(Dated: 7 January 2025)

In recent years, data-driven deep learning models have gained significant interest in the analysis of turbulent dynamical systems. Within the context of reduced-order models (ROMs), convolutional autoencoders (CAEs) pose a universally applicable alternative to conventional approaches. They can learn nonlinear transformations directly from data, without prior knowledge of the system. However, the features generated by such models lack interpretability. Thus, the resulting model is a black-box which effectively reduces the complexity of the system, but does not provide insights into the meaning of the latent features. To address this critical issue, we introduce a novel interpretable CAE approach for high-dimensional fluid flow data that maintains the reconstruction quality of conventional CAEs and allows for feature interpretation. Our method can be easily integrated into any existing CAE architecture with minor modifications of the training process. We compare our approach to Proper Orthogonal Decomposition (POD) and two existing methods for interpretable CAEs. We apply all methods to three different experimental turbulent Rayleigh-Bénard convection datasets with varying complexity. Our results show that the proposed method is lightweight, easy to train, and achieves relative reconstruction performance improvements of up to 6.4% over POD for 64 modes. The relative improvement increases to up to 229.8% as the number of modes decreases. Additionally, our method delivers interpretable features similar to those of POD and is significantly less resource-intensive than existing CAE approaches, using less than 2% of the parameters. These approaches either trade interpretability for reconstruction performance or only provide interpretability to a limited extend.

I. INTRODUCTION

Deep learning methods and algorithms provided numerous new pathways for the analysis and deeper physical insights into the evolution of high-dimensional dynamical systems, such as fluid flows, in the past decade.¹⁻¹¹ Rayleigh-Bénard convection (RBC), a buoyancy-driven turbulent flow, is one prominent example of such complex dynamical systems. This kind of flow is important for many natural scenarios like for example weather or climate simulations and many engineering applications including heat transfer. Therefore in recent years, related research applied and evaluated the application of deep learning methods like convolutional autoencoders (CAEs) as reduced-order models (ROMs) for thermal convection flows¹²⁻¹⁶. CAE-based ROM are often compared to the data-driven Proper Orthogonal Decomposition (POD)¹⁷⁻¹⁹ approach and have the advantage of providing a nonlinear transformation from the given input space into the reduced lower-dimensional latent space²⁰⁻²². This is attributed to the use of nonlinear activation functions in the corresponding deep neural network architecture. However, in most cases CAE, similarly to many other deep learning models, operate as black boxes that give few guarantees and make it hard to interpret their inner functioning and latent features. This is an inherent problem of deep learning models, which typically needs to be addressed on a task-specific basis 2^{23-25} . Further, the CAE is primarily trained to preserve features that are relevant for an optimal reconstruction regarding its objective function. This, however, may be harmful when the downstream analysis depends on the present small-scale behaviour, such as when modeling the temporal evolution of a nonlinear dynamical system. POD enables the interpretation of the reduced space representation by optimal modes w.r.t. the (kinetic) energy. Most of it is contained in some first modes. The primary modes are not necessarily the dynamically most relevant ones, such as for the transition to turbulence in wallbounded shear flows²⁶.

Alternative solutions have been developed in the past. Ahmed *et al.*²¹ proposed a modified nonlinear-POD that keeps the first *k* modes covering 99.9% of the cumulative energy. The authors use the time coefficients of the first *k* modes as an input representation for a downstream fully-connected autoencoder (AE). They compared their approach to a standard POD and a conventional CAE. All three models perform a data reduction to two latent features. For the reconstruction with nonlinear-POD, the authors first apply the decoder to receive a prediction of the time coefficients of the first *k* POD modes. Subsequently, they reconstruct the full-order snapshot via reverse POD.

Fresca and Manzoni²⁷ introduced a similar approach to form a POD-deep learning-based reduced order model. However, their model involves the utilization of a CAE instead of a fully connected AE on the time coefficients. Therefore, the time coefficients are reshaped before they are processed by the CAE. Both approaches take advantage of a linear decomposition to reduce the computational costs for the subsequent deep learning model. As a result, by utilizing these approaches, one can find nonlinear transformations, but will still lose interpretability of the POD.

Murata, Fukami, and Fukagata²⁸ proposed a mode decomposing convolutional neural network autoencoder (MD-CNN-AE) as a deep learning approach that has the nonlinear capabilities of a CAE and allows for latent feature interpretation. Each feature captures information about a separate additive component of the reconstructed flow field snapshot. MD-CNN-AE involves the training of a separate sub-decoder for each latent variable. Each sub-decoder produces a snapshot reconstruction component. To retrieve the full order snapshot reconstruction, the components are added together elementwise. Fukami, Nakamura, and Fukagata²⁹ proposed a variation of MD-CNN-AE. Instead of adding the reconstructions of different sub-decoders, they build a hierarchical autoencoder (H-AE) model and training structure. Each hierarchy level has its own latent features but also makes use of the latent features of all previous hierarchy levels. At the same time, each hierarchy level tries to reconstruct the original flow field. This way, the H-AE can learn to combine the latent feature information at different levels in a more complex and nonlinear way. Both approaches were evaluated for a cylinder wake flow at Re = 100 and a latent space dimension of 2 was used.

In this paper, we propose a training strategy for CAEs that trains the model to extract latent features which are sorted in decreasing order of importance for the reconstruction. While existing CAE-based methods, increase the required resources by orders of magnitude, we will show that our proposed method does not require larger modifications of the network architecture and can be applied to any conventional CAE. Hence, it only introduces minor modifications in the training process only. During inference, the model can operate just as if it was a conventional CAE, where it beats the reconstruction performance of existing approaches and POD by 4.9% to 229.8%. A novel aspect of our approach is that we can decide to further reduce the number of latent features used for a reconstruction later without retraining the autoencoder. In a nutshell, we will preserve a "modal-type" information for the features in our modified autoencoder algorithm, which is not available in a standard CAE.

To give an example, in order to perform time series forecasting of large-scale features of the data as a downstream task, we can simply zero out all other features at smaller scales. For the evaluation of our model, we apply the method to three measured RBC datasets at different turbulence intensity which is quantified by the dimensionless Rayleigh number; the data records are taken at Ra = 9.4×10^5 , 2.0×10^6 , and 5.5×10^6 . In detail, the data records comprise a sequence of *N* snapshots of the three-dimensional velocity vector fields $u(x,y,h/2,t_k)$ with k = 1,...N at the midplane between the top and bottom plates, at h/2. More details will be provided in Sec. II.

The outline of the paper is as follows. We describe the dataset generation in more detail in Sec. II. From there, we continue with a description of the used CAE architecture and

existing approaches in Sec. III. Sec. IV contains a detailed description of our approach. In Sec. V we evaluate our method on three RBC datasets and compare the results to MD-CNN-AE and the H-AE approach. We discuss the results in Sec. VI and end with a conclusion in Sec. VII.

II. LABORATORY MEASUREMENT DATA

The training data, that we use in this paper, stems from a laboratory experiment of a turbulent thermally driven fluid flow. In the following, we describe the flow system and the relevant parameters in detail. We also provide comprehensive information about the data pre-processing and augmentation.

A. Rayleigh-Bénard convection flow experiment

Turbulent thermal convection is at the heart of various natural flow phenomena, including the Earth's mantle, the outer shell of the Sun, circulations in the oceans, or clouds and cloud clusters in the atmosphere. RBC as a turbulent flow between two parallel and horizontally extended solid plates, cf. Fig. 1 for the flow geometry, is the simplest configuration of this class of flows and thus defines a paradigm^{30,31}. Turbulent thermal convection flows, including RBC, form one fundamental class of turbulent flows. The turbulent fluid motion between the plates is driven by the temperature dependence of the mass density in any fluid; lighter hotter fluid rises, heavier colder fluid sinks down. A maintained outer temperature difference between the hot bottom and colder top plate becomes the permanent driving mechanism of fluid motion (by buoyancy forces) which in addition carries the supplied heat through the layer, from the bottom to the top. For the current study, experimental data of RBC has been taken as a representative example of a challenging application for machine learning tasks providing high-dimensional data that follow a complex nonlinear temporal dynamics.

FIG. 1. A schematic sketch of the experimental Rayleigh-Bénard cell. The transparent heating plate provides the optical access to conduct stereoscopic particle image velocimetry in the horizontal midplane of the cell. The working fluid, compressed sulfur hexafluoride, is in turbulent motion between the top (in blue) and bottom plates (in red). The side faces, which close the cell, are thermally insulated such that all the supplied heat has to pass through the fluid layer, either by diffusion or by convection.

As already stated in Section. I, we use three experimental datasets of convection in pressurized sulfur-hexafluoride (SF₆), for Rayleigh numbers of Ra = 9.4×10^5 , 2.0×10^6 and 5.5×10^6 . The Rayleigh number is a dimensionless parameter which relates the buoyancy and viscous forces of the fluid. As Ra increases, the complexity of the turbulent flow increases as well. It is given by $Ra = g\alpha\Delta Th^3/(\nu\kappa)$. Here, $\Delta T = T_{\rm bot} - T_{\rm top} > 0$ is the temperature difference between the uniformly heated and cooled plates. The other quantities in the definition of Ra are the fluid properties namely, thermal expansion coefficient α , kinematic viscosity v, and thermal diffusivity κ together with the acceleration due to gravity, g. Two more parameters characterize the convective flow. The Prandtl number $Pr = v/\kappa = 0.7$ and the aspect ratio of the cell, which related lateral extension to height and is in our case $\Gamma = L/h = 10$.

We conducted stereoscopic particle image velocimetry (stereo PIV) in the horizontal mid-plane in order to measure the in-plane velocity components (u and v) along with the outof-plane velocity component w. Each of the 3 datasets has 20000 snapshots with 10 Hz recording frequency and the field of view which covers an area of $A = 7h \times 5.8h$ at the center of the cell, see again Fig. 1. There are 174×208 velocity vectors that define the flow field with a spatial resolution of 1×1 mm². Figure 2 shows an example of a measured instantaneous velocity field. Here, the vectors indicate the in-plane velocity components u and v, while the background color map shows the out-of-plane velocity component w. The values are normalized to the free-fall velocity $u_f = \sqrt{\alpha \Delta T g h}$. In order to further visualize the turbulent flow and to illustrate its chaotic behavior, a video of the flow field dynamics is available in the supplemental online material. Further details about the measurement setup and the physics of the flow can be found in Sharifi Ghazijahani et al. 32 and Sharifi Ghazijahani and Cierpka³³, respectively.

For the experimental evaluation of our model, we will use the out-of-place velocity component w only. We apply some data pre-processing and use a version with a reduced spatial resolution of 87×104 pixels. This is done to save memory and computation time. Finally, we trim the range of data values (w/u_f) between -0.6 and 0.6 to remove outliers. We set them to -0.6 and 0.6 respectively. The trimming affects 0.007%, 0.001% or 0.005% of all values, depending on the dataset. During training and testing, the input snapshots are generated by applying a 64×64 pixel crop on the reduced snapshots. This allows us to use data augmentation for the deep learning models.

B. Augmentation of the experimental snapshot data

When training deep learning models, we use data augmentation as a regularization measure. Although it is not mandatory to apply data augmentation during training, previous studies have shown, that it improves the generality of the resulting deep learning model and helps to avoid overfitting.^{34–37} As augmentation operations, we use a shift operation in horizontal and vertical direction followed by a

crop operation, described above (cf. Sec. II). We take advantage of the fact that the original dimensions of our data snapshots are larger than the input dimensions of our models. Data augmentation is only applied during training phase; it is omitted for validation and testing phase. Here, we always perform a center crop to match the desired snapshot dimensions. Figure 3 shows an example snapshot before and after the shift and crop operations. The data augmentation operations are applied for each training snapshot separately. The shift width in either direction is chosen at random each time.

III. EXISTING DATA-DRIVEN REDUCTION METHODS

In this section, we give a description of the existing datadriven methods which are used in our evaluation. We introduce the POD that acts as a baseline and the CAE architecture that we use as the foundation for different nonlinear datadriven ROM approaches that will be specified in subsection C and D.

A. Proper Orthogonal Decomposition by snapshot method

The Proper Orthogonal Decomposition³⁸ (POD) is a linear data decomposition method which transforms a data matrix $M \in \mathbb{R}^{T,\mathscr{X}}$ that contains *T* measurements (or snapshots) of \mathscr{X} spatial features (e.g. pixels, grid points or resolved flow components) to temporal modes and spatial modes. This can be interpreted as a singular value decomposition of the data matrix which is given by

$$M = U_T \Sigma U_{\mathscr{X}}, \qquad (1)$$

where $U_T \in \mathbb{R}^{T,T}$ is an orthogonal matrix storing *T* temporal modes for *T* time steps, $\Sigma \in \mathbb{R}^{T,\mathscr{X}}$ is a diagonal matrix storing the descending sorted singular values or principal components of the data and $U_{\mathscr{X}} \in \mathbb{R}^{\mathscr{X},\mathscr{X}}$ is an orthogonal matrix storing \mathscr{X} spatial modes with \mathscr{X} spatial components. A spatial mode corresponds herein to a static image of the out-of-plane velocity component. The first spatial mode is scaled with the first and thereby largest singular value, which has the largest contribution to the total kinetic energy. The corresponding temporal mode indicates how strongly this spatial mode is present in each of the *T* measurements.

In this work, $\mathscr{X} \ll T$, which implies that the rectangular and diagonal matrix Σ only stores \mathscr{X} singular values. Thereby, we can reduce Σ to a square matrix of size \mathscr{X} and U_T to a rectangular matrix in $\mathbb{R}^{\mathscr{X},T}$ to reconstruct M. We use T = 16000 measurements of $\mathscr{X} = 4096$ spatial features (or grid points), leading to 4096 temporal and spatial modes. We identify the spatial modes $U_{\mathscr{X}}$ and principal components Σ by the covariance matrix of the mean-centered data matrix \overline{M} by

$$C = \frac{1}{\mathscr{X} - 1} \, \bar{M}^T \bar{M} = \frac{1}{\mathscr{X} - 1} \, U_{\mathscr{X}}^T \Sigma^2 U_{\mathscr{X}} \,. \tag{2}$$

For the temporal modes, we use $U_T = \overline{M} U_{\mathscr{X}}^T \Sigma^{-1}$.

FIG. 2. Instantaneous turbulent velocity field in the horizontal mid-plane for a Rayleigh number $Ra = 5.5 \times 10^6$. The color map indicates the out-of-plane velocity component *w*, while the in-plane components *u* and *v* are represented by the vectors. Note that only one out of four vectors in each direction is plotted.

FIG. 3. Sketch of the shift and crop operation applied to an example snapshot for data augmentation.

B. Convolutional autoencoder

We compare different CAE approaches to the conventional POD analysis. For these, we use a conventional CAE with a customized architecture as base for all other CAE-based approaches. An autoencoder network in general consists of two parts, the encoder and the decoder part. The encoder part performs a function $E_{d,\theta} : \mathbb{R}^{h,w} \to \mathbb{R}^d$ that takes a data snapshot **x** as parameter and transforms it into a latent representation **z**, where *h* and *w* are the vertical and horizontal dimension of the input snapshot. The decoder performs a function $D_{d,\theta} : \mathbb{R}^d \to \mathbb{R}^{h,w}$. It takes a latent representation **z** and transforms it into the reconstruction of the data snapshot $\hat{\mathbf{x}}$. Hence, the autoencoder can be described by a function $F_{d,\theta} : \mathbb{R}^{h,w} \to \mathbb{R}^{h,w}$ that is composed of $E_{d,\theta}$ and $D_{d,\theta}$. Each

function represents a neural (sub-)network that depends on a parameter set θ . We omit the θ subscript in the rest of this paper for the sake of simplicity. Thus, we write F_d , E_d and D_d and only add θ when needed. As a result, the function of the autoencoder can be written as follows:

$$F_d(\mathbf{x}) = (E_d \circ D_d)(\mathbf{x}) = \hat{\mathbf{x}}.$$
(3)

The encoder E_d , used in this paper, consists of four encoder blocks, each of which utilizes two 2d-convolutional layers with leaky rectified linear unit (Leaky ReLU)³⁹ activation and a subsequent batch normalization⁴⁰ layer. The convolutional layers have kernel size 3×3 . Each encoder block ends with a max-pooling layer with kernel size 2×2 to perform the data reduction and a dropout layer as regularization measure. After the last encoder block, we perform a flatten operation that transforms the 3-dimensional output feature map into a 1-dimensional feature vector. The vector is processed through two fully connected layers with another batch normalization layer in between. These layers reduce the feature vector dimension to finally fit the desired latent dimension d. The last fully connected layer is followed by a hyperbolic tangent (tanh) activation.

The decoder D_d is constructed analogously to E_d in reverse order. It starts with two fully connected layers with Leaky ReLU activation and batch normalization. Their output is brought into the desired 3-dimensional shape to serve as input for the first of four decoder blocks. The first three decoder

FIG. 4. Basic convolutional autoencoder (CAE) architecture. Illustrated are the data dimensions at the different stages of the encoding and decoding process. The CAE takes a snapshot **x** and encodes it into a latent representation **z**. Subsequently it is expanded into the reconstructed snapshot $\hat{\mathbf{x}}$. The squared brackets contain the shape of input, output and features on the forward pass. Here, ρ is a hyper-parameter that controls the number of filters in the convolutional layers. Thus it determines the number of channels of the corresponding output feature maps.

blocks consist of a nearest neighbor up-sampling layer with a kernel size 2×2 to perform the data expansion. It is followed by two 2d-convolutional layers with Leaky ReLU activation and batch normalization. Here the kernel size is also 3×3 . The blocks end with another dropout layer. The last decoder block is built differently. Its second convolutional layer directly outputs the reconstructed data snapshot through a sigmoid activation function. Figure 4 provides an overview of the CAE structure and its dimensionality. The hyper-parameter ρ serves as scale factor for the number of channels of the feature maps between the different blocks.

The architectural and hyper-parameter choices made in this paper are not generalizable. They depend on the specific learning task, the available computational resources, and the complexity and size of the data. Therefore, different choices may be advised in other scenarios.

A CAE is usually trained in a self-supervised fashion, where the network's input is also its target. Thus, it aims to optimize the following problem:

$$\underset{\theta}{\operatorname{argmin}} \mathscr{L}(D_d(E_d(\mathbf{x})), \mathbf{x}), \qquad (4)$$

where \mathscr{L} is the objective function to reduce. The training is considered successful when $\mathbf{x} \approx \hat{\mathbf{x}}$.

In this and the following Section, we will introduce different CAE approaches that use a conventional CAE as foundation. We present a simplified sketch for each of them, to provide an intuition for their architecture, cf. Fig. 5.

C. Mode decomposing convolutional neural network autoencoder

The mode decomposing convolutional neural network autoencoder (MD-CNN-AE) as proposed by Murata, Fukami, and Fukagata²⁸, is an approach for a CAE-based nonlinear ROM that introduces an adapted architecture. While the encoder E_d remains unchanged in comparison to the conventional CAE, the decoder D_d is split into multiple sub-decoders $D_{i,d}$, where the number of decoders corresponds to the latent data space dimension d. Each sub-decoder learns to reconstruct a different additive component of the target snapshot, based on a separate latent feature $z_i \in \mathbf{z}$. Hence, we can formulate the decoder as

$$D_d(\mathbf{z}) = \sum_{i=1}^d D_{i,d}(z_i).$$
 (5)

Given E_d and D_d , the optimization problem remains similar to the base CAE.

D. Hierarchical autoencoder

The hierarchical autoencoder (H-AE) approach by Fukami, Nakamura, and Fukagata²⁹ implies to train a set of subencoders \tilde{E}_{i,c_i} and sub-decoders \tilde{D}_{i,d_i} in a hierarchical scheme to achieve an interpretability of the latent features. Subencoder \tilde{E}_{i,c_i} produces c_i output features and sub-decoder \tilde{D}_{i,d_i} takes d_i latent features as input. In the first stage, the training starts with sub-encoder \tilde{E}_{1,c_1} and sub-decoder \tilde{D}_{1,d_1} , where $c_1 = d_1$. As soon as the training converges, their weights are freezed and remain fixed for the rest of the training. With each following stage *i*, another pair of sub-encoder and decoder $\tilde{E}_{i,c_i}, \tilde{D}_{i,d_j}$ is trained. Sub-decoder \tilde{D}_{i,d_i} receives c_i latent features from \tilde{E}_{i,c_i} together with those of all previously trained sub-encoders, thus $d_i = \sum_{i=1}^{l} c_i$. The authors used $c_i = 1$ in their paper. Thus, d is not only the latent size, but also the number of sub-autoencoders. Therefore, we reduce the symbols for sub-encoder and sub-decoder to \tilde{E}_i and \tilde{D}_i for simplicity. Finally, the trained model can be written as:

$$F_d(\mathbf{x}) = \tilde{D}_d([\tilde{E}_i(\mathbf{x}); \dots; \tilde{E}_d(\mathbf{x})]).$$
(6)

During inference, we only require the last sub-decoder, but all sub-encoders. Due to the hierarchical training structure, we can also neglect some of the later latent features and still receive a valid reconstruction. For example, given that d > 2and we want to use only 2 latent features, we use the second decoder and the first two encoders:

$$F_2(\mathbf{x}) = \tilde{D}_2([\tilde{E}_1(\mathbf{x}); \tilde{E}_2(\mathbf{x})]).$$
(7)

The minimization problem addressed differs from that of the base CAE. In hierarchical training, it is instead approached as a series of minimization problems. Except for the first stage,

FIG. 5. Minimal schematic architectures that we study in this paper. Each model is visualized with only three latent features for illustration. Per architecture, the left hand side represents the features as they leave the encoder and while the right hand side shows how they enter the decoder. (a) is the basic CAE that is also shown in Figure 4 in detail. It simply forwards the latent features as they are. (b) and (c) show the existing interpretable CAE methods that have sub-encoders or -decoders that are responsible for a specific subset of features. (c) represents our method that randomly sets values to zero at the lower end of the latent feature vector during training.

the minimization problem at each successive stage i can be formulated as

$$\operatorname{argmin}_{\theta_i} \mathscr{L}(\tilde{D}_i([\tilde{E}_1(\mathbf{x});\ldots;\tilde{E}_{i-1}(\mathbf{x});\tilde{E}_i(\mathbf{x})]),\mathbf{x}), \qquad (8)$$

where θ_i represents the parameter set of the sub-encoder and decoder for stage *i*. The solution must also take the earlier sub-encoders $\tilde{E}_1, \ldots, \tilde{E}_{i-1}$ into account, which are dependent on the parameter sets $\theta_1, \ldots, \theta_{i-1}$. Therefore, $\theta_1, \theta_2, \ldots$ are optimized sequentially, with each subsequent stage utilizing the optimal parameter sets found for the previous stages.

IV. SLIM MULTI-SCALE CONVOLUTIONAL AUTOENCODER

We propose a novel approach which creates a slim multiscale convolutional autoencoder (SMS-CAE). SMS-CAE is inspired by POD and the interpretability of its modes. POD modes with higher kinetic energy hold information about the structures at the larger scale of the full system, while the energy proportion decreases with increasing mode index (since they are ordered with respect to their kinetic energy). Analogously, we propose to train a CAE that captures as much information as possible in the first latent features. In contrast to H-AE, which comes with a heavy increase of required training resources, SMS-CAE is lightweight in memory and time resources. While H-AE uses a number of sub-models that scale linearly with the number of latent features. SMS-CAE requires only a minimal architectural adaption to the base model. The training of the H-AE is performed in a hierarchical, stage-wise fashion, where sub-models are trained in series which results in a longer training time. The training of the SMS-CAE optimizes all model parameters in each gradient descent step just like the original base model. This avoids the imbalance between the reconstruction quality of the largescale and small-scale spatial features, that may appear due to H-AE training. The core working principle of SMS-CAE is inspired by the well-known dropout regularization⁴¹. Dropout helps to provide an effect comparable with ensembles training without the overhead of maintaining multiple models^{42,43}.

Similarly, we employ a restricted dropout mechanism that helps our model to train multiple sub-tasks at the same time and avoids the overhead associated with a hierarchical model. In contrast to an hierarchical training scheme, we allow the model to address all sub-tasks equally, thus preventing an imbalance in reconstruction quality. The constrained dropout mechanism is positioned immediately after the last encoder layer and sets a random number of latent features to zero during training. Hence, on the forward pass, we preserve a contiguous subset of features that always includes the first one. Thus, if $\mathbf{z} = (z_1, z_2, ..., z_d)$ is the latent feature vector, the decoder uses features with lower indices more often than those with higher indices. As a result, the model learns to encode the most important information in the first, more frequently trained features.

As described in Section III, F_d represents the function of a conventional autoencoder with latent dimension *d*. For our proposed SMS-CAE, we introduce a restricted dropout function φ_d :

$$\boldsymbol{\varphi}_{\hat{d}}(\mathbf{z}) = \mathbf{z} \odot [\mathbf{1}_{\hat{d}}; \mathbf{0}_{d-\hat{d}}], \qquad (9)$$

where latent vector $\mathbf{z} \in \mathbb{R}^d$, $\hat{d} \leq d$, $\mathbf{1}_{\hat{d}} \in \{1\}^{\hat{d}}$ and $\mathbf{0}_{d-\hat{d}} \in \{0\}^{d-\hat{d}}$. Thus, $\varphi_{\hat{d}}$ basically preserves the first \hat{d} features of \mathbf{z} and turns the remaining into 0. The constrained dropout mechanism $\varphi_{\hat{d}}$ is placed between the encoder E_d and decoder D_d of the CAE to restrict the information available for reconstruction. Thus, the SMS-CAE is formalized as

$$F_{d,\hat{d}}(\mathbf{x}) = (E_d \circ \varphi_{\hat{d}} \circ D_d)(\mathbf{x}).$$
(10)

During training, \hat{d} is a random variable drawn from a discrete uniform distribution on [1,d]. Hence, for 1/d of all samples, the model processes throughout training, it tries to encode into the first latent feature z_1 only. Therefore, z_1 holds as much information as possible on the large-scale structures of the snapshots. Additionally, the model tries to incorporate information of z_1 into the reconstruction of small-scale structures in the cases where more latent features are available. As a result, the model addresses the following optimization problem

$$\underset{\boldsymbol{\theta}}{\operatorname{argmin}}(\sum_{\hat{d}=1}^{d} \mathscr{L}(F_{d,\hat{d}}(\mathbf{x}), \mathbf{x})). \tag{11}$$

The mean squared error (MSE) is a common choice of ob-

FIG. 6. Reconstruction quality for training data for the experiment at a Rayleigh number of $Ra = 9.4 \times 10^5$ displayed as cumulative energy and normalized mean squared similarity (NMSS).

jective function \mathscr{L} for CAEs, and is considered reasonable for pure reconstruction tasks. However, SMS-CAE provides interpretability in terms of importance for reconstruction according to the objective function. Thus, the objective function is a hyper-parameter that mainly controls the desired interpretability. For example, if our goal is to encode information about the flow at the boundaries, we can alter the objective function to give more weight to the reconstruction error at the edges. The model will then be trained to encode boundary region information with higher priority in the first feature(s). It is also possible to adjust the objective depending on how many features are passed for a given sample to give certain features a very specific additional task. This shows that there are massive possibilities to tune the interpretability of the ROM dimensions beyond minimizing the squared reconstruction error. However, this analysis is beyond the focus of this paper and should be addressed in future research.

V. EVALUATION

In the evaluation, we compare POD and the three CAEbased ROM approaches discussed above. To ensure the comparability of the reconstruction results, we take specific measures addressing the data split and the evaluation metric.

A. Experimental setup

For deep learning models, the training is typically structured into three phases: training, validation and testing, where each phase uses a completely separate part of the whole dataset. The model solely adapts its weights on the training set, while the validation dataset can be used to compute a validation loss to decide whether the model is done training or to adjust hyper-parameters. To compare the model with others, the model is applied on the test set and the performance metric is calculated. To keep the CAE results comparable to POD we will follow this procedure for all methods. We apply an 80 - 10 - 10 split to divide each dataset into a training, validation and test set. Thus, also the POD modes and singular-values are retrieved solely relying on the information from the training set.

As a second measure, we aim to establish an evaluation metric to compare the reconstructions of the POD with those of the deep learning methods. In the case of the POD, we can use the retrieved singular-values to judge the amount of cumulative energy information preserved after discarding a certain number of modes. For CAEs based methods, we do not have this information. Instead, an error metric based on MSE or mean absolute error (MAE) is calculated. It is common practice to normalize the error with the mean or variance of the data. We use the MSE normalized by the average variance per grid point. Finally, we subtract the resulting error from 1. Thus, a large score refers to a high similarity. We refer to the resulting similarity metric as normalized mean squared similarity (NMSS). The NMSS behaves almost similar to the the preserved cumulative energy curve of the POD above 0:

NMSS
$$(\mathbf{x}, \hat{\mathbf{x}}) = 1 - \frac{\sum_{i=1}^{N_y} \sum_{j=1}^{N_x} (\mathbf{x}_{i,j} - \hat{\mathbf{x}}_{i,j})^2}{\sum_{k=1}^{N_y} \sum_{l=1}^{N_x} (\bar{\mathbf{x}}_{k,l} - \mathbf{x}_{k,l})^2},$$
 (12)

where $\bar{\mathbf{x}}_{k,l}$ is the average value of the training snapshots at position (k,l). The NMSS ranges from $-\infty$ to 1.0, where values smaller than 0.0 imply a result that is considered worse than using the average training snapshot as reconstruction. An NMSS value of 1.0 stands for a perfect reconstruction. Figure 6 shows the NMSS of the POD reconstructions on different numbers of modes on the training data at Ra = 9.4×10^5 . It also plots the cumulative energy based on the corresponding singular values. The NMSS curve almost exactly follows the cumulative energy curve with only a small deviation that is negligible. Therefore, we use NMSS as an evaluation metric for CAE and POD reconstruction.

For the batch-wise training, we used the Adam optimizer⁴⁴ with a learning rate of 10^{-5} and a batch size of 128 snapshots. Additionally, we applied a learning rate scheduler to adapt the learning rate in the later stages of training. The learning rate scheduler reduces the learning rate to 10% when the validation loss is stagnant for 30 epochs. To calculate the training and validation loss, we used the MSE as loss function. The hyper-parameter ρ which controls the number of filters in the convolutional layers (cf. Fig. 4) was set to 32. All hyper-parameters were selected during a greedy search and are fixed for all CAE-based models in all experiments. Before we feed the snapshots to a model, we normalized the dataset between 0.0 and 1.0. To calculate the evaluation metric, we reverse the normalization of the reconstructions and compare them to unnormalized target snapshots.

B. Baseline experiments: POD vs. CAE

In our first set of experiments, we compare the reconstruction performance of the conventional CAE and POD for different latent sizes and respective numbers of modes. We choose them according to the preserved cumulative energy to be at levels 0.5, 0.6, 0.7, 0.8 and 0.9. We list the corresponding numbers of modes for each dataset in Table I. We refer to these as energy levels. Figure 7 shows the average test NMSS at different energy levels for each dataset. It becomes clear that the CAE consistently surpasses the POD reconstruction performance throughout all energy levels and datasets. However, it is apparent that the absolute benefit of the CAE shrinks towards higher energy levels. We set the number of latent features according to the number of POD modes required to preserve the same amount of energy for each dataset. Nevertheless, the reconstruction quality on the test snapshots shrinks with increased Ra, which is due to the higher complexity of the more turbulent flow at higher Ra. Consistently, we observe this effect for both approaches.

Cumulative	9.4×10^{5}	Ra 2.0×10^6	5.5×10^{6}
0.5	38	2.0 × 10	35
0.6	57	58	57
0.7	86	91	95
0.8	136	149	166
0.9	245	280	333

TABLE I. Number of modes required for each dataset to reconstruct a certain proportion of the cumulative energy of the full-order model

C. Characteristics of SMS-CAE

For a conventional CAE the latent dimension is set during training and remains fixed. All latent features contribute approximately equally to the reconstruction and we cannot easily create a minimal sub-selection of features that cover most information. SMS-CAE approaches this issue with the separation of latent feature sub-sets during training. As a result, after a training with d latent features, we can use the same model to produce reconstructions from $\hat{d} = 1, \dots, d$ features without retraining. More specifically, we assume that an SMS-CAE model trained on d latent features is as good at reconstructing from $\hat{d} = |d/2|$ features as an SMS-CAE model that was originally trained on that many features. To test whether this assumption holds, we perform a second set of experiments. We train the SMS-CAE on d = 64, 128, 256, 512, 1024, 2048, 4096 latent features. Subsequently, we apply the model on the test set to reconstruct snapshots from $d = 1, \dots, d$ features respectively. The results reveal that the approximate progression of NMSS is similar regardless the number of latent features in training, cf. Fig. 8(a). Furthermore, we see that for $\hat{d} \gtrsim 400$ features the improvement saturates at an NMSS of ≈ 0.93 . In Fig. 8(b), we see how well the model can reconstruct from \hat{d} features depending on what *d* it was trained before. The surprising observation is that the model is not best when $\hat{d} = d$. In the tested cases, it seems to be advised to train the model on a *d* that is 2 to 4 times larger than the \hat{d} used during inference.

D. Interpretable latent features

As described in Sec. III, previous approaches for CAE based ROMs proposed interpretable features for highdimensional dynamical systems. We performed a third set of experiments in which we applied the SMS-CAE together with the MD-CNN-AE and the H-AE. Particularly the H-AE has increased memory and computation time requirements. Hence, we set $\hat{d} = 64$ to keep the resource requirements feasible. Because of our observations reported in the last subsection, namely that SMS-CAE is best trained for $d > \hat{d}$, we use 256 latent features during training. Nevertheless, the tests are performed on $\hat{d} = 64$ features. We also report the number of trainable model parameters along with test reconstruction NMSS to give an intuition for the model size, cf. Tab. II. For the POD baseline, we consider the size of the modes and the average snapshot as training parameters. These conclude to a total of about 266K values. A considerable small amount compared to the CAE-based methods. CAE and SMS-CAE are within a close range near 20M parameters. For MD-CNN-AE and H-AE the numbers increase by a factor of more than 30 respectively 63. The NMSS shows that all CAEs except the H-AE clearly outperform the conventional POD approach, with relative improvements ranging from 4.9% to 6.4%. However, the H-AE leads to a performance decrease ranging from -15.3 to -8.2%. CAE, MD-CNN-AE and SMS-CAE all perform quiet similarly regarding the NMSS. Thus, there is no visible performance decrease due to the focus on interpretability. Quite the opposite, most results of interpretable methods exceed the conventional CAE by a small margin.

However, the NMSS only gives insight on the reconstruction performance, but not the interpretability. Thus, we want to take a closer look on the latent spaces and reconstructions with different $\hat{d} \leq d$. The latent spaces of the conventional CAE and MD-CNN-AE exhibit similar dynamics throughout the different features, cf. Figs. 10 and 11. H-AE and SMS-CAE reveal different dynamics for different latent features just like the time-coefficients of POD as shown in Figs. 9, 12, and 13. It appears that earlier latent features $(z_i \text{ with smaller } i)$ have slower dynamics while at later features the time-series starts to oscillate. The earlier features produced by H-AE remain stable for some time steps before they change abruptly. SMS-CAE earlier features express a smoother temporal behavior that is more similar to the POD coefficients. To further analyse the features dynamics, we calculate the average frequency of feature over time and normalize with the maximum. The result is a curve that displays the course of the relative average frequency over the features which is shown in Fig. 14. We observe that the frequencies for CAE, MD-CNN-AE, H-AE are rather constant over the features. Only H-AE has a peak at the third feature. Also the test features of the other datasets have a similar peak at an early feature position (cf.

FIG. 7. Average test normalized mean squared similarity (NMSS) of POD and CAE reconstructions on a fixed set of energy preservation levels for each dataset: (a) $Ra = 9.4 \times 10^5$, (b) $Ra = 2.0 \times 10^6$, (c) $Ra = 5.5 \times 10^6$.

FIG. 8. Test NMSS of the SMS-CAE with different amounts of latent features in the training, *d*, and test phases, \hat{d} , for a Rayleigh number of Ra = 9.4×10^5 .

FIG. 9. Selection of time-coefficients of POD on the test dataset at $Ra = 9.4 \times 10^5$.

Fig. 15). The frequencies of the SMS-CAE show a comparable trend to the POD. Features with a higher index also show higher average frequencies.

The test snapshot reconstructions by SMS-CAE and H-AE visually behave similarly to the POD reconstructions (cf. Fig. 16). The autoencoder reconstructions appear smoother and less noisy than those of the POD. SMS-CAE outperforms POD for most \hat{d} except the lowest based on test NMSS. In the region of lower $\hat{d} \leq 4$, H-AE outperforms the SMS-CAE. However, as \hat{d} increases, SMS-CAE overtakes while

FIG. 10. Selection of latent features produced by CAE on the test dataset at $Ra = 9.4 \times 10^5$.

the NMSS of H-AE falls below that of the POD for $\hat{d} \ge 8$. This is due to the hierarchical training scheme of H-AE that primarily favors the lowest \hat{d} in the first stages. In later stages, larger \hat{d} have to cope with features that are optimized for a lower-dimensional task. MD-CNN-AE achieves NMSS similar to SMS-CAE, but rapidly loses reconstruction quality for $\hat{d} < d$. The NMSS score drops below 0 for $\hat{d} \le 32$, which shows that the kind of interpretability that the method provides is not directly comparable to POD. This is due to the applied training procedure and model architecture. They lead to every single features being similarly important for recon-

E. Very low dimensional ROMs

Our results have shown that SMS-CAE provides interpretability comparable to POD if trained with the MSE objective function. The reconstruction quality achieved by our method gains a relative improvement of up to 6.4% for 64 modes. However, as indicated by Figure 8, its reconstruction quality is capped at an NMSS of about 0.93. Furthermore, the relative improvement dwindles and falls below that of POD as \hat{d} exceeds $\approx 10\%$ of the input snapshot size. Therefore, we provide a set of experiments to compare the reconstruction performance of SMS-CAE and POD for very small latent sizes/numbers of modes. Hence, we train the SMS-CAE with fewer latent features on all three dataset. We report the reconstruction quality for $\hat{d} \in \{1, 2, 4, 8, 16, 32\}$, where d is chosen accordingly during training. We compare the results with the reconstruction quality of POD for the same number of modes on the test subsets per dataset (cf. Tab III). We report the NMSS and the relative improvement of SMS-CAE. The results show a relative improvement ranging from 8.3% and 229.8%. Where the most improvement can be observed with smaller ROMs.

FIG. 14. The relative average frequency over the 64 modes/latent features for POD and different CAE-based ROM methods. The curves for CAE, MD-CNN-AE, H-HAE show no clear trend, but remain relatively constant. POD and SMS-CAE are quiet similar in that the average frequency starts small and increases on average linearly with increasing feature index.

FIG. 15. The relative average frequency for H-AE for different Rayleigh numbers Ra which are given in the title of the panels. We always observe a peak in an early feature.

VI. DISCUSSION

We developed SMS-CAE, a novel lightweight multi-scale CAE that provides interpretability to an extend comparable to POD. SMS-CAE efficiently learns nonlinear ROMs for highdimensional and turbulent flows. Our method produces superior interpretability and reconstruction quality compared to existing deep learning-based ROM approaches. It also requires orders of magnitude less computational resources. We evaluated the performance of our method in a variety of experiments and compared it to related methods.

In our experimental evaluation, we applied a POD, a conventional CAE and three interpretable CAEs on three turbulent measured RBC datasets. We observed that the conventional CAE produces more precise reconstructions than the POD according to NMSS. The superiority of CAE is particularly evident when the number of modes is below 10%. However, our results indicate that the reconstruction quality of the CAE solutions saturates at about 93% cumulative energy for our data. Thus, increasing the number of latent features above 400 for our example case does not lead to recognizable improvements in reconstruction quality with our architecture. We argue that this is due to the data reduction with max-pooling layers. These, are not designed to simply forward information and inevitably lead to loss of information. The loss can no longer be compensated by the succeeding convolutional layers when the corresponding patterns in the data are too noisy. However, since our focus is on data reduction, we consider the advantage in smaller latent spaces to be more relevant to the domain than the disadvantages in ideal reproduction.

The three advanced CAEs do not only reduce the data, but are designed to produce interpretable features. For MD-CNN-AE, each latent feature encodes a separate piece of additive information of the reconstructed snapshot. However, we have no information about the importance of each feature. For SMS-CAE and H-AE, our results show that their latent representations provide an interpretability similar to POD. Thus, we know which latent features encode information about large scale high-energy flow patterns and which about low-energy small scale flow patterns. As a result, we can choose a smallest subset of latent features for reconstruction that preserves as much cumulative energy as possible. The reconstruction quality in terms of test NMSS shows that MD-CNN-AE and SMS-CAE keep and in some cases even slightly improve the reconstruction quality of the conventional CAE. However, the H-AE produces clearly poorer reconstructions. We argue that this is due to the curriculum training procedure of the H-AE. Curriculum learning strategies alter the task for the model over the course of training epochs which can stabilize training and speed up convergence⁴⁵. The training strategy of the H-AE is designed to find the best sub-model in the current training stage in a greedy way. Thus, the model cannot adapt parameters from earlier stages to be more fit for later ones. The model potentially stays in a local minimum that may turn out to be detrimental later in training. As a result the expressiveness of the whole model is limited. This assumption is supported by Figure 16, where H-AE provides the strongest reconstructions for small \hat{d} , but the weakest for $\hat{d} = d$. Similar behavior was observed in other curriculum learning approaches regarding recurrent neural network (RNN) training⁴⁶.

With SMS-CAE we apply a training procedure that considers the reconstruction from different numbers of latent features equally. This helps the model to find a minimum that takes all the different reconstruction scenarios into account. Our results show that SMS-CAE could not provide the same reconstruction quality as POD and H-AE for very small \hat{d} that

FIG. 16. Example test snapshot reconstructions by all tested interpretable methods on different \hat{d} . SMS-CAE was trained with d = 256 and MD-CNN-AE and H-AE were trained for a d = 64. The corresponding average test NMSS is displayed in the lower left corner of each snapshot.

FIG. 17. Example test snapshot reconstructions by POD and SMS-CAE based on different \hat{d} while in training d = 4096. The corresponding average test NMSS is displayed in the lower left corner of each snapshot.

are also much smaller than d. We argue that this is due to the data augmentation, which forces the model to encode the largest structures first³⁷. On the one hand, this is also true for the H-AE, but on the other hand, it compensates this due to its training scheme that focuses primarily on the reconstruction with very small \hat{d} .

To produce better results for very small \hat{d} with SMS-CAE, the *d* should be choosen accordingly during training. We conducted another set of comparative experiments for POD and SMS-CAE for reconstructions on very small numbers of modes. We observed that the relative improvement of our method, increases greatly as the number of modes/features decreases. We argue, that the nonlinear advantage of SMS-CAE develops mostly in the first most informative latent features.

In the feature analysis we observed that POD and SMS-CAE features behaved similarly. In both cases, the relative average frequency increased with the feature index. Thus, a feature with a smaller index holds information about slower temporal dynamics whereas features with a larger index take care of the faster dynamics. CAE and MD-CNN-AE do not

TABLE III. NMSS scores and relative improvement on the test data reconstructions with $\hat{d} \in \{1, 2, 4, 8, 16, 32\}$ modes/latent features for all datasets. The relative improvement score is calculated in relation to POD performance as baseline. The results show a clear trend of increased relative improvement for decreased \hat{d} .

show a similar trend and cannot be interpreted this way. The H-AE features for all tested datasets have shown a clear frequency peak at the second or third feature. Apart from that, we cannot deduce a trend in the feature frequencies.

Besides reconstruction quality and interpretability, our results also reveal a large margin between the different approaches' model sizes regarding trainable parameters. While SMS-CAE only weighs in at a minimum increase by about 10%, MD-CNN-AE and H-AE increase the number of parameters by 300% and 630% compared to the base CAE. For the SMS-CAE, this is due to an increased latent size during training. Our results show that a 2 to 4 times larger latent size dleads to improved reconstruction performance with the target latent size \hat{d} . Thus, during inference we can discard the additional parameters and the model size is equal to the conventional CAE. MD-CNN-AE uses multiple sub-decoders which leads to the immense increase in trainable parameters. For the H-AE this increase is even higher, because it uses multiple sub-encoders and multiple sub-decoders. This increased number of parameters alone leads not only to larger memory requirements, but also slows down training speed and inference in practice. Additionally, for the H-AE, hierarchical training procedure requires to let each pair of sub-encoder and subdecoder converge before the next pair is trained. This adds a number of epochs at each hierarchical stage to ensure the convergence. During these epochs, the model does not improve and their amount scales linearly with the number of sub-encoder-decoder pairs.

VII. CONCLUSION

In this paper, we studied interpretable CAE-based ROM approaches for high-dimensional turbulent flows. We contextualized them with the widely used POD and compared their output in terms of reconstruction quality and interpretability. To assess the reconstruction quality of POD and CAE, we used the NMSS as performance metric. It behaved similarly to the cumulative energy curve often used in the context of POD and can be applied to CAE reconstructions as well. As CAE-based ROMs, we used the MD-CNN-AE and the H-AE, both of which use an adapted architecture to improve the interpretability of the latent representations. As a new approach, we proposed the SMS-CAE. It adds a constrained dropout

layer to any existing conventional CAE. It controls the importance of each feature for reconstruction. In our experiments, we applied the different methods for three measured 2-dimensional RBC datasets. All CAE-based methods except for H-AE beat POD in terms of compression and reconstruction quality. Our results show that SMS-CAE offers interpretability similar to POD. It delivers excellent reconstruction performance, with relative improvements over POD ranging from 4.9% to 229.8% depending on dataset and number of modes. SMS-CAE is lightweight and easier to train compared to MD-CNN-AE and H-AE. SMS-CAE outperforms existing methods in terms of reconstruction quality and interpretability.

SMS-CAE not only achieves convincing results, but also motivates future research that opens the black box of deep learning based methods a little further. With SMS-CAE as a starting point this means developing and testing constrained dropout with different objective functions to shift the feature focus, and investigating how other types of models that are not autoencoders behave when forced to prioritize their latent features. For deep learning aided fluid mechanics, this means combining the technique with physics-informed approaches, with the ultimate goal of truly interpreting features in terms of absolute real-world scales.
