In the classical control of network systems, the control actions on a node are determined as a function of the states of all nodes in the network. Motivated by applications where the global state cannot be reconstructed in real time due to limitations in the collection, communication, and processing of data, here we introduce a control approach in which the control actions can be computed as a function of the states of the nodes within a limited state information neighborhood. The trade-off between the control performance and the size of this neighborhood is primarily determined by the condition number of the controllability Gramian. Our theoretical results are supported by simulations on regular and random networks and are further illustrated by an application to the control of power-grid synchronization. We demonstrate that for well-conditioned Gramians, there is no significant loss of control performance as the size of the state information neighborhood is reduced, allowing efficient control of large networks using only local information.

The study of dynamical processes on networks has been furthered by the prospect that many such processes can be controlled. An outstanding challenge is that large networks of current interest have high-dimensional state spaces and traditional control approaches are not scalable to high dimensions. A key factor limiting scalability is the information needed to compute the control actions at each controlled node of the network. In this study, we introduce a non-iterative, closedform solution for network control that only requires local information from a select set of nodes. The approach is based on the notion of *state infor*mation neighborhood and thus constitutes an openloop counterpart of a local approach recently introduced for feedback control [\[1\]](#page-5-0). A notable attribute of the approach is its ability to systematically and accurately determine both the number and the identity of the nodes in the state information neighborhoods of all nodes. The results show that large networks can be controlled using state information from small neighborhoods.

INTRODUCTION

The problem of controlling network dynamics is important in many applications, such as in mitigating cascading failures in power systems [\[2\]](#page-5-1), identifying drug targets in genetic networks [\[3,](#page-5-2) [4\]](#page-5-3), designing ecosystem management approaches [\[5,](#page-5-4) [6\]](#page-5-5), and coordinating the distributed control of robotic networks [\[7\]](#page-5-6), and has received significant attention in the recent physics literature [\[8–](#page-5-7)[10\]](#page-5-8). This attention stems from the systems-level nature of the control principles and the general notion that these principles can provide answers to fundamental questions on

complex systems that cannot be addressed by traditional research. From a theoretical standpoint, the problem is to find a control input that will drive the network from a given initial state to a desired state. In the synchronization of power-grid networks [\[11](#page-5-9)[–13\]](#page-5-10), for example, the initial state may correspond to a post-perturbation scenario in which the power generators would eventually desynchronize, thereby compromising their operation, while the desired state corresponds to a stable synchronous state.

In recent approaches for controlling networks, the control inputs are often expressed in terms of the inverse of the controllability Gramian (e.g., [\[14–](#page-5-11)[17\]](#page-5-12)). However, even when the dynamics are provably controllable, this formulation can fail numerically in large networks because the inversion of the Gramian can be computationally infeasible [\[14,](#page-5-11) [18\]](#page-5-13). Moreover, such approaches seek to determine the control inputs for a node as a function of the initial and desired states of all nodes in the network. In practice, a controlled node often can only assess the state information of nodes that are within a certain neighborhood in the network. Even when state information is not limited, computing the control actions as functions of the whole network state can be computationally prohibitive. These difficulties motivate us to consider the following questions: To what extent can the control actions for a node be determined on the basis of the state of its local neighborhood? How does the control performance depend on the size of this neighborhood, the controllability Gramian, and the properties of the network?

In this article, we show that in networks whose first few powers of the adjacency matrices are sparse—which include many regular, random, and real networks—the control actions on a node can be determined by only using the initial and desired state information in a neighborhood of the node. These neighborhoods will be referred to as state information neighborhoods (SINs). Our approach does not require explicit inversion of the controllability Gramian and is thus applicable even when the Gramian is ill-conditioned [\[14\]](#page-5-11). We show, however, that for fixed SINs the control performance improves as the condition number of the Gramian decreases. Moreover, for well-conditioned Gramians, we can choose very small SINs without incurring a significant loss of control performance. Our approach yields a closed-form solution that does not rely on iterative procedures that might suffer from convergence and implementation issues; unlike other closed-form decentralized and distributed methods [\[19,](#page-5-14) [20\]](#page-5-15), our control approach scales well (in fact linearly) with network size.

An important aspect of our approach is that it only requires communication within the local SINs. The approach leverages locality inherited from the sparsity and/or off-diagonal decay of the relevant matrices in a broad class of network systems, which is reflected in the solutions of various equations pertinent to control, including the Riccati and Lyapunov equations [\[21–](#page-5-16)[23\]](#page-5-17). Significant optimization and state estimation approaches that benefit from sparsity have been previously proposed, including approaches for nonlinear constrained optimization [\[24\]](#page-5-18), distributed implementation of Kalman filters [\[25\]](#page-5-19), and state estimation problems in distributed settings [\[26\]](#page-5-20). These approaches are iterative and generally involve network communication or consensus. We reiterate that, in contrast, our approach is non-iterative (with calculations implemented in a single step) and avoids large-scale communication, which favors scalability. The approach is thus an open-loop counterpart of a local approach recently introduced in Ref. [\[1\]](#page-5-0) for feedback control.

LOCALIZED CONTROL APPROACH

We consider networks consisting of N nodes described by the state equation $\mathbf{x}(k + 1) = A\mathbf{x}(k) +$ $B**u**(k)$, where the dynamics of the nodes is n dimensional, $\mathbf{x}(k) = \text{col}(\mathbf{x}_1(k), \mathbf{x}_2(k), \dots, \mathbf{x}_N(k)) \in \mathbb{R}^{Nn}$ is the network state at the discrete time k, $\mathbf{u}(k)$ = $col(\mathbf{u}_1(k), \mathbf{u}_2(k), \ldots, \mathbf{u}_N(k)) \in \mathbb{R}^{Nm}$ is the control input, $A \in \mathbb{R}^{N_n \times N_n}$ is the coupling matrix [\[27\]](#page-5-21), and $B \in \mathbb{R}^{Nn \times Nm}$ is a block diagonal input matrix formed by $n \times m$ blocks. The vectors $\mathbf{x}_i(k) \in \mathbb{R}^n$ and $\mathbf{u}_i(k) \in \mathbb{R}^m$ are, respectively, the state and control input of node i. If certain nodes or local state variables are not controlled, then the corresponding entries of B are zero. Starting with $k = 0$ and propagating the dynamics for f time steps, we obtain

$$
\mathbf{x}(f) = \mathcal{A}\mathbf{x}(0) + K_f \mathbf{u}^f,\tag{1}
$$

where $\mathcal{A} = A^f$, $K_f = \begin{bmatrix} A^{f-1}B & A^{f-2}B & \dots & AB & B \end{bmatrix} \in$ $\mathbb{R}^{Nn\times Nfm}$ is the f-step controllability matrix, and $\mathbf{u}^{\tilde{f}}=$ $col(\mathbf{u}(0), \mathbf{u}(1), \ldots, \mathbf{u}(f-1)) \in \mathbb{R}^{Nfm}$ is the *input se-*quence vector. Equation [\(1\)](#page-1-0) has an elegant graph interpretation as it shows that the state x_i of node i at time f is influenced by the states at time 0 of all nodes that are within distance f from node i in the network—further details are presented in Supplementary Material, Sec. S2. In the simulations below, unless otherwise noted, we use $m = n = 3$.

In our formulation, the control objective is to drive the network from the initial state $\mathbf{x}(0)$ to a desired state \mathbf{x}^{d} in f time steps by applying the input sequence $\underline{\mathbf{u}}^f$. The control problem is thus to find $\underline{\mathbf{u}}^f$ by solving Eq. [\(1\)](#page-1-0), under the condition that $\mathbf{x}(f) = \mathbf{x}^d$. In the following, we assume that A^l are sparse for all $l = 1, \ldots, 2f - 1$, which ensures that the matrices A and K_f are sparse. To guarantee the existence of the exact solution, we would also need to assume that $f \geq \nu$, where ν is the smallest integer such that K_{ν} is full rank [\[28\]](#page-5-22) (we anticipate that this condition can be relaxed within our approach below). To proceed, we permute the entries of vector $\underline{\mathbf{u}}^f$ [\[29\]](#page-5-23). First, for every node i , we define its input sequence vector $\overline{\mathbf{u}}_i^f = \text{col}(\mathbf{u}_i(0), \mathbf{u}_i(1), \dots, \mathbf{u}_i(f-1)).$ Then, we define the vector $\overline{\mathbf{u}}^f = \text{col}(\overline{\mathbf{u}}_1^f, \overline{\mathbf{u}}_2^f, \dots, \overline{\mathbf{u}}_N^f)$. The definition of $\overline{\mathbf{u}}^f$ induces a permutation matrix $P \in \mathbb{R}^{Nm \times Nm}$ such that $\overline{\mathbf{u}}^f = P \underline{\mathbf{u}}^f$. From $P^T P = I$ and Eq. [\(1\)](#page-1-0), we have

$$
\mathbf{x}(f) = \mathcal{A}\mathbf{x}(0) + \mathcal{K}_f \overline{\mathbf{u}}^f,\tag{2}
$$

where $\mathcal{K}_f = K_f P^T$. The minimum-energy input sequence that solves Eq. [\(2\)](#page-1-1) is determined as the solution of $\min_{\mathbf{u}} \left\| \overline{\mathbf{u}}^f \right\|$ 2 ² subject to $\mathbf{x}^d = A\mathbf{x}(0) + \mathcal{K}_f \overline{\mathbf{u}}^f$, where $\left\| \cdot \right\|_2$ is the 2−norm [\[30\]](#page-5-24). This solution can be expressed as

$$
\overline{\mathbf{u}}^{f} = \mathcal{K}_{f}^{T} W_{f}^{-1} \left[\mathbf{x}^{d} - \mathcal{A} \mathbf{x}(0) \right], \tag{3}
$$

where $W_f = \mathcal{K}_f \mathcal{K}_f^T = \sum_{j=0}^{f-1} A^j BB^T (A^T)^j \in \mathbb{R}^{Nn \times Nn}$ is the *controllability Gramian*; the condition $f \geq \nu$ guarantees the existence of W_f^{-1} . We note that, in addition to the minimal-energy formulation, the theory we present also applies to other optimal feedforward control formulations (Supplementary Material, Sec. S8).

We now examine Eq. [\(3\)](#page-1-2) more closely. The assumption that A^l is sparse for all $l = 1, \ldots, 2f - 1$ guarantees that W_f is also sparse. For example, for a square lattice network with $N = 35^2$, $f = 5$, and identity B, matrix W_f is (multi-) banded and its fill-in (percentage of nonzero entries) is 9.99%. However, W_f^{-1} is a dense matrix (inversion "destroys" the sparse matrix structure). Because W_f^{-1} is dense, from the block row of Eq. [\(3\)](#page-1-2) corresponding to $\overline{\mathbf{u}}_i^f$ we conclude that the control input sequence of node i is a function of the initial and desired states of potentially all nodes in the network. In other words, Eq. [\(3\)](#page-1-2) constitutes a centralized controller for the network.

FIG. 1. Ordered magnitudes of the entries of W_f^{-1} for (a) an ERN $(N = 598)$, (b) an RGN $(N = 702)$, and (c) a lattice $(N = 35^2)$, for $B = B_1$ (black), B_2 (blue), and B_3 (red). Inset in (c): corresponding envelope of the off-diagonal decay for the middle row as a function of the column. (d) SIN and effective SINs for the matrix Q around a central node for the $B = B_1$ case in (c) and thresholds $\delta_1 = 0, \delta_2 = 10^{-6}$, and $\delta_3 =$ 10^{-3} . Other parameters: $f = 5$ in (a-d) and $q = 3$ in (d) [\[35\]](#page-5-25). Details on network generation, sparsity of W_f , localization of W_f^{-1} , and (effective) SINs are presented in Supplementary Material, Secs. S3 and S4.

At first, it might appear that our attempt to find an input sequence for node i as a function of the states of only neighboring nodes is doomed to fail. However, even though W_f^{-1} is fully populated, this matrix exhibits the important property of being localized. This property is central to the solution we present. Localized matrices are characterized by having a relatively small number of entries that are (in absolute value) dominantly large compared to the others [\[29,](#page-5-23) [31\]](#page-5-26); prominent examples include (but are not limited to) off-diagonally decaying matrices [\[32–](#page-5-27)[34\]](#page-5-28). To investigate how the degree of localization may depend on the condition number κ of W_f , we first note that κ depends on the choice of B. To examine these dependencies, we consider three block diagonal matrices $B: B_1 = \text{diag}[B_{ii}^{(1)}], B_2 = \text{diag}[B_{ii}^{(2)}],$ and $B_3 = \text{diag}\big[B_{ii}^{(3)}\big],$ where $B_{ii}^{(1)} = \text{diag}\,(1,1,1),\,B_{ii}^{(2)} =$ diag $(1,1,0)$, and $B_{ii}^{(3)} = \text{diag}(1,0,0)$ for $i = 1,2,\ldots,N$.

Figure [1\(](#page-2-0)a-c) shows the absolute values of the entries of the inverse Gramians $W_f^{-1} = [z_{ij}]$ organized in decreasing order for an Erd˝os-R´enyi network (ERN), a random geometric network (RGN), and a square lattice network, respectively. The different curves correspond to $B = B_1$, B_2 , and B_3 . In each case, a small number of $|z_{ii}|$ values are significantly larger than the others, and the remaining values decrease faster than exponentially. This localization is more dominant for better-conditioned Gramians, especially for the RGN and lattice network. (The structures in the B_3 curves result from unevenness internal to the $n \times n$ blocks of W_f^{-1} .) These results are in accordance

with theoretical results on localization phenomena in the inverses of sparse symmetric matrices [\[31\]](#page-5-26) and demonstrate that many networks have localized W_f^{-1} .

To further analyze this property, we first consider the case of lattice networks, which have banded matrices A and W_f for suitable node orderings. Because W_f is posi-tive definite, from Ref. [\[32\]](#page-5-27) it follows that W_f^{-1} is an offdiagonally decaying matrix. Specifically, the off-diagonal decay rate of W_f^{-1} is given by $|z_{ij}| \le c\lambda^{|i-j|}$, where

$$
c = \left\| W_f^{-1} \right\|_2 \max \left\{ 1, \frac{\left(\sqrt{\kappa} + 1 \right)^2}{2\kappa} \right\}, \ \lambda = \left[\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right]^{2/\beta}, \tag{4}
$$

and β is the bandwidth of W_f [\[32\]](#page-5-27). From Eq. [\(4\)](#page-2-1) it follows that the off-diagonal decay rate of W_f^{-1} is faster if the condition number κ is smaller, indicating that the inverses of well-conditioned Gramians have fast offdiagonal decay. The inset of Fig [1\(](#page-2-0)c) shows a confirmation of this prediction for a lattice network. Relations between localization and condition number can also be established for other localized W_f^{-1} , as we show explicitly in Supplementary Material, Sec. S5, for general network structures.

The above inspires us to use the fundamental result that a localized matrix can be approximated by a sparse matrix [\[18,](#page-5-13) [31,](#page-5-26) [33,](#page-5-29) [36,](#page-6-0) [37\]](#page-6-1). We thus propose a sparse approximation X of the dense matrix W_f^{-1} . This approximation can be found by solving the constrained leastsquares problem

$$
\min_{X} \|I - W_f X\|_F^2, \text{ subject to } X \in \mathcal{X},\tag{5}
$$

where X is the set of matrices with a given sparsity pattern (i.e., the pattern of nonzero entries) and $\lVert \cdot \rVert_F$ denotes the Frobenius norm [\[36,](#page-6-0) [37\]](#page-6-1). In Eq. [\(5\)](#page-2-2) we have to choose the *a priori* sparsity pattern of X , which determines the set \mathcal{X} . For a sparse matrix, a good choice for the sparsity pattern of the inverse is given by a sum of powers of the matrix itself [\[38\]](#page-6-2). This, together with the fact that W_f can be expressed in terms of the form $A^{j}BB^{T}(A^{T})^{j}$, motivates us to choose the a priori sparsity pattern of X as the sparsity pattern of $\overline{X}_q = I + \sum_{l=0}^q A^l BB^T (A^T)^l$, where the integer $q \ge 0$ is a user choice (further theoretical justification is offered in Supplementary Material, Sec. S4). Assuming that \overline{X}_q is a sparse matrix, the computational and memory complexities of solving Eq. [\(5\)](#page-2-2) scale linearly with the dimension Nn (in contrast with the quadratic complexities of sparse matrix inversion that would be required to determine W_f^{-1} [\[39\]](#page-6-3)). Given that the optimization problem in Eq. (5) is also highly parallelizable [\[36,](#page-6-0) [37\]](#page-6-1), this enables us to compute X for very large networks.

Equipped with a sparse approximation X of W_f^{-1} , we can now define a localized controller with associated SINs determined by the sparsity pattern of X . Specifically,

FIG. 2. Control error for (a, b) ERNs and (c, d) RGNs as a function of (a, c) q and (b, d) N, where $B = B_1$ (\bullet), B_2 (\bullet), and B_3 (*). The fixed parameters are $f = 3$ in (a-d), $N = 598$ in (a), $N = 702$ in (c), and $q = 2$ in (b, d) [\[35\]](#page-5-25). Each data point is an average over 100 realizations of matrix A in (a, c) and of network topologies in (b, d). For the sparsity patterns of the associated matrices $\mathcal Q$ and $\mathcal R$, see Supplementary Material, Sec. S4.3.

substituting W_f^{-1} with X in Eq. [\(3\)](#page-1-2), we obtain the approximate input sequence $\hat{\mathbf{u}}^f = Q\mathbf{x}^d - R\mathbf{x}(0)$, where $\mathcal{Q} = \mathcal{K}_f^T X$ and $\mathcal{R} = \mathcal{K}_f^T X \mathcal{A}$. The input sequence of node i can then be expressed as

$$
\widehat{\overline{\mathbf{u}}}^f_i = \sum_{j \in \mathcal{N}_1(i)} \mathcal{Q}_{ij} \mathbf{x}^d_j - \sum_{j \in \mathcal{N}_2(i)} \mathcal{R}_{ij} \mathbf{x}_j(0),\tag{6}
$$

where $\mathcal{Q} = [\mathcal{Q}_{ij}], \mathcal{R} = [\mathcal{R}_{ij}],$ and $\mathcal{N}_1(i)$ and $\mathcal{N}_2(i)$ are sets of indices defining the corresponding SINs of node i. We can show that the SINs of node i are determined by the set of nodes that are up to a certain distance from i. For $B = B_1$, in particular, we obtain that for any undirected network, $\hat{\mathbf{u}}_i^f$ i_i is a function of \mathbf{x}_j^d for nodes j within distance $2q + f - 1$ from i and is a function of $\mathbf{x}_i(0)$ for nodes j within distance $2(q + f) - 1$ from i in the network (Supplementary Material, Sec. S4.1). From the relation between powers of the adjacency matrix and walks in the network, these neighborhoods are guaranteed to be generally small relative to N provided that $A_{q,f}^{\pm} = A^{2q + (3\pm 1)f/2-1}$ are sparse; moreover, as explained next, Eq. [\(6\)](#page-3-0) can define a localized controller even when this condition is violated. We first note, however, that a solution X in Eq. [\(5\)](#page-2-2) can be found, and thus a suitable localized controller may still be defined, even when W_f is not invertible (i.e., when $f < \nu$, where smaller f leads to sparser $A_{q,f}^{\pm}$).

An example of a SIN associated with Q in a lattice network is shown in Fig. [1\(](#page-2-0)d), where $||\mathcal{Q}_{ii}||_F$ decreases rapidly away from i . This rapid decay, which is common across the networks we consider, can be used to define further reduced *effective* SINs by ignoring all nodes j in the SIN of node *i* for which $||\mathcal{Q}_{ij}||_F$ are smaller than a certain threshold δ , as shown in Fig. [1\(](#page-2-0)d) for $\delta = 10^{-6}$

FIG. 3. Control error versus the fraction of controlled nodes in (a) an ERN $(N = 598)$ and (b) an RGN $(N = 702)$, for $q = 1$ (\blacksquare), $q = 2$ (\bullet), and $q = 3$ (\blacktriangle). Each point is an average over 100 realizations of randomly chosen nodes to control. Insets: corresponding condition numbers of W_f color-coded as in the main panels. The other settings are $f = 5$ and $B_{ii} = B_{ii}^{(1)}$ if node i is controlled (and zero otherwise) [\[35\]](#page-5-25).

and 10−³ . The use of effective SINs, which are defined analogously for R , can significantly reduce the computational and communication costs. For ERNs, for instance, matrices $A_{q,f}^{\pm}$ are generally not sparse, which leads to larger SINs. However, the effective SINs are still relatively small and lead only to a modest reduction in accuracy (Supplementary Material, Sec. S4, where the sizes of the SINs and effective SINs are quantified by the fill-ins of the matrices $\mathcal Q$ and $\mathcal R$). This shows that our approach can be applied even when $A_{q,f}^{\pm}$ are not sparse.

The approximation involved in replacing W_f^{-1} by X could in principle reduce the performance of the localized controller [\(6\)](#page-3-0) compared to the centralized controller [\(3\)](#page-1-2). This approximation depends on the size of the SINs in Eq. [\(6\)](#page-3-0), which are in turn modulated by our choice of q. From our results above for localized W_f^{-1} , it follows that, for well-conditioned W_f , the SINs of the localized controller can be very small without significant loss of performance. When W_f is not wellconditioned, on the other hand, there should be a tradeoff between the performance of the localized controller and the size of the SINs. To quantify this trade-off, we measure the performance of the localized controller using as a metric the relative distance from the desired state $\varepsilon_{q,f} = \left\|\mathbf{x}^d - \widehat{\mathbf{x}}(f)\right\|_2 / \left\|\mathbf{x}^d - \mathbf{x}(0)\right\|_2$, where $\widehat{\mathbf{x}}(f)$ is the right side of Eq. [\(2\)](#page-1-1) for $\overline{\mathbf{u}}^f$ replaced by $\hat{\overline{\mathbf{u}}}^f$. Note that $\varepsilon_{q,f}$ measures the control error over all nodes in the network.

ILLUSTRATIONS OF THE APPROACH

Figure [2](#page-3-1) shows $\varepsilon_{q,f}$ for both ERNs and RGNs, where X is computed using the SPAI algorithm [\[36\]](#page-6-0) to solve Eq. [\(5\)](#page-2-2). Similar results are obtained for lattices (Supplementary Material, Sec. S6). As shown in Fig. [2\(](#page-3-1)a, c), the control performance is excellent already for small q (hence small SINs) and further improves as q is increased. For fixed SINs, the performance also improves

FIG. 4. Control of Iceland's power grid when driving the generators to the desired synchronous state. (a) Control error for several f as a function of q . Each point is an average over 100 realizations of $\mathbf{x}(0)$ generated by randomly perturbing each state variable by ± 0.01 away from x^d , and B is the identity matrix. (b) SIN of the node marked by the arrow for the matrix Q and $f = q = 2$. Details of the dynamics are presented in Supplementary Material, Sec. S9.

as κ is decreased $(\langle \kappa \rangle)$ indicates the average κ for the realizations shown). Moreover, as a function of N , the error $\varepsilon_{q,f}$ does not vary significantly for large network sizes [Fig. [2\(](#page-3-1)b, d)]. The latter confirms the potential of the approach for efficient control of large networks. This potential becomes even more evident when communication constraints are accounted for, since small SINs imply that the communication complexity and delays for each node become independent of the network size, which further enhances the overall performance of the localized approach (Supplementary Material, Sec. S7).

The localized control approach is also effective when only a fraction r of the nodes is controlled, as shown in Fig. [3](#page-3-2) for ERN and RGN systems. The error $\varepsilon_{q,f}$ is small for relatively small r and becomes significantly smaller as r increases. The increase in r is accompanied by a significant decrease of κ , and thus by a higher localization in W_f^{-1} . Therefore, the relationship between the condition number and localization also governs the trade-off between control performance and the fraction of controlled nodes.

To demonstrate the applicability of the approach to real networks of significant interest, we consider the problem of controlling the synchronization of power generators in a power grid. We explicitly consider the Iceland's power grid [\[40\]](#page-6-4), which comprises 35 generators and 189 buses (nongenerator nodes). We focus on scenarios for which the synchronization of all generators at the required frequency—a condition for the system to operate—corresponds to an unstable state and we seek to control the system with this state serving as x^d . This system is described by a nonlinear set of dynamical equations, with two state variables (phase and frequency) for each generator and one state variable (phase) for each bus. Using our approach, we compute the control law for the dynamics linearized around x^d . Figure [4\(](#page-4-0)a) shows that we are indeed able to reach the desired target state efficiently; the scaling of $\varepsilon_{q,f}$ versus q shows similar be-havior to that of model networks (cf. Fig. [2\)](#page-3-1). Figure [4\(](#page-4-0)b)

shows for a typical node that the resulting SINs remain generally small. Moreover, provided that the initial state is not too far from x^d , the control actions defined by the linearized dynamics successfully drive the system to the desired state when applied directly to the full nonlinear dynamics, which illustrates the usefulness of the approach in the study of nonlinear systems (details are offered in Supplementary Material, Secs. S9 and S10).

CONCLUDING REMARKS

In the localized control approach developed here, the control actions for a node are determined solely using state information in a neighborhood around the node. The resulting control is generally only approximate but the reduction in computational and communication complexity can vastly overcompensate the loss of accuracy by allowing more frequent control inputs. This provides a foundation for the use of our approach not only in networks for which the global state information is not readily available but also in networks for which the control actions would be too costly to compute using all the available state information. It follows that even very large networks can be controlled with efficiency and efficacy in a localized manner.

Our approach for linearized systems also serves as a foundation for developing a localized control methodology for nonlinear systems. For nonlinear systems, the equivalent formulation is feedforward model predictive control, where the control problem becomes a nonlinear optimization problem. While such optimization problems generally lack closed-form solutions, they can be solved numerically, often using variations of Newton's method. Arguments similar to those presented above can then be used to show once again that sparsity and localized inverses of control matrices imply localized control laws. Exploring this for nonlinear network systems is an important problem for future research.

We conclude by noting that there is now a significant demand for the local and computationally efficient implementation of control, state estimation, optimization, and machine-learning algorithms that can avoid or minimize long-distance data communication across networks. Thus, in addition to its immediate significance for openloop control, our approach may serve as a fundamental building block for more complex algorithms.

SUPPLEMENTARY MATERIAL

The online Supplementary Material presents further details, examples, analyses, and figures in support of the core results presented in this article. Additionally, the following GitHub repository includes images of the state information neighborhoods for all nodes in Iceland's power grid considered in Fig. [4](#page-4-0) and the random geometric network in Fig. S13: [https://github.com/](https://github.com/fmolnar-notredame/network_control_paper/) [fmolnar-notredame/network_control_paper/](https://github.com/fmolnar-notredame/network_control_paper/).

A.E.M. thanks Prof. David K. Campbell—on the occasion of this Focus Issue to celebrate his career—for his many direct and indirect contributions as a pioneer and model scientist in nonlinear science and for his role in the creation of the journal Chaos and the Center for Nonlinear Studies. This work was supported by Simons Foundation Award No. 342906, ARPA-E Award No. DE-AR0000702, ARO Grant No. W911NF-19-1-0383, MURI ARO Grant No. W911NF-14-1-0359, and MURI ARO Grant No. W911NF-24-1-0228. The views and opinions of authors expressed herein do not necessarily state or reflect those of the United States Government or any agency thereof.

AUTHOR DECLARATIONS

Author Contributions

Aleksandar Haber: Conceptualization (equal); Formal analysis (lead); Investigation (lead); Software (equal); Visualization (equal); Writing – original draft (lead); Writing – review $\&$ editing (equal). Ferenc Molnar: Investigation (supporting); Formal analysis (supporting); Investigation (supporting); Software (equal); Visualization (equal); Writing – original draft (supporting); Writing – review $\&$ editing (equal). **Adil**son E. Motter: Conceptualization (equal); Funding acquisition (lead); Project administration (lead); Supervision (lead); Visualization (supporting); Writing – original draft (supporting); Writing – review $\&$ editing (equal).

Conflict of Interest

The authors have no conflicts to disclose.

Data Availability

The data that support the findings of this study are available within the article, supplementary material, and associated GitHub repository.
