Abstract—Binaural audio generation (BAG) aims to convert monaural audio to stereo audio using visual prompts, requiring a deep understanding of spatial and semantic information. However, current models risk overfitting to room environments and lose fine-grained spatial details. In this paper, we propose a new audio-visual binaural generation model incorporating an audiovisual conditional normalisation layer that dynamically aligns the mean and variance of the target difference audio features using visual context, along with a new contrastive learning method to enhance spatial sensitivity by mining negative samples from shuffled visual features. We also introduce a cost-efficient way to utilise test-time augmentation in video data to enhance performance. Our approach achieves state-of-the-art generation accuracy on the FAIR-Play and MUSIC-Stereo benchmarks.

Index Terms—Audio-visual learning, audio spatialisation, binaural audio generation

I. INTRODUCTION

Binaural audio is gaining significant attention in streaming media, revolutionising how listeners experience sound in a digital environment. This technology finds applications in various domains, including virtual reality (VR) [1], 360-degree videos [2], and music [3]. By simulating a two-dimensional soundscape, binaural audio creates a deeply immersive experience, allowing listeners to feel as though they are physically present within the auditory scene.

Binaural audio recording typically requires specialised hardware like dummy head systems [4]. These systems are costly and lack portability, making them impractical for everyday use. To address this, researchers have developed methods to spatialise audio from monaural recordings, known as binaural audio generation (BAG) [4]-[6]. These methods use visual information to estimate the differential audio between left and right channels. However, existing frameworks often rely on simple feature fusion strategies, which may struggle to capture complex visual-spatial relationships, limiting their generalisability and performance. To better utilise the visual information, previous works [4]-[9] have explored various strategies to enhance semantic and spatial awareness across modalities. These approaches aim to improve cross-modal feature interaction [5]–[7], [10], strengthen spatial understanding [8], [9], [11], and incorporate 3D environmental cues [11]. Despite promising results, these methods still lack a dense spatial understanding, which limits their ability to accurately capture local spatial relationships between multimodal features.

In addition, existing models remain prone to overfitting the training environment due to their reliance on specific data distributions and insufficient regularisation mechanisms. These issues often result in limited generalisation to diverse or unseen scenarios [6]. Unfortunately, the structure of the widely used FAIR-Play [4] dataset fails to address this concern, as a significant amount of scene overlap has been observed between the training and testing sets [6], resulting in overly optimistic evaluation results on the current benchmark. Xu et al. [6] tackled this issue by reorganising the dataset based on clustering results of scene similarity. Additionally, methods involving training on synthetic stereophonic data from external sources [5], [6] and incorporating depth estimation [7] have also shown potential in mitigating the overfitting problem. However, these methods still rely on concatenation or cross-attention to control the generation process, which is less effective at integrating fine-grained conditioning information [12].

In this paper, we introduce a new U-Net-based generation framework that aims to mitigate the problems above, called Contextual and Contrastive Stereophonic Learning (CC-Stereo), which consists of a visually adaptive stereophonic learning method and a cost-effective inference strategy to enhance cross-modal interaction and mitigate overfitting by improving spatial reasoning. Unlike previous methods that rely solely on concatenated [4]–[6], [8], [13] or cross-attended [10] features for differential audio generation, we adopted the concept of conditional normalisation layers [12], [14], [15] from image synthesis field to control the generation process through estimated mean and variance shifts informed by visual context. Additionally, we propose a novel audio-visual contrastive learning method that enhances the model's spatial sensitivity by incorporating contrastive learning across the feature maps of the anchor frame, nearby frames, and the spatially shuffled anchor frame. Moreover, the widely used sliding window inference strategy [4] introduces significant redundancy due to substantial frame overlap, which is common in video data. We argue that this overlap presents an opportunity to adopt test-time augmentation (TTA), leveraging the redundant information to enhance robustness and improve prediction accuracy. We introduce video test-time augmentation (V-TTA), which divides the video into N sets of five consecutive frames and applies five-crop augmentation to each set across the entire video. To summarise, our main contributions are

- A new audio-visual conditional normalisation layer that leverages visual context to dynamically align the mean and variance of the target difference audio features.
- A novel audio-visual contrastive learning method that enhances spatial sensitivity by mining negative samples from randomly shuffled visual feature representations.
- A cost-efficient approach for applying TTA to video data, improving robustness and prediction accuracy.

We demonstrate the effectiveness of our CCS tereo model on established benchmarks, including the FAIR-Play dataset [4] with both the original 10-splits [4] and the more challenging 5-splits protocol [6]. Additionally, we extend our evaluation to the MUSIC-Stereo dataset [6], demonstrating generalisation across diverse audio-visual scenarios and superior generation quality with an efficient architecture. Code will be released.

II. RELATED WORKS

Binaural audio generation (BAG) methods aim to create binaural audio from monaural recordings using visual information. Mono2Binaural [4], the first binaural audio generation method, uses a U-Net [16] to estimate the differential audio between the left and right channels by leveraging visual-spatial cues. However, operations like tiling and concatenation at the bottleneck layer [5] and average pooling [17] can lead to overfitting and loss of spatial details, limiting the model's ability to capture complex spatial relationships. Enhancing the use of visual information in binaural audio generation has been a primary focus of recent research. Various methods are proposed to improve the model's understanding of semantic and spatial information. These methods can broadly be categorised into three major directions: 1) improving cross-modal feature interaction [10] via attention mechanism [18] to better fuse the information between audio and visual modalities; 2) employing proxy learning tasks that help the model better understand the spatial correlation between the two modalities, such as discriminating the position of sound sources [13] or identifying their locations [9]; and 3) introducing the geometry clue of the scene, such as depth information [7] and room impulse response [11] to leverage the 3D environment during model reasoning. Additionally, prior studies [5], [6] have pointed out challenges like limited data availability and overfitting to visual environments. Efforts have been made to tackle these issues by using external monaural datasets [5] and reorganising benchmarks [6] to enhance model robustness and generalisation evaluation.

Conditional normalisation layers have been studied in style transfer [15] and conditional image synthesis [12]. Unlike standard normalisation methods [15] that rely on batch or instance statistics (e.g., mean and variance), conditional normalisation modulates these statistics through an affine transformation learned from external conditioning data [19]. In semantic image synthesis (e.g., SPADE [12]), this modulation is achieved using semantic segmentation maps, enabling the preservation of semantic information during decoding. Inspired by the SPADE layer, we incorporate spatially adaptive normalisation into the audio generation process, conditioning it on visual

context to enable more precise control over the generation process.

Contrastive learning has shown promise in audio-visual learning methods [20], [21], aligning augmented representations of the same instance as positives while separating those of different instances as negatives within a batch. Binaural audio generation can similarly benefit from self-supervised learning tasks by leveraging contrastive objectives to distinguish left and right information in both audio [22] and visual [13] modalities.

Test-time augmentation (TTA) improves model performance by applying data augmentation at inference, creating multiple variations of the input and aggregating predictions. TTA is widely used in computer vision to enhance robustness without additional training [23]. Studies have shown that TTA effectively improves model generalisation [24], though it comes at the cost of significantly reduced inference speed. To handle moving sound sources and camera motion, previous binaural audio generation methods [4]–[6], [9], [13], [22] often adopted a sliding window strategy with a small hop size (e.g., 0.1), which leads to a large number of duplicated frames. We leverage this unique inference characteristic to integrate TTA into the process without incurring additional computational costs, thereby enhancing model performance.

III. METHOD

We denote an unlabelled video dataset as $\mathcal{D} = \{(\mathbf{w}_i, \mathbf{v}_i)\}_{i=1}^{|\mathcal{D}|}$, where $\mathbf{v}_i \in \mathcal{V} \subset \mathbb{R}^{T \times H \times W \times 3}$ is a set of TRGB images with resolution $H \times W$, $\mathbf{w}_i \in \mathcal{W} \subset \mathbb{R}^{C \times T}$ denotes the waveform data with $C \in \{L, R\}$ channels and total number of sample T. Given monaural audio ($\mathbf{w}_i^M = \mathbf{w}_i^L + \mathbf{w}_i^R$), We apply the short-time Fourier transform (STFT) [25] on \mathbf{w}_i^M , resulting in $\mathbf{a}_i^M \in \mathcal{A} \subset \mathbb{C}^{T_s \times F}$, where F is the number of frequency bins and T_s denotes the number of time frames. The model predicts the spectrogram of the target difference audio, defined as ($\mathbf{a}_i^D = \text{STFT}(\mathbf{w}_i^L - \mathbf{w}_i^R)$).

Preliminaries. During training, we randomly sample an audio segment and its corresponding frame start at time step $t \in \mathcal{T}$ from each video (i.e., $(\mathbf{a}_{i,t}^M, \mathbf{v}_{i,t})$) to form an input pair for the model. Our goal is to learn the parameters $\theta \in \Theta$ for the model $f_{\theta} : \mathcal{V} \times \mathcal{A} \to [-1,1]^{F \times T}$, which comprises the image and audio encoder that extract features with $\mathbf{u}_{i,t}^a = f_{\gamma}(\mathbf{a}_{i,t}^{\widetilde{M}})$ and $\mathbf{u}_{i,t}^v = f_{\phi}(\mathbf{v}_{i,t})$, respectively, where $\gamma, \phi \in \theta$, and $\mathbf{u}_{i,t}^a, \mathbf{u}_{i,t}^v \in \mathcal{U}$, with \mathcal{U} denoting a unified feature space. Our approach adopted a multi-head attention block [18], which estimates the co-occurrence of audio and visual data. We simply define the cross-attention process as $\hat{\mathbf{u}}_{i,t}^a = f_{CA}(\mathbf{u}_{i,t}^a, \mathbf{u}_{i,t}^v)$, where $\mathbf{u}_{i,t}^a$ represent the query and $\mathbf{u}_{i,t}^v$ is the key and value. We decode the $\hat{\mathbf{u}}_{i,t}^a$ through an audio decoder $\hat{\mathbf{a}}_{i,t}^{D} = f_{\psi}(\hat{\mathbf{u}}_{i,t}^{a}) \cdot \mathbf{a}_{i,t}^{M}$, where $\psi \in \theta$. We use the MSE loss $\ell_{\text{MSE}}(\mathbf{a}_{i,t}^{D}, \hat{\mathbf{a}}_{i,t}^{D}) = \frac{1}{L} \sum (\mathbf{a}_{i,t}^{D} - \hat{\mathbf{a}}_{i,t}^{D})^{2}$ and magnitude loss [26] $\ell_{\text{AMP}}(\mathbf{a}_{i,t}^{D}, \hat{\mathbf{a}}_{i,t}^{D}) = \frac{1}{L} \sum ||\mathbf{a}_{i,t}^{D}| - |\hat{\mathbf{a}}_{i,t}^{D}||$ to constrain the prediction of the difference audio, where $L = T \times F$ and $|\cdot|$ is the modulus of the complex number. Different from [7], we argue that even though the phase of the difference audio is inherently linked to the phases

Fig. 1: Illustration of our **CCStereo** method. Given a pair of mono audio $\mathbf{a}_{i,t}^M$ and a corresponding frame $\mathbf{v}_{i,t}$ as input, our goal is to predict the spectrogram of the difference audio $\hat{\mathbf{a}}_{i,t}^D$. We replace the BatchNorm layer in the "uplayer" of the decoder f_{ψ} with AVAD, a visual feature-guided normalization layer to control the mean and variance during the decoding process. The overall training objective consists of two tasks: 1) accurately reconstructing $\hat{\mathbf{a}}_{i,t}^D$, and 2) a contrastive learning task aimed at learning discriminative representations concerning spatial changes.

of the left and right channels, it does not fully represent the binaural phase dynamics, hence apply the phase loss [7] $\ell_{\text{PHS}}(\mathbf{a}_{i,t}, \hat{\mathbf{a}}_{i,t}) = \frac{1}{L} \sum \|\angle(\mathbf{a}_{i,t}) - \angle(\hat{\mathbf{a}}_{i,t})\|_2$ on the final predicted binaural audio $(\hat{\mathbf{a}}_{i,t})$ and the ground truth binaural audio $(\mathbf{a}_{i,t})$ instead of different audio. We denote the overall reconstruction loss as $\ell_{\text{REC}} = \ell_{\text{MSE}} + \ell_{\text{MAG}} + \ell_{\text{PHS}}$.

Audio-Visual Adaptive De-normalisation (AVAD). Our AVAD adopted the concept of conditional normalisation [12], [14] that leverages the interaction between audio and visual modality to control the normalisation of decoded feature representation. The AVAD is incorporated into the U-Net decoder f_{ψ} by replacing the batch normalisation layers with visually-informed normalisation layers. This modification aims to effectively integrate both spatial and semantic information into the network's input. Please note that, for simplicity, we omit the subscripts i and t in the following. As depicted in Fig. 1, we first pass $\bar{\mathbf{u}}_k^a = \operatorname{Conv}(\hat{\mathbf{u}}_k^a)$ through a batch normalisation layer (BN) at k-th layer, and then scale and shift the normalised feature using the estimated α and β via $\tilde{\mathbf{u}}_{k}^{a} =$ $(1 + \alpha) \cdot BN(\bar{\mathbf{u}}_k^a) + \beta$. To compute these scaling factors, we calculate the similarity activate map $\mathbf{c}_k = \bar{\mathbf{u}}_k^a \cdot \operatorname{Conv}_v(\mathbf{u}^v)$ and then estimate the scale (α) and shift (β) tensors through shared and specific MLP layers, such that $\alpha = \text{MLP}_{\alpha}(\text{MLP}_{\text{share}}(\mathbf{c}_k))$ and $\beta = \text{MLP}_{\beta}(\text{MLP}_{\text{share}}(\mathbf{c}_k)).$

Spatial-aware Contrastive Learning (SCL). The capability to learn discriminative feature presentation is crucial for the audio-visual system. One limitation of previous binaural audio generation methods is their exclusive focus on proxy tasks within the audio domain (e.g., classifying whether the audio channels are flipped), which not only under-utilises visual positional information but also hinders the learning of a joint audio-visual representation. We argue that two requirements must be satisfied to achieve effective contrastive learning: 1) spatial awareness in the learned joint representation, and 2) inclusion of a diverse set of examples. Unfortunately, previous audio-visual contrastive learning methods [20], [21] may not be suitable for the current task, as they generally failed to satisfy these two requirements. Motivated by the Jigsaw puzzle self-supervised learning method [27], we observe that these two challenges can be addressed simultaneously by introducing perturbations to the visual-spatial order.

Since the BAG problem cannot access video-level labels, we adopt a classic instance discrimination pipeline (e.g., SimCLR [28]), where each audio-visual pair is treated as its own class. For a randomly sampled minibatch of N examples, we perform the contrastive prediction task on pairs of positive and negative pairs derived from the minibatch. We define the anchor set \mathcal{E} , positive set \mathcal{P} and negative set \mathcal{N} as follows:

$$\mathcal{E} = \{ \mathbf{z}_{i,t} \mid \mathbf{z}_{i,t} = p\left(f_{CA}(\mathbf{u}_{a}, f_{\phi}(\mathbf{v}_{i,t}))\right), i \in \mathcal{D}, t \in \mathcal{T} \},\$$

$$\mathcal{P} = \{ \mathbf{z}_{i,t}^{+} \mid \mathbf{z}_{i,t}^{+} = p\left(f_{CA}(\mathbf{u}_{a}, f_{\phi}(\mathbf{v}_{i,t-1}))\right), i \in \mathcal{D}, t \in \mathcal{T} \},\$$

$$\mathcal{N} = \{ \mathbf{z}_{i,t}^{-} \mid \mathbf{z}_{i,t}^{-} = p\left(f_{CA}(\mathbf{u}_{a}, f_{\phi}(S(\mathbf{v}_{i,t})))\right), i \in \mathcal{D}, t \in \mathcal{T} \},\$$

(1)

where $p(\cdot)$ is the 2D average pooling and $S(\cdot)$ represent a shuffle process over the spatial dimension H and W of $\mathbf{v}_{i,t}$. Adopting the InfoNCE [28], we define the objective function as follows:

$$\ell_{\text{SCL}}(\mathbf{z}_j) = -\log \frac{\exp\left(\mathbf{z}_j \cdot \mathbf{z}_j^+ / \tau\right)}{\exp\left(\mathbf{z}_j \cdot \mathbf{z}_j^+ / \tau\right) + \sum_{\mathbf{z}_n^- \in \mathcal{N}} \exp\left(\mathbf{z}_j \cdot \mathbf{z}_n^- / \tau\right)},\tag{2}$$

where $\mathbf{z}_j \in \mathcal{E}$ is an anchor feature, $\mathbf{z}_j^+ \in \mathcal{P}$ is its corresponding positive pair, $\mathbf{z}_n^- \in \mathcal{N}$ are the negative features, and $\tau = 0.1$ is the temperature hyperparameter.

Overall Training. The overall training objective is $\ell = \ell_{\text{REC}} + \lambda \ell_{\text{SCL}}$, where λ is a hyperparameter.

Video Test-Time Augmentation (V-TTA). During inference, we firstly estimate the left and right complex spectrograms through $\hat{\mathbf{a}}_i^L = (\mathbf{a}_i^M + \hat{\mathbf{a}}_i^D)/2$ and $\hat{\mathbf{a}}_i^R = (\mathbf{a}_i^M - \hat{\mathbf{a}}_i^D)/2$. Then, we use inverse STFT (ISTFT) [25] to recover the audio signal from both channels and concatenate

Fig. 2: Overview of the model inference procedure.

them together to form the final binaural waveform prediction $\hat{\mathbf{w}}_i = \text{Concat}[ISTFT(\hat{\mathbf{a}}_i^L), ISTFT(\hat{\mathbf{a}}_i^R)].$ We use a sliding window of 0.63 seconds and a hop size of 0.1 seconds to binauralise 10-second audio clips, following an approach similar to that of the baseline methods [4]. While this process improves binaural audio generation by focusing on smaller audio segments, it introduces significant computational redundancy. Motivated by the small visual differences in 10 fps music videos, we design V-TTA to leverage this redundancy for better performance and robustness. As depicted in Fig. 2, instead of directly resizing every video frame to 448×224 [4]–[6], we first resize each frame to 480×240 and then crop a 448×224 window from one of the five regions [top-left, top-right, bottom-left, bottom-right, centre] based on the current frame index (i.e., "i % 5", where i is a frame index). For example, if the first two audio segments are paired with the 5th and 6th frames, we crop the top-left corner of the 5th frame and the top-right corner of the 6th frame, respectively. Please refer to the Supplementary Material for additional details on sliding window integration.

IV. EXPERIMENTS

A. Evaluation Protocols

Datasets. We adopt two widely used music video datasets FAIR-Play [4] and MUSIC-Stereo [6], [29] for the model evaluation process. The FAIR-Play [4] dataset contains 1,871 10-second clips of videos recorded in a music room, with a total playtime of 5.2 hours. The videos were recorded using a professional binaural microphone, preserving high-quality binaural audio. The FAIR-Play dataset has two commonly used train/validation/test split setups. The first is the 10-split setup [4], which randomly divides the videos into subsets. The second is the 5-split setup [6], designed to evaluate the model's true generalisation ability by reducing scene overlap between training and testing, providing a more challenging evaluation setting. The videos are extracted to frames at 10 fps [4].

We also evaluate our approach on the MUSIC-Stereo dataset [6], which is based on the MUSIC dataset [29] con-

taining 21 types of musical instruments, featuring both solo and duet performances. We follow previous works [5]-[7] by filtering out non-binaural cases using a threshold of 0.001 for the sum of left-right channel differences. We obtained 1,047 unique videos to have binaural audio. We then divided the videos into 80-10-10 for training, validation, and testing. Following previous works [6], [7], we split the videos into 10-second clips and finally arrived at 20,351 clips, which is 10x larger than the FAIR-Play dataset. As MUSIC-Stereo is a YouTube-based dataset, the total number of available samples may fluctuate. The videos are extracted to frames at 10 fps [6]. **Evaluation Metrics.** We follow the previous methods [5]–[8] to report the STFT L2 distance (STFT), Magnitude distance (Mag) and Difference Phase Distance (Phs) on the timefrequency domain; and waveform L2 distance (WAV), envelope distance (ENV) and Signal-to-Noise Ratio (SNR) on time domain to assess the fidelity and quality of generated binaural audios.

B. Implementation Details

We follow previous methods [5]-[8] to fix the audio sampling rate to 16 kHz and normalise each segment's RMS level to a constant value. We adopted a widely used audio pre-processing protocol by applying the STFT with a Hann window of 25 ms, a hop length of 10 ms, and an FFT size of 512. During training, we randomly sample 0.63-second audio segments from each 10-second clip, along with the corresponding central visual frame. The selected frame is resized to 480×240, then randomly cropped to 448×224. We also apply colour and intensity jittering as data augmentation, following [4]. We use a convolutional U-Net architecture [4] for the audio backbone and a ResNet [30] (pre-trained on ImageNet [31]) for the image backbone. The networks are trained using the Adam optimiser with a learning rate of 5e-5 for the image backbone and 5e-4 for the audio backbone, using a batch size of 128. We set λ to 0.1.

C. Results

Results on FAIR-Play Dataset. We adopt established benchmarks for conducting model evaluations, such as FAIR-Play 10-splits [4] and 5-splits [6]. We first show the comparison on FAIR-Play 10-splits [4] benchmark in Tab. II. The results demonstrate that our model surpasses the second-best models by 0.026 in STFT, 0.001 in ENV, 0.182 in WAV, and 0.1 in SNR, respectively. Please note that we exclude CLUP [9] from this table, as it introduces additional computational complexity (e.g., diffusion [32] and VGGish [33]) and their method is not publicly available for inference comparison. To evaluate the true generalisation ability as suggested by PseudoBinaural [6], we also utilise the newly proposed FAIR-Play (5-split) [6] for the evaluation, as shown in the left part of Tab. I. Our method outperforms the second-best model by 0.023 in STFT, 0.045 in Mag, 0.025 in Phs, and 0.078 in SNR.

Results on MUSIC-STEREO Dataset. To further evaluate model scalability and generalisability on larger-scale datasets,

we follow [6], [7] to assess performance on the MUSIC-STEREO dataset [6], as shown in the right part of Tab. I. Our method outperforms the second-best method by 0.046 in STFT, 0.011 in ENV, 0.092 in Mag, and 2.231 in SNR. The results indicate that our method achieves higher prediction fidelity and contains less noise relative to the signal, demonstrating that CCStereo generalises better in complex scenarios.

D. Ablation Study

We perform an **analysis of CCStereo components** on the second split of FAIR-Play (5-split) [6], as shown in Tab.III. Starting from a baseline (1st row) consisting of a simple U-Net model similar to Mono2Binaural [4] that resizes the input

Fig. 4: Ablation study on the ℓ_{REC} loss for the FAIR-Play dataset. The evaluation begins with ℓ_{MSE} (blue), and sequentially adds ℓ_{AMP} (red) and ℓ_{PHS} (green).

frame directly to 448×224 during the inference. We utilise the V-TTA method to enhance the inference process, resulting in a STFT improvement of 2.49%. Integrating AVAD into the system (3rd row) provides an additional improvement of 1.03%. Subsequently, adding ℓ_{AMP} and ℓ_{PHS} (i.e., ℓ_{REC}) (4th row) and incorporating the ℓ_{SCL} contrastive learning method (5th row) yield further improvements of 1.80% and 0.65%, respectively. To separately **analyse each loss term in** ℓ_{REC} , we conducted an ablation study, as shown in Fig.4, to evaluate the individual contributions of ℓ_{AMP} and ℓ_{PHS} . Starting with the third row in Tab.III, we progressively added ℓ_{AMP} and ℓ_{PHS} during model training. We observed improvements of 0.41% and 1.40% on STFT, respectively, highlighting the importance of aligning phase information for accurate binaural prediction.

E. Qualitative Results

We present qualitative results of visual activation estimated by our method in Fig. 3. Specifically, we extract the output from the convolution layer for Mono2Binaural [4] and AVAD, average the activation map across channels, and normalise it using min-max normalisation. The results in Fig. 3a, 3b, 3c indicate that our method can better focus on the sounding object and its position. However, Tab. 3d illustrates a failure case, where the model is unable to localise the occluded object "piano" and instead shows a tendency to focus on the room environment (Room Env). We hypothesise that when the model fails to identify the sounding object, it associates the audio with the room environment. These observations highlight the limitations of the current method. For further results on videos, please refer to the *Supplementary Material*.

V. DISCUSSION AND CONCLUSION

We introduced CCStereo, a new audio-visual training method designed for the U-Net-based framework to enhance spatial awareness and reduce overfitting to room environments. We proposed a visually conditioned adaptive de-normalisation method that utilises the object's spatial information to guide the decoding of the difference audio. To enhance the representation learning of spatial awareness, we design a new audio-visual contrastive learning based on mining negative samples from randomly shuffled visual feature representation. Furthermore, our cost-efficient test-time augmentation strategy enhanced robustness without adding computational overhead. Our approach consistently outperformed existing methods on the FAIR-Play and MUSIC-Stereo datasets, achieving stateof-the-art results across various metrics.
