degeneracy detection, as well as the problem we aim to address. Finally, an overview of the LP-ICP system framework is provided.

A. Optimization-Based Point Cloud Registration

An optimization-based state estimation problem can be formulated by solving a function:

$$\arg \min_{\mathbf{x}} \mathbf{f}^2(\mathbf{x}). \quad (1)$$

Here, \mathbf{x} is an $n \times 1$ state vector, where n is the dimension of the state space.

In point cloud registration, the optimal solution can be obtained by iteratively solving for the pose transformation between the source and target point clouds through minimizing a cost function. Let $f_i(\mathbf{x})$ denotes the residual for each correspondence between the source and target point clouds. The problem is then equivalent to solving the following:

$$\arg \min_{\mathbf{x} \in \mathbb{R}^6} \sum_{i=1}^N \|f_i(\mathbf{x})\|^2. \quad (2)$$

Here, $\mathbf{x} = (\mathbf{r}^T \ \mathbf{t}^T)^T \in \mathbb{R}^6$. \mathbf{x} is the pose state vector, where \mathbf{r} denotes the 3-DoF rotation representation, \mathbf{t} denotes the 3-DoF translation vector, and N denotes the number of matching correspondences.

Currently, the ICP algorithm combining point-to-line and point-to-plane distance metrics remains one of the preferred choices. It has been applied in many advanced SLAM systems, such as [2], [10], [11], [27]. To balance efficiency, accuracy, and robustness, representative geometric feature points are often extracted for optimization. For example, edge points are used with point-to-line cost functions, and planar points with point-to-plane cost functions, with both types of points combined to participate together in the ICP optimization [2].

The combined point-to-line and point-to-plane ICP minimization problem is defined as follows:

$$\min_{\mathbf{R}, \mathbf{t}} \sum_{i=1}^{N_1} \|f_{ei}(\mathbf{x})\|^2 + \sum_{j=1}^{N_2} \|f_{pj}(\mathbf{x})\|^2 \quad (3)$$

where

$$f_{ei}(\mathbf{x}) = \|(\mathbf{R}\mathbf{p}_i^L + \mathbf{t} - \mathbf{q}_i^M) \times \mathbf{l}_i^M\| \quad (4)$$

$$f_{pj}(\mathbf{x}) = \|(\mathbf{R}\mathbf{p}_j^L + \mathbf{t} - \mathbf{q}_j^M) \cdot \mathbf{n}_j^M\|. \quad (5)$$

Here, $f_{ei}(\mathbf{x})$ is the residual for an edge point to a line. $f_{pj}(\mathbf{x})$ is the residual for a planar point to a plane. N_1 is the number of edge points, N_2 is the number of planar points, and the total number of points is $N = N_1 + N_2$.

Specifically, the alignment of the current scan point cloud \mathbf{p}^L in the LiDAR frame (denoted as L) with the map point cloud \mathbf{q}^M in the map frame (denoted as M) is achieved through the transformation $\mathbf{T} = [\mathbf{R} \mid \mathbf{t}]$ (or $\mathbf{x} = (\mathbf{r}^T \mathbf{t}^T)^T \in \mathbb{R}^6$). Here, $\mathbf{R} \in SO(3)$ denote the rotation matrix and $\mathbf{t} \in \mathbb{R}^3$ denote the translation vector. \mathbf{p}_i^L and \mathbf{p}_j^L are the edge and planar points extracted from the LiDAR frame, respectively. \mathbf{q}_i^M and \mathbf{q}_j^M are the corresponding matching points in the map frame, typically found using a search method, such as k-d tree search. \mathbf{l}_j^M is the unit direction vector of the edge line passing through \mathbf{q}_i^M , and \mathbf{n}_j^M is the unit normal vector of the plane passing through \mathbf{q}_j^M .

The problem can be solved iteratively using the Gauss-Newton method.

B. Degeneracy Detection

In degraded environments, the performance of point cloud registration deteriorates. Therefore, it is necessary to detect and handle degeneracy. Zhang et al. [20] pioneered the use of a degeneracy factor D to evaluate whether the 6-DoF pose solution \mathbf{x} is degenerate in a certain direction. The meaning of D is expressed as follows: by perturbing the constraint with a displacement of distance δd , the resulting shift δx_c of the true solution \mathbf{x}_0 in the direction of perturbation c is given by $D = \frac{\delta d}{\delta x_c}$. In other words, D denotes the stiffness of the solution under constraint perturbation. If D is smaller, meaning that for the same perturbation δd , the amount of movement δx_c of the solution in that direction is larger. It indicates that the stiffness w.r.t. disturbances is lower in that direction. Through the mathematical derivation in [20], it is concluded that:

$$D = \frac{\delta d}{\delta x_c} = \lambda + 1. \quad (6)$$

Here, λ is the eigenvalue of the matrix $\mathbf{A}^T \mathbf{A}$, where \mathbf{A} comes from the following equation (i.e. the linearized form of (1)):

$$\arg \min_{\mathbf{x}} \|\mathbf{A}\mathbf{x} - \mathbf{b}\|. \quad (7)$$

The Gauss-Newton method is a commonly used approach for solving optimization problems. In optimization problems solved using the Gauss-Newton method, λ is the eigenvalues corresponding to the Hessian matrix of the original optimization problem. λ can be used to evaluate whether optimization in a specific direction suffers from degeneracy. However, it cannot assess the localizability contribution of individual correspondence constraints in that direction. As a result, geometric information cannot be more effectively utilized in the optimization process to improve localization accuracy. Therefore, obtaining more fine-grained localizability detection results is one of the objectives of this study.

C. System Overview

LP-ICP is divided into two modules: the Localizability Detection Module (LocDetect-Module) and the Optimization Module with soft and hard constraints (Optimization-Module). The proposed framework is shown in Fig. 2. LP-ICP is integrated into the point cloud registration framework of LVI-SAM [11] for evaluation and validation. LVI-SAM integrates the LIO (LiDAR-Inertial Odometry) submodule and the VIO (Visual-Inertial Odometry) submodule. The LIO submodule is the primary component, and the VIO submodule provides the initial estimates to the LIO submodule. Note that in LVI-SAM, the 3-DOF rotation in the pose are represented using Euler angles.

The LocDetect-Module first derives the formula for calculating the localizability contribution of individual correspondence constraints. Note that in the ICP algorithm, we refer to a correspondence used to constrain pose estimation, such as a point-to-line or point-to-plane correspondence, as an individual correspondence constraint. This approach is not only applicable to point-to-line and point-to-plane ICP algorithms but can also be extended to pose estimation problems optimized using the Gauss-Newton method, such as variants of ICP or pose estimation through optimizing the reprojection error. This corresponds to Section IV-A. Then, the localizability contribution vectors for each edge point \mathbf{p}_i in the point-to-line metric are computed: $\mathbf{F}_{ri}^e \in \mathbb{R}^{3 \times 1}$ in the rotation direction and $\mathbf{F}_{ti}^e \in \mathbb{R}^{3 \times 1}$ in the translation direction. Similarly, the localizability contribution vectors for each planar point \mathbf{p}_j in the point-to-plane metric are computed: $\mathbf{F}_{rj}^p \in \mathbb{R}^{3 \times 1}$ in the rotation direction and $\mathbf{F}_{tj}^p \in \mathbb{R}^{3 \times 1}$ in the translation direction. The localizability vectors in each direction of the 6-DOF pose are aggregated to assess the localizability in the corresponding direction. They are then compared with thresholds to categorize the localizability into three types: non-localizable (None), partially localizable (Partial), and fully localizable (Full). This corresponds to Section IV-B and Section IV-C.

The Optimization-Module (Section V) utilizes the categorization results from the LocDetect-Module for each direction of the 6-DOF pose, along with higher localizability contributions. It constructs optimization equations to solve for the optimal pose estimate \mathbf{x}^* . We use a method combining soft and hard constraints. Hard constraints are applied in non-localizable directions to prevent pose updates in those directions. Soft constraints are added in partially localizable directions, allowing the pose to be updated under the constraint, with the pose tending toward the constraint value rather than being strictly equal to it. This reduces the risk of large pose fluctuations or drift, which could otherwise lead to localization failure. The pose update in fully localizable directions is unaffected.

IV. LOCALIZABILITY DETECTION MODULE

This section first derives the formula for calculating the localizability contribution of individual correspondence constraints, and then elaborates on the LocDetect-Module.

A. Localizability of an Individual Correspondence Constraint

It is known that the degeneracy factor D can be used to evaluate the level of degeneracy in each direction of the 6-DOF pose, and it is applicable to general pose estimation problems.

If the pose estimation problem in (2) is solved using the Gauss-Newton method, then λ in (6) is also the eigenvalue corresponding to the Hessian matrix of the original optimization problem in (2). The Hessian matrix is as follows:

$$\mathbf{H} = \mathbf{J}^T \mathbf{J} = \sum_{i=1}^N \mathbf{J}_i^T \mathbf{J}_i \in \mathbb{R}^{6 \times 6} \quad (8)$$

where \mathbf{J}_i is the Jacobian matrix of $f_i(\mathbf{x})$ w.r.t. the pose $\mathbf{x} = (\mathbf{r}^T \ \mathbf{t}^T)^T \in \mathbb{R}^6$, i.e. $\mathbf{J}_i = \frac{\partial f_i(\mathbf{x})}{\partial \mathbf{x}} = \left(\frac{\partial f_i(\mathbf{x})}{\partial x_1}, \dots, \frac{\partial f_i(\mathbf{x})}{\partial x_6} \right) \in \mathbb{R}^{1 \times 6}$. So for N correspondence constraints, we have: $\mathbf{J} = (\mathbf{J}_1^T \dots \mathbf{J}_N^T)^T \in \mathbb{R}^{N \times 6}$.

Since \mathbf{H} is a real symmetric matrix, it can be diagonalized by eigenvalue decomposition as follows:

$$\mathbf{H} = \mathbf{V} \mathbf{\Lambda} \mathbf{V}^T.$$

Here, $\mathbf{V} = (\mathbf{v}_1 \ \dots \ \mathbf{v}_6)$ are the eigenvectors in matrix form and $\mathbf{v}_i \in \mathbb{R}^{6 \times 1}$ is the eigenvector corresponding to the eigenvalues λ_i in the diagonal matrix $\mathbf{\Lambda}$.

So we obtain:

$$\mathbf{\Lambda} = \mathbf{V}^T \mathbf{H} \mathbf{V} = \mathbf{V}^T \mathbf{J}^T \mathbf{J} \mathbf{V} = (\mathbf{J} \mathbf{V})^T \mathbf{J} \mathbf{V}.$$

Here, the calculation formula for $\mathbf{J} \mathbf{V}$ is as follows:

$$\mathbf{J} \mathbf{V} = \begin{pmatrix} \mathbf{J}_1 \mathbf{v}_1 & \dots & \mathbf{J}_1 \mathbf{v}_6 \\ \vdots & \ddots & \vdots \\ \mathbf{J}_N \mathbf{v}_1 & \dots & \mathbf{J}_N \mathbf{v}_6 \end{pmatrix} \in \mathbb{R}^{N \times 6}$$

where $\mathbf{J}_i \mathbf{v}_j$ denotes the projection of \mathbf{J}_i in the direction of the eigenvector \mathbf{v}_j .

Since $\mathbf{\Lambda}$ is a diagonal matrix, we have:

$$\begin{aligned} \mathbf{\Lambda} &= (\mathbf{J} \mathbf{V})^T \mathbf{J} \mathbf{V} \\ &= \begin{pmatrix} \sum_{i=1}^N (\mathbf{J}_i \mathbf{v}_1)^2 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \sum_{i=1}^N (\mathbf{J}_i \mathbf{v}_6)^2 \end{pmatrix} \in \mathbb{R}^{6 \times 6} \\ &= \begin{pmatrix} \lambda_1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \lambda_6 \end{pmatrix}. \end{aligned} \quad (9)$$

Thus, we obtain:

$$\lambda_j = \sum_{i=1}^N (\mathbf{J}_i \mathbf{v}_j)^2 \quad (10)$$

That is, λ_j equals the sum of the squared projections of \mathbf{J}_i onto the eigenvector \mathbf{v}_j , where \mathbf{J}_i is the Jacobian of the i -th residual $f_i(\mathbf{x})$ w.r.t. the pose \mathbf{x} .

According to (6), λ_j can be compared with a threshold to determine whether the state estimation problem in (2) is degenerate in the \mathbf{v}_j direction. λ_j can be used to evaluate the level of degeneracy in the \mathbf{v}_j direction. This is equivalent to using

(10) to compare with the threshold to assess degeneracy in the \mathbf{v}_j direction. In other words, it evaluates the localizability of the N correspondence constraints in the \mathbf{v}_j direction.

We take one of the terms in the summation formula (10) and define F_{ji} as the localizability contribution of an individual correspondence constraint, as follows:

$$F_{ji} = (\mathbf{J}_i \mathbf{v}_j)^2 \quad (11)$$

It is used to evaluate the localizability contribution of the i -th correspondence constraint in the direction along \mathbf{v}_j .

So we have:

$$\lambda_j = \sum_{i=1}^N F_{ji} \quad (12)$$

Note that We provide two equations similar to (11) and (12), as follows:

$$L_j = \sum_{i=1}^N |\mathbf{J}_i \mathbf{v}_j| \quad (13)$$

$$F_{ji} = |\mathbf{J}_i \mathbf{v}_j| \quad (14)$$

We consider (11) and (14), as well as (12) and (13), to be similar in nature but different in value. When (13) and (14) are used in the point-to-plane ICP algorithm, and rotation is represented using Lie algebra, they become identical to the localizability evaluation formula of X-ICP [21]. In other words, the localizability detection formula of [21] is a special case of the conclusions derived in this study.

For the convenience of subsequent calculations and usage, we choose to decouple translation and rotation in the above derivation. That is, for N correspondence constraints, we have: $\mathbf{J}_r = (\mathbf{J}_{r1}^T \dots \mathbf{J}_{rN}^T)^T \in \mathbb{R}^{N \times 3}$ in the rotation directions and $\mathbf{J}_t = (\mathbf{J}_{t1}^T \dots \mathbf{J}_{tN}^T)^T \in \mathbb{R}^{N \times 3}$ in the translation directions, where $\mathbf{J}_{ri} \in \mathbb{R}^{1 \times 3}$ is the Jacobian of the i -th residual $f_i(\mathbf{x})$ w.r.t. the 3-DOF rotation and $\mathbf{J}_{ti} \in \mathbb{R}^{1 \times 3}$ is the Jacobian of the i -th residual $f_i(\mathbf{x})$ w.r.t. the 3-DOF translation. That is, it is equivalent to performing eigenvalue decomposition on the top-left 3×3 matrix \mathbf{H}_r and the bottom-right 3×3 matrix \mathbf{H}_t of the Hessian matrix \mathbf{H} , as follows:

$$\mathbf{H}_r = \mathbf{J}_r^T \mathbf{J}_r = \mathbf{V}_r \mathbf{\Lambda}_r \mathbf{V}_r^T \quad (15)$$

$$\mathbf{H}_t = \mathbf{J}_t^T \mathbf{J}_t = \mathbf{V}_t \mathbf{\Lambda}_t \mathbf{V}_t^T \quad (16)$$

In the rotation direction, we have $\mathbf{V}_r = (\mathbf{v}_{r1} \ \mathbf{v}_{r2} \ \mathbf{v}_{r3})$, where $\mathbf{v}_{rj} \in \mathbb{R}^{3 \times 1}$ is the eigenvector corresponding to the eigenvalue λ_j in the diagonal matrix $\mathbf{\Lambda}_r$. In the translation direction, we have $\mathbf{V}_t = (\mathbf{v}_{t1} \ \mathbf{v}_{t2} \ \mathbf{v}_{t3})$, where $\mathbf{v}_{tj} \in \mathbb{R}^{3 \times 1}$ is the eigenvector corresponding to the eigenvalue λ_j in the diagonal matrix $\mathbf{\Lambda}_t$.

Similarly, we can derive conclusions analogous to (11) and (12). In the rotation direction, we obtain:

$$\lambda_j = \sum_{i=1}^N (\mathbf{J}_{ri} \mathbf{v}_{rj})^2 \quad (17)$$

where $j = 1, 2, 3$. That is, λ_j equals the sum of the squared projections of \mathbf{J}_{ri} onto the rotation-related eigenvector \mathbf{v}_{rj} .

The localizability contribution vectors of the i -th correspondence constraint in the three directions \mathbf{v}_{r1} , \mathbf{v}_{r2} and \mathbf{v}_{r3} of the rotational eigenspace are as follows:

$$\mathbf{F}_{ri} = \begin{pmatrix} (\mathbf{J}_{ri}\mathbf{v}_{r1})^2 \\ (\mathbf{J}_{ri}\mathbf{v}_{r2})^2 \\ (\mathbf{J}_{ri}\mathbf{v}_{r3})^2 \end{pmatrix} \in \mathbb{R}^{3 \times 1} \quad (18)$$

Similarly, in the translation direction, we have:

$$\lambda_j = \sum_{i=1}^N (\mathbf{J}_{ti}\mathbf{v}_{tj})^2 \quad (19)$$

where $j = 1, 2, 3$.

The localizability contribution vectors of the i -th correspondence constraint in the three directions \mathbf{v}_{t1} , \mathbf{v}_{t2} and \mathbf{v}_{t3} of the translational eigenspace are as follows:

$$\mathbf{F}_{ti} = \begin{pmatrix} (\mathbf{J}_{ti}\mathbf{v}_{t1})^2 \\ (\mathbf{J}_{ti}\mathbf{v}_{t2})^2 \\ (\mathbf{J}_{ti}\mathbf{v}_{t3})^2 \end{pmatrix} \in \mathbb{R}^{3 \times 1} \quad (20)$$

Eq. (18) and (20) are used to evaluate the localizability contribution of the i -th correspondence constraint in each direction of the 6-DOF pose. And subsequent calculations are performed using (18) and (20).

B. Localizability Contribution of Edge Point-to-Line and Planar Points-to-Plane Correspondences

Here, we compute the localizability contribution of each edge point-to-line correspondence constraint and each planar point-to-plane correspondence constraint in (3), respectively.

The localizability contribution vector for an individual correspondence constraint can be computed using (18) and (20). First, we calculate the Jacobian, and then project it onto the eigenspace to obtain the localizability contribution vector for each correspondence constraint.

Note that for the 3-DOF rotation, we will provide two versions of the Jacobian for reference: one calculated using Lie algebra and the other using Euler angles. We integrate LP-ICP into the point cloud registration framework of the LVI-SAM [11]. Since the rotation in the LVI-SAM algorithm is represented using Euler angles, we will use the Euler angle-based Jacobian for subsequent calculations.

1) *Jacobian of the Point-to-Line Cost Function*: In the point-to-line cost function (4), the Jacobians of the distance residual f_{ei} w.r.t. translation \mathbf{t} for the edge point $\mathbf{p}_i^L = (p_{ix}, p_{iy}, p_{iz})^T \in \mathbb{R}^{3 \times 1}$ are calculated as follows:

$$\mathbf{J}_{ti}^e = (\mathbf{d}_i^M)^T. \quad (21)$$

Here, $\mathbf{d}_i^M = (d_{ix}, d_{iy}, d_{iz})^T \in \mathbb{R}^{3 \times 1}$ is the unit distance vector from the edge point \mathbf{p}_i^M to the associated line in the map frame.

The Jacobians of the distance residual $f_{ei}(\mathbf{x})$ w.r.t. rotation \mathbf{r} for the edge point \mathbf{p}_i^L are calculated, when the rotation is represented using Lie algebra, as follows:

$$\mathbf{J}_{ri}^e = (\mathbf{p}_i^L \times \mathbf{d}_i^L)^T. \quad (22)$$

When the rotation is represented using Euler angles (α, β, γ) , it is as follows:

$$\mathbf{J}_{ri}^e = (\mathbf{J}_{rix}^e, \mathbf{J}_{riy}^e, \mathbf{J}_{riz}^e) \quad (23)$$

where

$$\begin{aligned} \mathbf{J}_{rix}^e &= [(s\alpha s\gamma + c\alpha s\beta c\gamma)p_{iy} + (s\alpha c\gamma - c\alpha s\beta s\gamma)p_{iz}] \times d_{ix}^M \\ &\quad + [(-c\alpha s\gamma + s\alpha s\beta c\gamma)p_{iy} + (-c\alpha c\gamma - s\alpha s\beta s\gamma)p_{iz}] \times d_{iy}^M \\ &\quad + [c\beta c\gamma p_{iy} - c\beta s\gamma p_{iz}] \times d_{iz}^M, \\ \mathbf{J}_{riy}^e &= [-c\alpha s\beta p_{ix} + (c\alpha c\beta s\gamma)p_{iy} + (c\alpha c\beta c\gamma)p_{iz}] \times d_{ix}^M \\ &\quad + [-s\alpha s\beta p_{ix} + (s\alpha c\beta s\gamma)p_{iy} + (s\alpha c\beta c\gamma)p_{iz}] \times d_{iy}^M \\ &\quad + [-c\beta p_{ix} - s\beta s\gamma p_{iy} - s\beta c\gamma p_{iz}] \times d_{iz}^M, \\ \mathbf{J}_{riz}^e &= [-s\alpha c\beta p_{ix} + (-c\alpha c\gamma - s\alpha s\beta s\gamma)p_{iy} \\ &\quad + (c\alpha s\gamma - s\alpha s\beta c\gamma)p_{iz}] \times d_{ix}^M \\ &\quad + [c\alpha c\beta p_{ix} + (-s\alpha c\gamma + c\alpha s\beta s\gamma)p_{iy} \\ &\quad + (s\alpha s\gamma + c\alpha s\beta c\gamma)p_{iz}] \times d_{iy}^M. \end{aligned}$$

Here, $s\alpha = \sin(\alpha)$, $c\alpha = \cos(\alpha)$, and similarly for others.

Subsequent calculations for \mathbf{J}_{ti}^e and \mathbf{J}_{ri}^e in this paper will use (21), and (23), respectively.

2) *Jacobian of the Point-to-Plane Cost Function*: Similarly, in the point-to-plane cost function (5), the Jacobian of the distance residual $f_{pi}(\mathbf{x})$ w.r.t. the translation \mathbf{t} for the planar point $\mathbf{p}_i^L = (p_{ix}, p_{iy}, p_{iz})^T \in \mathbb{R}^{3 \times 1}$ is calculated as follows:

$$\mathbf{J}_{ti}^p = (\mathbf{n}_i^M)^T. \quad (24)$$

Here, $\mathbf{n}_i^M = (n_{ix}, n_{iy}, n_{iz})^T \in \mathbb{R}^{3 \times 1}$ is the unit normal vector of the plane associated with the planar point \mathbf{p}_i^M in the map frame.

The Jacobians of the distance residual $f_{pi}(\mathbf{x})$ w.r.t. rotation \mathbf{r} for the planar point \mathbf{p}_i^L are calculated, when the rotation is represented using Lie algebra, as follows:

$$\mathbf{J}_{ri}^p = (\mathbf{p}_i^L \times \mathbf{n}_i^L)^T. \quad (25)$$

When the rotation is represented using Euler angles (α, β, γ) , it is as follows:

$$\mathbf{J}_{ri}^p = (\mathbf{J}_{rix}^p, \mathbf{J}_{riy}^p, \mathbf{J}_{riz}^p) \quad (26)$$

where

$$\begin{aligned} \mathbf{J}_{rix}^p &= [(s\alpha s\gamma + c\alpha s\beta c\gamma)p_{iy} + (s\alpha c\gamma - c\alpha s\beta s\gamma)p_{iz}] \times n_{ix}^M \\ &\quad + [(-c\alpha s\gamma + s\alpha s\beta c\gamma)p_{iy} + (-c\alpha c\gamma - s\alpha s\beta s\gamma)p_{iz}] \times n_{iy}^M \\ &\quad + [c\beta c\gamma p_{iy} - c\beta s\gamma p_{iz}] \times n_{iz}^M, \end{aligned}$$

$$\begin{aligned} \mathbf{J}_{riy}^p &= [-c\alpha s\beta p_{ix} + (c\alpha c\beta s\gamma)p_{iy} + (c\alpha c\beta c\gamma)p_{iz}] \times n_{ix}^M \\ &\quad + [-s\alpha s\beta p_{ix} + (s\alpha c\beta s\gamma)p_{iy} + (s\alpha c\beta c\gamma)p_{iz}] \times n_{iy}^M \\ &\quad + [-c\beta p_{ix} - s\beta s\gamma p_{iy} - s\beta c\gamma p_{iz}] \times n_{iz}^M, \end{aligned}$$

$$\begin{aligned} \mathbf{J}_{riz}^p &= [-s\alpha c\beta p_{ix} + (-c\alpha c\gamma - s\alpha s\beta s\gamma)p_{iy} \\ &\quad + (c\alpha s\gamma - s\alpha s\beta c\gamma)p_{iz}] \times n_{ix}^M \\ &\quad + [c\alpha c\beta p_{ix} + (-s\alpha c\gamma + c\alpha s\beta s\gamma)p_{iy} \\ &\quad + (s\alpha s\gamma + c\alpha s\beta c\gamma)p_{iz}] \times n_{iy}^M. \end{aligned}$$

Subsequent calculations for \mathbf{J}_{ti}^p and \mathbf{J}_{ri}^p in this paper will use (24) and (26), respectively.

3) *Localizability Contribution Vector*: The Jacobian in the rotation direction is influenced by the magnitude of the coordinates of point \mathbf{p} , which often leads to larger values. To facilitate the subsequent setting of uniform thresholds for translation and rotation directions, the scales of localizability in these two directions are unified. Here, we adopt the matrix normalization method from [21] to normalize the results in the rotation direction. If $\|\mathbf{J}_{ri}^e\|$ in (23) or $\|\mathbf{J}_{ri}^p\|$ in (26) is greater than 1, the operation is performed as follows:

$$\mathbf{J}_{ri}^e = \begin{cases} \frac{\mathbf{J}_{ri}^e}{\|\mathbf{J}_{ri}^e\|}, & \text{if } \|\mathbf{J}_{ri}^e\| > 1 \\ \mathbf{J}_{ri}^e, & \text{otherwise} \end{cases}$$

$$\mathbf{J}_{ri}^p = \begin{cases} \frac{\mathbf{J}_{ri}^p}{\|\mathbf{J}_{ri}^p\|}, & \text{if } \|\mathbf{J}_{ri}^p\| > 1 \\ \mathbf{J}_{ri}^p, & \text{otherwise} \end{cases}$$

Finally, based on (18) and (20), combined with (15), (16), (21), and (23), the localizability contribution vector of the edge point \mathbf{p}_i to the line correspondence constraint can be obtained as follows:

$$\mathbf{F}_{ri}^e = \begin{pmatrix} (\mathbf{J}_{ri}^e \mathbf{v}_{r1})^2 \\ (\mathbf{J}_{ri}^e \mathbf{v}_{r2})^2 \\ (\mathbf{J}_{ri}^e \mathbf{v}_{r3})^2 \end{pmatrix} \in \mathbb{R}^{3 \times 1} \quad (27)$$

$$\mathbf{F}_{ti}^e = \begin{pmatrix} (\mathbf{J}_{ti}^e \mathbf{v}_{t1})^2 \\ (\mathbf{J}_{ti}^e \mathbf{v}_{t2})^2 \\ (\mathbf{J}_{ti}^e \mathbf{v}_{t3})^2 \end{pmatrix} \in \mathbb{R}^{3 \times 1} \quad (28)$$

Similarly, based on (18) and (20), combined with (15), (16), (24), and (26), the localizability contribution vector of the planar point \mathbf{p}_j to the plane correspondence constraint can be obtained as follows:

$$\mathbf{F}_{ri}^p = \begin{pmatrix} (\mathbf{J}_{ri}^p \mathbf{v}_{r1})^2 \\ (\mathbf{J}_{ri}^p \mathbf{v}_{r2})^2 \\ (\mathbf{J}_{ri}^p \mathbf{v}_{r3})^2 \end{pmatrix} \in \mathbb{R}^{3 \times 1} \quad (29)$$

$$\mathbf{F}_{ti}^p = \begin{pmatrix} (\mathbf{J}_{ti}^p \mathbf{v}_{t1})^2 \\ (\mathbf{J}_{ti}^p \mathbf{v}_{t2})^2 \\ (\mathbf{J}_{ti}^p \mathbf{v}_{t3})^2 \end{pmatrix} \in \mathbb{R}^{3 \times 1} \quad (30)$$

All the localizability contribution vectors related to edge points and planar points are stacked together to form the following information matrix:

$$\mathbf{F}_r = [\mathbf{F}_{r1}^e \cdots \mathbf{F}_{rN_1}^e \quad \mathbf{F}_{r1}^p \cdots \mathbf{F}_{rN_2}^p]^T \quad (31)$$

$$\mathbf{F}_t = [\mathbf{F}_{t1}^e \cdots \mathbf{F}_{tN_1}^e \quad \mathbf{F}_{t1}^p \cdots \mathbf{F}_{tN_2}^p]^T \quad (32)$$

C. Determining the Categories of Localizability

All the localizability contribution vectors related to edge points and planar points have been obtained. Next, these vectors will be used to determine the localizability categories for each direction of the 6-DOF pose.

First, in order to reduce the influence of noise, low localizability contributions will be filtered out. At the same time, higher localizability contributions will be selected for subsequent constraint calculations. Furthermore, the localizability in each direction of the 6-DOF pose will be summed and compared with thresholds to determine the corresponding localizability category for each direction.

1) *Filtering Out Noise and Picking Out High Localizability Contributions*: Define $\mathbf{F} = [\mathbf{F}_r, \mathbf{F}_t] \in \mathbb{R}^{N \times 6}$ as the localizability matrix. In order to filter out low localizability contributions and reduce the interference of noise, we set a low contribution threshold h_f . For each localizability component $F(i, j)$ in \mathbf{F} (i.e. the localizability contribution of the i -th correspondence constraint in the direction \mathbf{v}_j), if it is lower than h_f , it is set to 0 and considered as noise, as shown in (33). Then, we further distinguish between moderate localizability contributions F_f and high localizability contributions F_u .

$$F_f(i, j) = \begin{cases} F(i, j), & \text{if } F(i, j) \geq h_f \\ 0, & \text{otherwise} \end{cases} \quad (33)$$

This paper empirically suggests $h_f = 0.03$. The value of h_f can be adjusted based on the noise characteristics of the LiDAR. The greater the noise, the larger the value. Additionally, non-zero localizability contributions in F_f can be considered as moderate localizability contributions. The sum of all moderate localizability contributions in the direction of \mathbf{v}_j is calculated as follows:

$$L_f(j) = \sum_{i=1}^{N_1+N_2} F_f(i, j) \quad (34)$$

$L_f(j)$ is the sum of the localizability contributions of all useful correspondence constraints in the direction of \mathbf{v}_j . The larger its value, the stronger the overall localizability contribution in the direction, indicating less degeneracy.

Next, we set a high contribution threshold h_u . Localizability contributions in $F_f(i, j)$ greater than h_u are considered high localizability contributions, indicating that the corresponding correspondence constraint has a strong influence in the direction of \mathbf{v}_j , as follows:

$$F_u(i, j) = \begin{cases} F(i, j), & \text{if } F(i, j) \geq h_u \\ 0, & \text{otherwise} \end{cases} \quad (35)$$

Fig. 3. Two exemplary double Y-axis histograms presenting L_f and L_u along each eigenvector direction of the 6-DOF pose. The calculated localizability contributions are from a LiDAR scan. It indicates smaller values of $L_f(j)$ and $L_u(j)$ in the v_{r3} , v_{t2} and v_{t3} directions. The red region represents the localizability contribution from edge point-to-line correspondences, while the pink region represents the contribution from planar point-to-plane correspondences.

This paper empirically suggests $h_u = 0.4998$.

The sum of all high localizability contributions in the direction of v_j is calculated as follows:

$$L_u(j) = \sum_{i=1}^{N_1+N_2} F_u(i, j) \quad (36)$$

$L_u(j)$ is the sum of the localizability contributions of all high localizability points in the direction of v_j . The larger its value, it indicates that more high-quality constraints can be provided in that direction.

An example of the calculation results for $L_f(j)$ and $L_u(j)$ is provided in Fig. 3. They are computed from the localizability contributions of a LiDAR scan performed in an open area with slightly undulating terrain. In the directions along v_{r1} , v_{r2} and v_{t1} , the values of $L_f(j)$ and $L_u(j)$ are large, indicating well-constrained conditions. In the directions along v_{r3} , v_{t2} and v_{t3} , the values of $L_f(j)$ and $L_u(j)$ are small, indicating ill-conditioned constraints. In ill-conditioned directions, the localizability contribution from edge point-to-line correspondences (red region) dominates, especially in the calculation of $L_u(j)$, which represents the sum of high localizability contributions. Therefore, it is essential to utilize the localizability information from edge point-to-line correspondences.

2) *Categorization*: The localizability contributions of all correspondence constraints related to edge points and planar points along the directions of the eigenvectors in the 6-DOF pose are summed to determine the localizability category for each corresponding direction. $L_f(j)$ represents the overall localizability contribution in the direction of v_j . $L_u(j)$ represents the localizability contribution of high-quality constraints in the direction of v_j . Based on their characteristics, thresholds T_1 , T_2 , T_3 and T_4 are set to determine the localizability category of the 6-DOF pose along the eigenvectors directions as follows:

in the direction along v_j ,

$$\text{Category} = \begin{cases} \text{Full}, & \text{if } L_f(j) \geq T_1 \text{ or } L_u(j) \geq T_2 \\ \text{Partial}, & \text{if } L_f(j) \geq T_3 \text{ and } L_u(j) \geq T_4 \\ \text{None}, & \text{otherwise} \end{cases} \quad (37)$$

That is, when $L_f(j) \geq T_1$ or $L_u(j) \geq T_2$, the localizability category of the direction along v_j is considered fully localizable, i.e. the category is “Full”. When $L_f(j) \geq T_3$ and $L_u(j) \geq T_4$, the localizability category of the direction along v_j is considered partially localizable, i.e. the category is “Partial”. In this direction, both $L_f(j)$ and $L_u(j)$ must meet their respective thresholds. This means that there must be a sufficient number of points with high localizability contributions in the direction along v_j , which helps improve the optimization quality after additional constraints are added in the subsequent steps. Otherwise, the localizability category of the direction of v_j is considered non-localizable, i.e. the category is “None”. In this study, based on experimental validation, for all subsequent experiments, T_1 is set to 50, T_2 is set to 30, T_3 is set to 15 and T_4 is set to 9.

The LocDetect-Module uses a scan from LiDAR to assign the localizability category of the 6-DOF pose along each eigenvector direction. An example is shown in Fig. 4, which illustrates the following process: In an open area with undulating terrain, the current scan from LiDAR is used as input. By calculating the localizability contributions of all edge point-to-line and planar point-to-plane correspondences, the values of $L_f(j)$ and $L_u(j)$ in the direction along v_j are obtained. These values are presented in the same double y-axis histograms as in Fig. 3, shown in Fig. 4(b). Subsequently, the values of $L_f(j)$ and $L_u(j)$ for each direction are conditionally evaluated and compared with predefined thresholds to determine the localizability category for that direction. The decision-making process is illustrated in Fig. 4(c). The categorization results for all directions are shown in Fig. 4(d) as follows:

The categories for directions along v_{r1} , v_{r2} and v_{t1} are fully localizable, indicating good geometric constraints. the

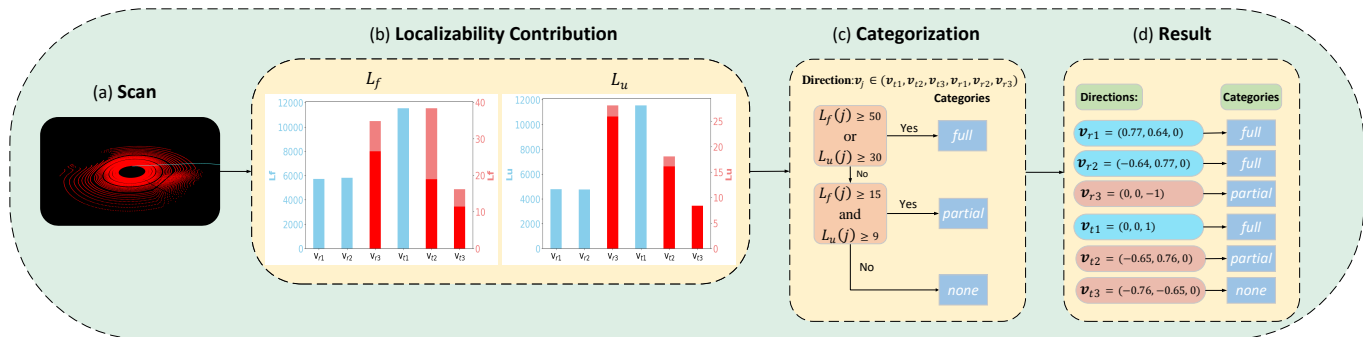

Fig. 4. An example of the Localizability Detection Module. (a) Scan: A LiDAR scan obtained in an open area with slightly undulating terrain. (b) Localizability Contribution: Two double Y-axis histograms identical to those in Fig. 3. They are calculated based on the localizability contribution of the scan in (a). (c) Categorization: The localizability category along each eigenvector direction of the 6-DOF pose is assigned through conditional judgment. The threshold is set according to Section IV-C. (d) Result: The results of the localizability categories along the eigenvector directions are shown.

categories for directions along v_{r3} , v_{t2} are partially localizable, suggesting that although these directions exhibit degeneracy, some geometric information is still usable. The category for directions along v_{t3} is non-localizable, indicating severe degeneracy in this direction with minimal usable geometric information.

V. OPTIMIZATION MODULE

The Optimization Module utilizes the localizability information provided by the LocDetect-Module. Based on the localizability categories of the 6-DOF pose along the directions of the eigenvectors, additional soft and hard constraints are incorporated into the optimization equation to achieve robust pose estimation. Specifically, in partially localizable directions, soft constraints are added using constraint values computed from higher localizability contributions. This allows the pose to trend toward the constraint values without being strictly equal, thereby avoiding significant pose fluctuations and drift that could result in localization failure. In non-localizable directions, hard constraints are applied to prevent pose updates. In fully localizable directions, pose updates remain unrestricted.

Note that to improve time efficiency in the subsequent experiments, the localizability category determination and additional constraint calculations are performed only during the first iteration of each ICP execution. For all subsequent iterations before convergence, the categories and additional constraint information computed in the first iteration are used directly in the optimization. Because in most SLAM algorithms, ICP-based pose estimation is typically performed at a relatively high frequency (e.g., 10 Hz in LVI-SAM), this configuration has little impact on accuracy.

A. Optimization Strategy

Zhang et al. [20] uses binary degeneracy judgment and applies solution remapping to set the pose update in degenerate directions to zero. However, it has the limitation of insufficient utilization of constraint information. [21] classifies localizability into three categories. During optimization, it adds hard constraints in partially localizable directions, forcing the

update value to be equal with the pose update calculated from a small subset of high-localizability points, thus utilizing more constraint information. However, we find that when integrating X-ICP into some SLAM systems, this approach increases the risk of large fluctuations in pose updates, which can easily cause localization failure.

To address the above issue, we use an optimization method that combines soft and hard constraints in the Optimization-Module, utilizing the localizability information from the LocDetect-Module. Each time the ICP algorithm starts, the process begins with the initial pose estimate x_0 , which can be obtained through various methods in SLAM, such as previous odometry. Through iteration, the goal is to find the optimal pose update Δx , which is added to x_0 to obtain the optimal pose solution x^* .

Specifically, the optimization strategy is as follows:

In the case of the localizability category in the direction along v_j , if it is:

- 1) Fully Localizable (Full): No additional constraints are added in this direction. The pose is updated without any extra constraints in this direction.
- 2) Partially Localizable (Partial): First, obtain the edge point-to-line correspondences and planar point-to-plane correspondences with moderate localizability contributions in the direction of v_j from the LocDetect-Module (i.e., satisfying (33)). Then, use them for a small local ICP optimization, which combines point-to-line and point-to-plane cost functions, to obtain an additional constraint value $\Delta r_0 \in \mathbb{R}^{3 \times 1}$ or $\Delta t_0 \in \mathbb{R}^{3 \times 1}$ for the pose update in the direction of v_j . Then, a soft constraint is added with weights, making the final pose update along the v_j direction tend toward the constraint value. The specific process is described in Section V-B.
- 3) Non-localizable (None): The information available in the direction of v_j is scarce, so a hard constraint is added to make the pose update value zero. The specific process is described in Section V-C.

B. Adding Soft Constraints in Partially Localizable Directions

According to the LocDetect-Module, if $L_f(j) \geq T_3$ and $L_u(j) \geq T_4$ hold in the direction of v_j , it is classified

as a partially localizable category. In this direction, geometric constraints are not as abundant as in fully localizable directions, but there is still usable information. First, pick out all edge point-to-line and planar point-to-plane correspondences in this direction used for calculating $L_f(j)$ in (34). They are correspondences with moderate localizability contributions. Then, the constraint value is calculated. We refer to the method used in [21] and [30] for constraint calculation, which optimizes the pose in that direction by using correspondences that contribute more in that direction. A small ICP optimization is performed using these correspondences, which combines point-to-line and point-to-plane loss functions. If \mathbf{v}_j is an eigenvector in the rotational direction, the small ICP optimizes only the 3-DOF rotational state variables \mathbf{r} . If \mathbf{v}_j is an eigenvector in the translational direction, the small ICP optimizes only the 3-DOF translational state variables \mathbf{t} . The pose update estimate $\Delta\mathbf{r}_0$ or $\Delta\mathbf{t}_0$ obtained from this optimization is projected onto the direction of \mathbf{v}_j and treated as a constraint value for the final pose update in the direction of \mathbf{v}_j . A soft constraint is then added to the pose update optimization equation (2) to guide the pose update in the direction of \mathbf{v}_j toward the constraint value. The algorithm process is as follows:

- 1) According to the category information from the LocDetect-Module, the category in the direction of \mathbf{v}_j is partially localizable.
- 2) Pick out all the m edge point-to-line correspondences and n planar point-to-plane correspondences in this direction, which are used to calculate $L_f(j)$ in (34). They are correspondences with moderate localizability contributions.
- 3) Using the correspondences selected in step 2, solve the following small ICP problem using the Gauss-Newton method.

When \mathbf{v}_j corresponds to a rotational direction, solve the following optimization problem to update only the 3-DOF rotation \mathbf{r} .

$$\min_{\Delta\mathbf{r}} \sum_{i=1}^m \|f_{ei}(\mathbf{r} + \Delta\mathbf{r})\|^2 + \sum_{j=1}^n \|f_{pj}(\mathbf{r} + \Delta\mathbf{r})\|^2 \quad (38)$$

Starting from the initial estimate, iterate to solve for the update $\Delta\mathbf{r}$ and find the optimal update value $\Delta\mathbf{r}_0$ that minimizes the residual, which will be used as the constraint value.

When \mathbf{v}_j corresponds to a translational direction, solve the following optimization problem to update only the 3-DOF translation \mathbf{t} .

$$\min_{\Delta\mathbf{t}} \sum_{i=1}^m \|f_{ei}(\mathbf{t} + \Delta\mathbf{t})\|^2 + \sum_{j=1}^n \|f_{pj}(\mathbf{t} + \Delta\mathbf{t})\|^2 \quad (39)$$

Starting from the initial estimate, iterate to solve for the update $\Delta\mathbf{t}$ and find the optimal update value $\Delta\mathbf{t}_0$ that minimizes the residual, which will be used as the constraint value.

Then, $\Delta\mathbf{r}_0$ or $\Delta\mathbf{t}_0$, along with \mathbf{v}_j , are each extended into a six-dimensional vector.

If \mathbf{v}_j corresponds to a rotational direction, as follows:

$$\mathbf{v}'_j = \begin{pmatrix} \mathbf{v}_j \\ \mathbf{0}_{3 \times 1} \end{pmatrix}, \quad \Delta\mathbf{x}'_j = \begin{pmatrix} \Delta\mathbf{r}_0 \\ \mathbf{0}_{3 \times 1} \end{pmatrix}. \quad (40)$$

If \mathbf{v}_j corresponds to a translational direction, as follows:

$$\mathbf{v}'_j = \begin{pmatrix} \mathbf{0}_{3 \times 1} \\ \mathbf{v}_j \end{pmatrix}, \quad \Delta\mathbf{x}'_j = \begin{pmatrix} \mathbf{0}_{3 \times 1} \\ \Delta\mathbf{t}_0 \end{pmatrix}. \quad (41)$$

- 4) A soft constraint is added to the final optimization equation, ensuring that the final pose update in the direction of \mathbf{v}_j tends to approach the projection of the constraint value $\Delta\mathbf{r}_0$ or $\Delta\mathbf{t}_0$ in the direction of \mathbf{v}_j . A squared loss function is used, as follows:

$$\mu_j (\mathbf{v}'_j{}^T \Delta\mathbf{x} - \mathbf{v}'_j{}^T \Delta\mathbf{x}'_j)^2 \quad (42)$$

$$\text{where } \mu_j = \begin{cases} 2, & \text{if } L_u(j) < T_5 \\ 5, & \text{if } L_u(j) \geq T_5. \end{cases}$$

μ_j is the set weight. By adjusting the value of μ_j , the extent to which the final pose update's projection in the \mathbf{v}_j direction tends toward the projection of the constraint values $\Delta\mathbf{r}_0$ or $\Delta\mathbf{t}_0$ in the \mathbf{v}_j direction can be controlled. In this paper, T_5 is set to 15 for all subsequent experiments. When $L_u(j)$ in the direction of \mathbf{v}_j is greater than T_5 , it indicates that more correspondences with high localizability contributions are used to compute $\Delta\mathbf{r}_0$ or $\Delta\mathbf{t}_0$, making the calculated values more reliable, and thus the weight μ_j is increased. If the quality and quantity of the correspondences used in (38) or (39) are high, the weight μ_j can be appropriately increased. However, if μ_j is too large, it may cause fluctuations and jaggedness in the optimized trajectory, leading to instability. The setting of μ_j should ensure that the pose estimate in the direction of \mathbf{v}_j tends toward the constraint value, while also maintaining the smoothness and stability of the trajectory.

Soft constraint terms in (42) are added to all directions \mathbf{v}'_{j_i} categorized as partially locatable. Note that \mathbf{v}'_{j_i} here refers to the direction vector of the i -th partially locatable direction. If there are k_p partially locatable directions ($k_p \leq 6$), the following soft constraints are added to the final optimization equation:

$$\sum_{i=1}^{k_p} \mu_{j_i} (\mathbf{v}'_{j_i}{}^T \Delta\mathbf{x} - \mathbf{v}'_{j_i}{}^T \Delta\mathbf{x}'_{j_i})^2 \quad (43)$$

where $\Delta\mathbf{x}'_{j_i}$ here refers to the constraint $\Delta\mathbf{x}'_j$ for the i -th partially locatable direction.

C. Adding Hard Constraints in Non-Locatable Directions

For the direction along \mathbf{v}'_{j_i} , categorized as non-locatable, a hard constraint is added to ensure that the projection of the final pose update along \mathbf{v}'_{j_i} is zero, as follows:

$$\mathbf{v}'_{j_i}{}^T \Delta\mathbf{x} = 0 \quad (44)$$

Note that $\mathbf{v}'_j \in \mathbb{R}^{6 \times 1}$ is extended from $\mathbf{v}_j \in \mathbb{R}^{3 \times 1}$, with the extension method similar to (40) or (41).

The final optimization equation incorporates the hard constraint in (44) for all direction \mathbf{v}'_{j_i} categorized as non-localizable. Note that \mathbf{v}'_{j_i} here denotes the direction vector of the i -th non-localizable direction. If there are k_n directions categorized as non-localizable ($k_n \leq 6$), the following hard constraints are added to the final optimization equation:

$$\mathbf{D}_{k_n \times 6} \Delta \mathbf{x} = 0 \quad (45)$$

where $\mathbf{D}_{k_n \times 6} = (\mathbf{v}'_{j_1} \cdots \mathbf{v}'_{j_{k_n}})^T$.

D. Optimization Equation with Soft and Hard Constraints

1) *Optimization Equation*: Formulate the optimization equation. Then, Starting from the initial estimate, the pose update value $\Delta \mathbf{x}$ is iteratively solved using the Gauss-Newton method to minimize the residual. The optimal update value $\Delta \mathbf{x}$ is then added to the initial estimate to obtain the optimal pose solution \mathbf{x}^* .

By combining (2), (43), and (45), the final optimization equation with soft and hard constraints is obtained as follows:

$$\begin{aligned} \min_{\Delta \mathbf{x} \in \mathbb{R}^6} \sum_{i=1}^N \|f_i(\mathbf{x} + \Delta \mathbf{x})\|^2 + \sum_{i=1}^{k_p} \mu_{j_i} (\mathbf{v}'_{j_i}{}^T \Delta \mathbf{x} - \mathbf{v}'_{j_i}{}^T \Delta \mathbf{x}'_{j_i})^2 \\ \text{s.t. } \mathbf{D} \Delta \mathbf{x} = 0. \end{aligned} \quad (46)$$

Here, let $\mu_j = \begin{cases} 2, & \text{if } L_u(j) < T_5 \\ 5, & \text{if } L_u(j) \geq T_5 \end{cases}$, with $T_5 = 15$.

2) *Solve*: Using Lagrange multipliers methods, the constrained optimization problem (46) is transformed into an unconstrained optimization problem. The pose update value can then be obtained by solving it using the Gauss-Newton method, as follows:

$$\begin{pmatrix} \mathbf{H}' & \mathbf{D}^T \\ \mathbf{D} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \Delta \mathbf{x} \\ \boldsymbol{\lambda} \end{pmatrix} = \begin{pmatrix} \mathbf{b} \\ \mathbf{0} \end{pmatrix}$$

where $\boldsymbol{\lambda} \in \mathbb{R}^{k_n \times 1}$,

$$\mathbf{H}' = 2 \sum_{i=1}^N \mathbf{J}_i^T(\mathbf{x}) \mathbf{J}_i(\mathbf{x}) + 2 \sum_{i=1}^{k_p} \mu_{j_i} \mathbf{v}'_{j_i} \mathbf{v}'_{j_i}{}^T, \quad (47)$$

$$\mathbf{b} = -2 \sum_{i=1}^N \mathbf{J}_i^T(\mathbf{x}) f_i(\mathbf{x}) + 2 \sum_{i=1}^{k_p} \mu_{j_i} \mathbf{v}'_{j_i} \mathbf{v}'_{j_i}{}^T \Delta \mathbf{x}'_{j_i}.$$

Here, $\boldsymbol{\lambda} \in \mathbb{R}^{k_n \times 1}$ are Lagrangian multipliers. $\mathbf{J}_i(\mathbf{x}) \in \mathbb{R}^{1 \times 6}$ is the Jacobian of the residual $f_i(\mathbf{x})$ w.r.t. \mathbf{x} .

Eq. (47) can be solved using QR decomposition to obtain the pose update $\Delta \mathbf{x}$ which is then added to the initial estimate. Through multiple iterations, the optimal pose solution \mathbf{x}^* is obtained. The proposed algorithm is summarized in Algorithm 1.

VI. EXPERIMENT

In this section, the experimental setup is introduced in Section VI-A. The proposed method is then evaluated through experiments on a simulated planetary-like environment dataset (Section VI-B) and a real-world underground tunnel dataset

(Section VI-C), with comparisons to state-of-the-art methods. Finally, the runtime performance of the algorithm is evaluated (Section VI-D).

A. Experimental Setup

1) *Implementation Details*: The proposed framework, LP-ICP, is integrated into the point cloud registration framework of LVI-SAM [11]. LVI-SAM combines LIO and VIO sub-modules, with the LIO sub-module serving as the main component, while the VIO sub-module provides initial estimates for the LIO sub-module. The LIO module performs scan-to-map registration using edge point-to-line and planar point-to-plane correspondences. All experiments and evaluations in this paper are performed on a laptop equipped with an Intel i7-12700H CPU.

2) *Algorithmic Comparisons*: We integrate the current state-of-the-art methods Zhang et al. [20] and X-ICP [21] into the point cloud registration framework of LVI-SAM for experiments and comparisons. In LVI-SAM, the degeneracy detection method used is based on Zhang et al. [20]. To ensure that [20] performs well for degeneracy detection and handling in all experiments, we empirically set the threshold of Zhang et al. [20] to 50. We also conducted experiments to evaluate its performance with different threshold settings, as shown in Table I. Finally, we choose a threshold of 50 for the subsequent experimental evaluations. Additionally, since the source code for X-ICP [21] is not yet publicly available, we reproduced the method based on the paper and integrated it into the point cloud registration framework of LVI-SAM. However, during our experiments, adding the hard constraints in the partially locatable directions, as described in [21], caused large fluctuations in pose updates, often resulting in localization failures. Therefore, we modified these partially locatable directions to be non-locatable for the experiment. The other threshold values used are based on the original threshold settings in [21]. In the experiments, we refer to it as Xn-ICP. Moreover, when implementing Xn-ICP in LVI-SAM, since X-ICP [21] is designed for point-to-plane ICP, we only used point-to-plane correspondences for localizability detection. However, for fairness, both edge point-to-line and planar point-to-plane correspondences were used during optimization to retain as much usable information as possible for the optimization.

Note that in all experiments, considering the algorithm’s time efficiency, for the three methods being compared, the localizability categories of the directions are only detected during the first iteration of point cloud registration. However, the categories and added additional constraints are used in every iteration during the optimization.

In this paper, the three methods integrated into the LVI-SAM framework for comparison are referred to as: LVI-SAM + Ours, LVI-SAM + Zhang et al. [20], and LVI-SAM + Xn-ICP [21].

In addition, we also tested the performance of other advanced SLAM systems in our experiments for comparison with the accuracy of our method.

B. Simulation Experiments in a Planetary-like Environment

Planetary-like environments are typical degraded scenarios that pose significant challenges to existing SLAM algorithms. Conducting field experiments and collecting data directly in

Fig. 5. Simulated environment of the PLAM dataset and lunar color images from the Yutu rover are shown. The lunar images are sourced from [https://planetary.s3.amazonaws.com/data/change3/pcam.html].

unstructured environments such as the Moon or Mars is currently difficult and costly. Therefore, we collected a simulated SLAM dataset, the PLAM dataset, in a visually realistic lunar-like simulation environment, which includes sensor data from LiDAR, a camera, and an IMU.

1) *PLAM Dataset*: We built a visually realistic lunar-like simulation environment using AIRSIM and UE4. The scene’s visual rendering is based on the color photographs of the Moon taken by the Yutu rover, as shown in Fig. 5 for comparison. A drone equipped with a monocular camera, IMU, and LiDAR was used to collect the PLAM dataset, which is designed to test and evaluate the localization accuracy of SLAM algorithms in large-scale extreme environments. The dataset is provided in rosbag format and includes the ground truth trajectory of the robot during its operation.

The scene features uneven terrain with hills, pits, as well as rocky and non-rocky areas. It also presents challenges due to varying lighting conditions. The PLAM dataset exhibits typical characteristics of planetary-like environments, such as visual ambiguity, blurriness, a lack of features and geometric structure, as well as variations in lighting and shadowed regions. The PLAM dataset includes 10 sequences, with a total trajectory length of 10 km. It can be used to test different SLAM modules and evaluate the performance of various tasks in planetary exploration, such as odometry, loop closure detection, home and traverse tasks, and more. The rocky areas contain rocks of various sizes, providing more visual features and geometric structure. Non-rocky areas pose a greater challenge for both vision-based and LiDAR-based SLAM methods.

2) *Results*: We evaluate the localization performance of LVI-SAM + Ours, LVI-SAM + Zhang et al. [20], and LVI-SAM + Xn-ICP [21] on the PLAM dataset and compare and analyze the results. At the same time, we test and evaluate the performance of some advanced SLAM systems, such as ORB-SLAM3 [43] in monocular camera-IMU mode, VINS-MONO [44], and LIO-SAM [31]. The estimated trajectory obtained by

The units are in meters. Bold values indicate the best results. “%” denotes the length of the ground truth associated with the estimated trajectory divided by the total length of the ground truth for the sequence.

Fig. 6. Trajectories estimated by LVI-SAM + Ours and the state-of-the-art methods on the sequences a1_home, a3_odom, a2_traverse, a4_home, a7_loop, and a3_final, and ground truth trajectories are shown.

each algorithm with the ground truth trajectory are compared. The first 50 poses of both trajectories are aligned using the EVO tool [46], and the Absolute Trajectory Error (ATE) [47] between them is calculated. The results are presented in the form of root mean square error (RMSE). Additionally, we provide an extra metric, which is the ratio of the algorithm’s estimated poses to the total length of the ground truth for each sequence. This value is calculated as the length of the ground truth associated with the estimated trajectory divided by the total length of the ground truth for the sequence. When large drift or fluctuations in the trajectory occurred, preventing the algorithm from continuing, we stopped the experiment. Table II reports these metrics for the tested algorithms on each sequence of the dataset. These results show that the extreme environment of the PLAM dataset poses significant

challenges to VINS-MONO, ORB-SLAM3, and LIO-SAM. The long-term visual ambiguity, lack of features and geometric structure, and poor lighting conditions in the PLAM dataset lead to instability and low accuracy during their operation. In comparison, the multi-sensor fusion algorithm LVI-SAM achieves better accuracy than them.

The degeneracy detection algorithms in LVI-SAM + Ours, LVI-SAM + Zhang et al. [20], and LVI-SAM + Xn-ICP [21] were further compared. The trajectories estimated by these three methods on six sequences of the dataset are presented in Fig. 6. Our method, LP-ICP, utilizes localizability information from edge point-to-line and planar point-to-plane correspondences to detect degeneracy, achieving the best localization accuracy across all sequences. LVI-SAM + Zhang et al. [20] also demonstrates good accuracy in the rocky-area sequences

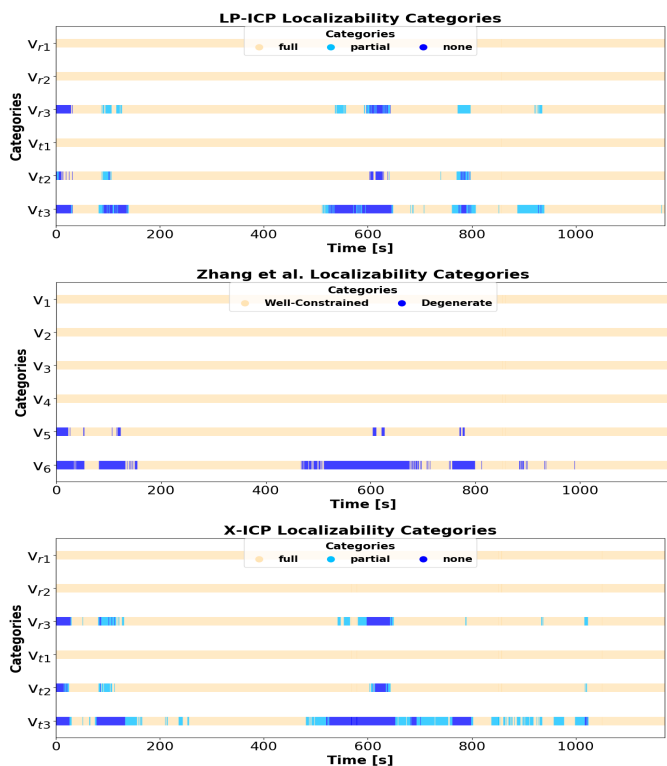

Fig. 7. Estimated localizability categories of LP-ICP and the state-of-the-art methods in the a2_traverse sequence.

a2_home, a4_loop, and a7_loop, as the abundance of rocks provides more features and geometric structures. However, in sequences from other non-rocky areas, on the one hand, the method cannot pick out high-contribution correspondence constraints in ill-conditioned directions, thus failing to utilize more effective information in binary degeneracy detection. On the other hand, the scales of rotational and translational directions differ. If the same threshold settings are applied, it limits the degeneracy detection, leading to a decrease in performance. For instance, as shown in Fig. 7, in the a2_traverse sequence, when the robot is in an open area of the scene at 620s, LiDAR degeneracy occurs in the three directions: translation along the x-axis and y-axis, and rotation around the z-axis. However, the method by Zhang et al. [20] can only detect two of these directions. X-ICP improves performance by adding partial localizability categories, which

allows it to utilize more constraint information. It also unifies the scale of localizability for both rotation and translation. In the a2_odom and a4_home sequences, it shows better accuracy compared to Zhang et al. [20]. However, X-ICP cannot utilize the localizability information from edge point-to-line correspondences. As shown in Fig. 7, compared to our method, it has more instances of non-localizable categories. This prevents further improvement in its localization accuracy. Additionally, in partially localizable directions, it adds hard constraints to the optimization process. This is sensitive to the quality of resampled points and increases the risk of significant trajectory drift and fluctuations, which can lead to localization failure. This is particularly problematic for long-range sequences or sequences without loops in non-rock areas, such as a2_traverse and a3_odom. Although, for the purpose of comparison, when reproducing X-ICP, we handled the optimization in partially localizable directions as non-localizable directions. This avoided direct localization failure. However, its accuracy remains unsatisfactory on some challenging sequences.

C. Real-World Experiment on the CERBERUS DARPA Subterranean Challenge Dataset

The CERBERUS DARPA Subterranean Challenge Datasets [19] were collected in the Louisville Mega Cavern in Kentucky. During the Final Event of the DARPA Subterranean (SubT) Challenge, the quadruped robot ANYmal, equipped with cameras, IMU, and LiDAR, collected the CERBERUS dataset. The underground tunnel environment is shown in Fig. 1. Features such as poor lighting conditions, cave environments resembling long corridors, self-similar areas, and motion vibrations caused by rugged terrain pose challenges to existing SLAM methods [48]. These factors result in increased localization and mapping errors. The dataset contains four sequences.

We test and evaluate the localization and mapping performances of LVI-SAM + Ours, LVI-SAM + X_n-ICP [21], and LVI-SAM + Zhang et al. [20] on the CERBERUS dataset. Additionally, the performances of several state-of-the-art SLAM systems, such as VINS-MONO, LIO-SAM, and R3LIVE [45], is also tested. Similarly, we use the EVO tool to evaluate the results. The estimated trajectory is aligned with the ground truth trajectory and the Absolute Trajectory

Fig. 8. Resulting maps from the compared methods and LP-ICP on the ANYmal 1 sequence.

Error (ATE) is calculated. Table III reports the localization performance metrics of the tested algorithms on the various sequences of the dataset. Note that the results of the R3LIVE are presented using the better performance between our test results and those from [35].

As shown in Table III, the characteristics of underground tunnel pose significant challenges to many methods. Poor lighting conditions and darkness, along with self-similar scenes, create difficulties for vision-based approaches. LiDAR-based methods struggle with accuracy in degenerate scenarios, such as long corridor-like passages in tunnels. Uneven terrain and vibrations during movement also negatively impact the final localization results. These factors result in unsatisfactory accuracy for VINS-MONO, LIO-SAM, and R3LIVE. By employing multi-sensor fusion and incorporating degeneracy detection and handling, LVI-SAM + Ours, LVI-SAM + Zhang et al., and LVI-SAM + Xn-ICP achieve significantly better localization accuracy. Among these three localizability-aware algorithms, our method achieves the best accuracy on the ANYmal 1, ANYmal 2, and ANYmal 3 sequences. On the ANYmal 4 sequence, its accuracy is comparable to that of LVI-SAM + Zhang et al.

Additionally, the mapping results of the three methods on the ANYmal 1 sequence are shown in Fig. 8. The magnified parts show the most accurate map to be produced by the proposed method. In the dashed box of Fig. 8(b), which marks the tunnel connection area A, the robot approached A from both ends during operation but ultimately did not reach this location. This posed a challenge for mapping. As shown in the mapping result (b) of Xn-ICP, which presents the top-down

TABLE IV
THE AVERAGE TIME CONSUMPTION (MILLISECONDS) OF SCAN-TO-MAP REGISTRATION USING DIFFERENT METHODS ON THE SEQUENCE ANYMAL 1

	Time Consumption (Average)
LVI-SAM + Ours	35.87
LVI-SAM + Zhang et al. [20]	33.69
LVI-SAM (without Degeneracy Detection)	38.04

view in the x-y plane, there are noticeable disconnections in the map at location A. As shown in the mapping result (c) of Zhang et al. [20], which presents the front view in the x-z plane at the same location, the mapping result contains an error where the top of the tunnel on the right side of A is lower than the ground of the left side tunnel. This causes an incorrect tunnel connection at location A. In contrast, the result of our method, LP-ICP, does not exhibit these errors.

D. Runtime Evaluation

Table IV shows the runtime results of LP-ICP on the ANYmal 1 sequence of the CERBERUS DARPA subterranean challenge dataset. We tested the average time consumption of the scan-to-map registration module for three methods: LVI-SAM (without degeneracy detection), LVI-SAM + Ours, and LVI-SAM + Zhang et al [20]. The tests were conducted on a laptop with an Intel i7-12700H CPU. As shown in Table IV, the time consumption of the three methods is quite similar. Interestingly, the method without degeneracy detection takes the most time, which we believe is due to optimization in ill-conditioned directions that makes it harder to converge, resulting in an increased number of iterations. This demonstrates that our method, LP-ICP, has the capability to run in real time on robotic systems.

VII. CONCLUSION

To improve the accuracy of LiDAR-based SLAM algorithms in challenging unstructured environments, degeneracy detection and handling are essential. This paper proposes a new ICP algorithm framework, LP-ICP, which combines point-to-line and point-to-plane cost functions, along with localizability detection and handling. LP-ICP detects degeneracy by calculating the localizability contribution of geometric correspondences and adds additional constraints to improve the accuracy of pose estimation. The efficacy of the proposed method is validated through experimental evaluation on our planetary-like simulation dataset and a real-world underground tunnel dataset, demonstrating higher or comparable accuracy than the state-of-the-art methods.

Haosong Yue (Member, IEEE) received the B.S. degree in control science and engineering from the University of Science and Technology Beijing, Beijing, China, in 2009, and the Ph.D. degree in control science and engineering from Beihang University, Beijing, in 2015.

He is currently an Associate Professor at the School of Automation Science and Electrical Engineering, Beihang University. His research interests include robot vision and control, simultaneous localization and mapping, and depth completion.

Weihai Chen (Member, IEEE) received the B.Eng. degree from Zhejiang University, Hangzhou, China, in 1982, and the M.Eng. and Ph.D. degrees from Beihang University, Beijing, China, in 1988 and 1996, respectively.

He is currently a Professor with the School of Automation Science and Electrical Engineering, Beihang University. He has published more than 200 technical articles in refereed journals and conference proceedings and filed more than 20 patents. His research interests include computer vision, image processing, automation, bio-inspired robotics, and precision mechanisms.

Dr. Chen is a member of the Technical Committee on Manufacturing Automation of the IEEE Robotics and Automation Society. He was a recipient of the 2017 Best Paper Award from IEEE TRANSACTIONS ON INDUSTRIAL ELECTRONICS and the 2018 IET Premium Award for the IET Intelligent Transport Systems.

Qingyuan Xu received the B.S. degree in robotics engineering from Beihang University, Beijing, China, in 2023, where he is currently pursuing the M.S. degree in control engineering. His current research interests include LiDAR SLAM, visual SLAM, and sensor fusion for robotics.

Fei Chen (Senior Member, IEEE) received the B.S. degree in computer science from Xi'an Jiaotong University (XJTU), Xi'an, China, in 2006, the M.S. degree in computer science from the Harbin Institute of Technology (HIT), Harbin, China, in 2008, and the Dr.Eng. degree from the Fukuda Laboratory, Department of Micro-Nano Systems Engineering, Nagoya University, Nagoya, Japan, in 2012.

In June 2013, he joined the Department of Advanced Robotics, Italian Institute of Technology (IIT), Genoa, Italy. He was the Head of the Active Perception and Robot Interactive Learning (APRIL) Laboratory, IIT. Since 2020, he has been an Assistant Professor leading the Smart Manipulation Robots (SMART) Laboratory with the T-Stone Robotics Institute (CURI), The Chinese University of Hong Kong (CUHK), Hong Kong, and the Hong Kong Centre for Logistics Robotics (HKCLR), Hong Kong. His research interests lie in robot learning, planning, and control for different formats of robot mobile manipulators.

Dr. Chen is the Co-Chair of the IEEE Robotics and Automation Society of the Technical Committee on Neuro-Robotics Systems. He also chairs several international conferences and workshops.

Jia Pan (Senior Member, IEEE) received the Ph.D. degree in computer science from the University of North Carolina at Chapel Hill, Chapel Hill, NC, USA, in 2013. He is currently an Associate Professor with the Department of Computer Science, University of Hong Kong, Hong Kong. He is also a member of the Centre for Garment Production Limited, Hong Kong. His research interests include robotics and artificial intelligence as applied to autonomous systems, particularly for navigation and manipulation in challenging tasks such as effective

movement in dense human crowds and manipulating deformable objects for garment automation.
