Abstract

Large-scale multi-layer networks with large numbers of nodes, edges, and layers arise across various domains, which poses a great computational challenge for the downstream analysis. In this paper, we develop an efficient randomized spectral clustering algorithm for community detection of multi-layer networks. We first utilize the random sampling strategy to sparsify the adjacency matrix of each layer. Then we use the random projection strategy to accelerate the eigen-decomposition of the sum-of-squared sparsified adjacency matrices of all layers. The communities are finally obtained via the k-means of the eigenvectors. The algorithm not only has low time complexity but also saves the storage space. Theoretically, we study the misclassification error rate of the proposed algorithm under the multi-layer stochastic block models, which shows that the randomization does not deteriorate the error bound under certain conditions. Numerical studies on multi-layer networks with millions of nodes show the superior efficiency of the proposed algorithm, which achieves clustering results rapidly. A new R package called MLRclust is developed and made available to the public.

Keywords: Community detection, Stochastic block models, Randomization, Computational efficiency.

1 Introduction

Multi-layer networks have gained considerable attention in modern data analysis due to their ability to incorporate multiple relationships among the same set of entities, where the nodes are the entities of interest and each layer represents a different type of relationship. The multi-layer networks provide more information and insights than the single-layer network does (Kivelä et al., 2014; Boccaletti et al., 2014; Bianconi, 2018), and they have been widely studied and analyzed in various scientific fields including gene co-expression (Liu et al., 2018), social science (Omodei et al., 2015), and neuroimaging (Paul and Chen, 2020a), among others. Due to the advancements in computing and measurement technologies, the size of the multi-layer networks—nodes, edges and layers—are all increasing, making the analysis of multi-layer networks more challenging.

Community detection is a fundamental task in multi-layer network analysis and has seen rapid developments in recent years (Han et al., 2015; Matias and Miele, 2017; Pensky, 2019; Paul and Chen, 2020b; Lei et al., 2020; Wang et al., 2021; Arroyo et al., 2021; Jing et al., 2021; Lei and Lin, 2023), especially within the framework of multi-layer Stochastic Block Models (SBMs) (Han et al., 2015). Unless otherwise specified, the communities are assumed to be consensus across layers. Specifically, the spectral clustering-based methods become popular due to the computational tractability. Paul and Chen (2020b) considered several spectral clustering-based methods including the spectral clustering of average adjacency matrices corresponding to all layers and the co-regularized spectral clustering. Arroyo et al. (2021) developed a joint spectral embedding method of adjacency matrices, where the eigenspace of each network layer is properly aggregated to obtain the common eigenspace. Jing et al. (2021) developed a tensor-based spectral clustering method to detect the communities where there exist several classes of communities among layers. Lei and Lin (2023) proposed a spectral clustering method based on the bias-adjusted sum of squared adjacency matrices. Other spectral clustering-based methods include Bhattacharyya and Chatterjee (2018); Pensky and Zhang (2019); Noroozi and Pensky (2024); Su et al. (2024), among others. Despite the tractability of the aforementioned methods, they are computationally expensive when the network size increases. Take the simple spectral clustering method of the average adjacency matrices as an example. The partial eigen-decomposition is burdensome when the number of nodes or the number of non-zero entries in the average adjacency matrices is large, where the latter would happen even if every single network is sparse. In this regard, the computational issues in multi-layer networks are more severe than those in single networks.

Randomization has been a useful probabilistic technique for solving large-scale linear algebra problems with high precision, beyond the computational capabilities of classical methods (Mahoney and Drineas, 2009; Woodruff, 2014; Martinsson and Tropp, 2020). Generally, it utilizes a certain degree of randomness, such as random projection and random sampling, to construct a *sketch* of the full dataset, which retains the main information of the original dataset but has a much lower dimensionality or increased sparsity. Hence, by using the sketched dataset, the computational cost is largely reduced. Randomization techniques have been thoroughly studied in linear regression and low rank matrix approximation problems; see Drineas et al. (2012); Raskutti and Mahoney (2016); Ahfock et al. (2021); Halko et al. (2011), among others. In the context of community detection, several works study randomized algorithms in the *single* network set-up; see Zhang et al. (2022); Guo et al. (2023); Deng et al. (2024), for example. However, as mentioned earlier, the computational issues in multi-layer networks are much more severe. For the community detection of multi-layer networks, an efficient algorithm using randomization techniques is imminent and essential.

In this paper, we study the efficient community detection of large-scale multi-layer networks via randomization. We use the method in Lei and Lin (2023), i.e., spectral clustering of the debiased sum of squared adjacency matrices, as the basis of our algorithm. The reason for choosing this method lies in the following aspects. First, in the real multi-layer networks, some layers are assortative mixing (nodes in the same community are more likely to link than nodes from distinct communities) and others are disassortative mixing (the opposite of assortative mixing), the squaring operator in the method of Lei and Lin (2023) is well accommodated to this unknown *layer identity* problem. By contrast, aggregating the adjacency matrix without squaring can result in community cancellation. Second, the

method is theoretically sound. It nearly attains optimal network density threshold when restricted to polynomial-time algorithms in terms of community recovery and detection (Lei et al., 2023).

The main contributions of this paper are three-folds. First, we propose an efficient randomized spectral algorithm for detecting the communities of multi-layer networks. In particular, we first use the random sampling strategy to sparsify the adjacency matrices of all layers. Then, we use the random projection strategy to accelerate the eigen-decomposition of the sum of squared sparsified adjacency matrices. Notably, we utilize the randomized block Krylov subspace (Musco and Musco, 2015) in the approximation of eigenspace, which can attain better accuracy under the same number of power iterations than the subspace method (Halko et al., 2011) used in Guo et al. (2023); Zhang et al. (2022). The proposed randomized algorithm greatly reduces both the time complexity and space complexity compared to non-randomized methods. Second, we study the clustering performance of the resulting algorithms under the multi-layer SBM. It turns out that under certain conditions, the misclassification rate is the same as that of the corresponding algorithm without randomization. The algorithm and theory are both extended to the co-clustering (Rohe et al., 2016) of multi-layer directed networks. Last but not least, to facilitate the implementation of the algorithm, we develop an R package called MLRClust¹. It turns out that the proposed algorithm is capable of processing large-scale multi-layer networks with millions of nodes in less than one minute. By contrast, the non-randomized counterpart algorithm, where the partial eigen-decomposition of the sum of squared original adjacency matrix is implemented by the fast iterative method (Baglama and Reichel, 2005), fails when the number of nodes exceeds approximately twenty thousand in our experiment.

The remainder of the paper is organized as follows. Section 2 provides the preliminaries. Sections 3 and 4 develop the randomized spectral clustering algorithm and provide its theoretical property, respectively. Sections 5 and 6 include the simulation and real data experiments, respectively. Section 7 concludes the paper. In the Appendix, we provide the technical proofs. The extension of the method and theory to multi-layer stochastic co-block models for co-clustering is also included.

2 Preliminaries

In this section, we introduce the widely used multi-layer SBMs and the spectral clustering algorithm for the purpose of developing the randomized algorithm. The following notation is used throughout the paper.

Notation: We use [n] to denote the set $\{1,...,n\}$. For a matrix $A \in \mathbb{R}^{n \times n}$, $||A||_0$ and $||A||_F$ denote the number of its non-zero elements and its Frobenius norm, respectively. $||\cdot||_2$ denotes the spectral norm of a matrix or the Euclidean norm of a vector. $||A||_{2,\infty}$ denotes the maximum row-wise l_2 norm. For two sequences f_n and g_n , $f_n = o(g_n)$ denotes that $f_n/g_n \to 0$ as n goes to infinity. We write $f_n \lesssim g_n$ or $f_n = O(g_n)$ if there exists some constant c > 0 such that $f_n \leq cg_n$, and write $f_n \approx g_n$ if both $g_n \lesssim f_n$ and $f_n \lesssim g_n$ hold.

We consider the following multi-layer SBM (Han et al., 2015; Paul and Chen, 2016; Barbillon et al., 2017) for generating the multi-layer network data. Suppose the multi-layer network has L layers and n nodes. For $l \in [L]$, $A_l \in \{0,1\}^{n \times n}$ corresponds to the network adjacency matrix of layer l, which is a symmetric matrix. We assume that each layer of network shares common community structure but has possibly different link probabilities. Specifically, for each l, A_l is generated independently as follows,

$$A_{l,ij} \sim_{i.i.d.} \text{Bernoulli}(B_{l,g_ig_j}) \text{ if } i < j \text{ and } A_{l,ij} = 0 \text{ if } i = j,$$
 (1)

where $g_i \in \{1, ..., K\}$ denotes the community assignments of node i for $i \in [n]$, and $B_l \in [0, 1]^{K \times K}$ denotes the block probability matrix of layer l. Here, K is the number of communities, for which we assume to be fixed throughout the paper. The population of A_l can be formulated as $P_l := \Theta B_l \Theta$, where $\Theta \in \{0, 1\}^{n \times K}$ is the membership matrix whose ith row corresponds to node i and has exactly one 1 on the g_i 's column and K-1 0's elsewhere.

To estimate the communities in the multi-layer SBM, the spectral clustering method performed on the following aggregated matrix M has become popular and studied by Lei

and Lin (2023); Lei et al. (2023); Su et al. (2024); Xie (2024) among others,

$$M := \frac{1}{Ln} \sum_{l=1}^{L} (A_l^2 - D_l), \tag{2}$$

where D_l is a diagonal matrix consisting of the degree of A_l with $D_{l,ii} = \sum_{j=1}^n A_{l,ij}$. Instead of summing the matrices A_l directly, squaring each A_l before the summation could adapt to the heterogeneity that some layers of networks may be densely connected within communities while other layers may be densely connected across communities. Subtracting D_l is to reduce the statistical bias caused by squaring. The spectral clustering on M consists of two steps, the eigen-decomposition is first performed on M to obtain the top K eigenvectors of M, and then the k-means clustering is conducted on them to estimate the communities. It turns out that M can well-approximate its population counterpart

$$\Pi := \frac{1}{L} \sum_{l=1}^{L} \frac{P_l^2}{n} := \frac{1}{L} \sum_{l=1}^{L} \Pi_l.$$
 (3)

Though the spectral clustering algorithm is conceptually easy, it is actually computationally inefficient from the following aspects. First, squaring all A_l generally requires $O(Ln \max_l ||A_l||_0)$ time, which is costly when some of L, n and $||A||_0$ are large. Second, after the summation of A_l^2 in (2), M would be a dense matrix. The full eigen-decomposition of M would thus generally takes $O(n^3)$ time. The iterative algorithm for partial eigen-decomposition takes $O(n^2T)$ time, which is also time costly when n is large, where T denotes the number of iterations. We will see in the next section how the randomized sketching techniques could be used to speed up the spectral clustering algorithm.

3 Randomized spectral clustering for multi-layer SBMs

In this section, we introduce random sampling and random projection strategies, and provide the randomized spectral clustering algorithm designed for multi-layer SBMs.

3.1 Randomization

Random sampling. To reduce the computational burden of squaring A_l , we employ the following random sampling strategy to construct sparsified matrices \tilde{A}_l . Specifically, for each pair $1 \leq i < j \leq n$,

$$\tilde{A}_{l,ij} = \begin{cases}
\frac{A_{l,ij}}{p}, & \text{if } (i,j) \text{ is selected,} \\
0, & \text{if } (i,j) \text{ is not selected,}
\end{cases}$$
(4)

and $\tilde{A}_{l,ij} = \tilde{A}_{l,ji}$ for each i > j. Here, $A_{l,ij}$ is divided by p in order to satisfy that $\mathbb{E}(\tilde{A}_l) = \mathbb{E}(A_l)$. Hopefully, when the sampling probability p is not too small, the characteristics of \tilde{A}_l would be close to those of A_l without sacrificing too much accuracy.

Time complexity. The time complexity of $\sum_{l=1}^{L} \tilde{A}_{l}^{2}$ would generally be reduced to $O(Ln \max_{l} \|\tilde{A}_{l}\|_{0})$, which can be even smaller in practice, depending on the structure of \tilde{A}_{l} 's. The time complexity for random sampling is only $O(L \max_{l} \|A_{l}\|_{0})$.

Random projection. One can imagine that $\sum_{l=1}^{L} A_l^2$ is biased from its population counterpart $\sum_{l=1}^{L} P_l^2$. But before carefully calculating the bias, for the moment, we assume that we have obtained a bias-corrected counterpart of $\frac{1}{Ln} \sum_{l=1}^{L} \tilde{A}_l^2$, denoted by \overline{M} . We now focus on illustrating how we can use the random projection strategy to accelerate the eigen-decomposition of \overline{M} . The general idea is to use the following randomized block Krylov methods (Musco and Musco, 2015; Li and Zhu, 2021) developed by the computer science community. First, an orthogonal basis $Q \in \mathbb{R}^{n \times (q+1)K}$ is obtained via the QR decomposition of a compressed matrix

$$G := [\overline{M}^1 \Omega, \overline{M}^3 \Omega, \dots, \overline{M}^{2q+1} \Omega],$$

where Ω is an $n \times K$ random test matrix whose entries could be i.i.d. standard Gaussian and Rademacher, among others. Then the eigenvectors of \overline{M} could be approximated by QU_K , where U_K consists of the top K eigenvector of the small matrix $Q^T\overline{M}Q$. In essence,

the random projection here aims to identify an orthogonal basis Q that facilitates the construction of a low-rank approximation of \overline{M} such that

$$\overline{M} \approx QQ^T \overline{M} Q Q^T.$$

Time complexity. The time complexity of the whole procedure is dominated by the matrix multiplications for forming G, which is $O((2q+1)n^2K)$. And thus the computational burden of the eigen-decomposition of \overline{M} is largely reduced.

Discussions. The practical time complexity of the random projection procedure is much lower, as we do not need to compute the dense matrix \overline{M} when forming G. Instead, the matrix multiplications for forming G are accomplished by left-multiplying the random test matrix Ω by the sparsified adjacency matrices, which have a time complexity of $O(LqK \max_l \|\tilde{A}_l\|_0)$. Notably, \tilde{A}_l is relatively sparse, and the number of layers L is typically much less than n in large-scale multi-layer networks, thus this complexity is less than in cases where \overline{M} is computed directly, which takes $O((2q+1)n^2K)$ time.

More importantly, this methodology not only avoids the extensive computational requirements associated with computing \overline{M} but also mitigates the challenges of space complexity. This is crucial because the space complexity of a dense matrix is $O(n^2)$, potentially leading to memory overflows in scenarios where n is relatively large, say networks with millions of nodes.

It is worth mentioning that the random projection can be made more efficient with parallel and distributed computing and it has low communication costs due to requiring only a few passes over the input matrix.

Remark 1 There have been several prior works on spectral clustering using randomized methods, see Yan et al. (2009); Sakai and Imiya (2009); Sinha (2018); Tremblay et al. (2016); Wang et al. (2019); Tremblay and Loukas (2020), among others. These works focus on general dataset and convergence theory. Different from these works, we develop a randomization method for clustering multi-layer network data. The statistical theory explains how randomization influences the misclassification error rate. On the other hand,

the randomization has also been studied under single statistical network models (Li et al., 2020; Zhang et al., 2022; Deng et al., 2024). In this work, we turn to focus on the multi-layer networks, which are more computationally challenging than single networks. We tailor the randomization techniques for the spectral clustering on the sum of squared matrix and study the misclassification rate of the proposed algorithm under the multi-layer SBM and its directed variant.

3.2 Bias-adjustment

As mentioned earlier, $\sum_{l=1}^{L} \tilde{A}_{l}^{2}$ would introduce bias compared to its population counterpart $\sum_{l=1}^{L} P_{l}^{2}$. We now proceed to debias.

It is easy to see that, ignoring the diagonal elements, \tilde{A}_l is an unbiased estimator for P_l . Our main effort is to show how the diagonal elements of \tilde{A}_l^2 would cause bias for P_l^2 . Denote the non-diagonal part of P_l by $\bar{P}_l := P_l - \text{diag}(P_l)$ and let $X_l := \tilde{A}_l - \bar{P}_l$. Then,

$$\tilde{A}_{l}^{2} = (X_{l} + \bar{P}_{l})^{2} = X_{l}^{2} + \bar{P}_{l}^{2} + X_{l}\bar{P}_{l} + \bar{P}_{l}X_{l}.$$

By plugging in $\bar{P}_l^2 = (P_l - \text{diag}(P_l))^2$, we further have

$$\tilde{A}_{l}^{2} - P_{l}^{2} = E_{l,0} + E_{l,1} + E_{l,2} + E_{l,3} \tag{5}$$

with

$$E_{l,0} := -P_l \operatorname{diag}(P_l) - \operatorname{diag}(P_l) \cdot P_l + (\operatorname{diag}(P_l))^2,$$

$$E_{l,1} := X_l (P_l - \operatorname{diag}(P_l)) + (P_l - \operatorname{diag}(P_l)) X_l,$$

$$E_{l,2} := X_l^2 - \operatorname{diag}(X_l^2),$$

$$E_{l,3} := \operatorname{diag}(X_l^2).$$

The first three terms $E_{l,0}$, $E_{l,1}$, and $E_{l,2}$ turn out to be small. We thus focus on the fourth

term $E_{l,3}$. Note that

$$(E_{l,3})_{ii} = \sum_{j=1}^{n} X_{l,ij}^{2} = \sum_{j=1,j\neq i}^{n} (\tilde{A}_{l,ij} - P_{l,ij})^{2}$$

$$= \sum_{j=1}^{n} \mathbb{I}(\tilde{A}_{l,ij} = 0) P_{l,ij}^{2} + \sum_{j=1}^{n} \mathbb{I}(\tilde{A}_{l,ij} = 1/p) (1/p - P_{l,ij})^{2}$$

$$\leq n \cdot \max_{l,ij} P_{l,ij}^{2} + \tilde{d}_{l,i} \cdot \frac{1}{p^{2}},$$
(6)

where $\tilde{d}_{l,i} := \sum_{j=1}^n \mathbb{I}(\tilde{A}_{l,ij} = 1/p)$ denotes the number of edges of node i in the l-th network. Simple calculation shows that the expectation of the second term in (6) is $\mathbb{E}(\tilde{d}_{l,i})/p^2 = \sum_{j=1}^n P_{l,ij}/p \le n \max_{l,ij} P_{l,ij}/p$. Hence, $\tilde{d}_{l,i}/p^2$ dominates $n \cdot \max_{l,ij} P_{l,ij}^2$ since 1/p > 1.

In light of the above calculation, we derive the following debiased estimator \overline{M} ,

$$\overline{M} := \frac{1}{L} \sum_{l=1}^{L} \overline{M}_{l}$$

with

$$\overline{M}_l := \frac{\tilde{A}_l^2}{n} - \frac{\tilde{D}_l}{np^2},\tag{7}$$

where \tilde{D}_l is a diagonal matrix with $\tilde{D}_{l,ii} = \tilde{d}_{l,i}$. \overline{M} can then be used as the input of the random projection strategy for fast eigen-decomposition.

Remark 2 Note that the bias-adjustment for the sum of squared original adjacency matrices is first developed in Lei and Lin (2023) and further refined by Xie (2024). Equation (7) is in a similar spirit of Lei and Lin (2023) except that we deal with the matrix after random sampling.

3.3 Algorithm

Based on the above discussions, we propose the randomized spectral clustering algorithm (RSC) for multi-layer SBMs, summarized in Algorithm 1.

For clarity, we retain the step of forming the matrix \overline{M} in the algorithm; however, as mentioned earlier, this step can be omitted in practical implementations. Typically, matrix

G can be efficiently constructed directly by left-multiplying the random test matrix Ω by the sparsified adjacency matrices, offering significant computational savings in both time and space complexity.

Algorithm 1 Randomized spectral clustering for multi-layer SBMs (RSC)

- 1: Input: Multi-layer network adjacency matrices $\{A_l\}_{l=1}^L$, number of clusters K, sampling probability p, and power parameter q.
- 2: for l = 1 to L do
- **Random sampling:** Randomly sample A_l 's elements to obtain a sparsified matrix A_l according to (4);
- **Bias-correction:** Squaring \tilde{A}_l 's and construct the debiased estimator \bar{M}_l according to (7). 4:
- 5: end for
- 6: Random-projection-based eigen-decomposition:
- Form \overline{M} by $\overline{M} := \sum_{l=1}^{L} \overline{M}_l / L;$
- Draw an $n \times K$ random test matrix Ω ; 8:
- Form the matrix $G = [\overline{M}^1\Omega, \overline{M}^3\Omega, \dots, \overline{M}^{2q+1}\Omega];$ 9:
- Construct $Q \in \mathbb{R}^{n \times (q+1)K}$ via QR decomposition of G, G =: QR; Form $C = Q^T \overline{M} Q \in \mathbb{R}^{(q+1)K \times (q+1)K}$; 10:
- 11:
- Set $\hat{U} := QU_K$ with U_K being the top K eigenvectors of the small matrix C. 12:
- 13: Clustering: Conduct k-means clustering on \hat{U} with cluster number being K. The resulting clusters are formalized as the membership matrix Θ .
- 14: **Output:** The estimated membership matrix Θ .

4 Consistency

In this section, we study how the randomization affects the clustering performance of RSC. We measure the clustering performance using the misclassification rate defined as

$$\mathcal{L}(\Theta, \widehat{\Theta}) = \min_{\Psi \in \Psi_K} \frac{1}{n} \|\widehat{\Theta}\Psi - \Theta\|_0,$$

where $\widehat{\Theta} \in \{0,1\}^{n \times K}$ and Θ correspond to the estimated and true membership matrices, and Ψ_K is the set of all $K \times K$ permutation matrices.

The following assumptions are needed to bound the misclassification rate of RSC.

Assumption 1 (Balanced communities) For $k \in [K]$, n_k denotes the number of nodes within the k-th community. The community is balanced such that for any $k \in [K]$ and some constants c and C,

$$c\frac{n}{K} \le n_k \le C\frac{n}{K}.$$

Assumption 2 (Eigen-gap and full rank) $\sum_{l=1}^{L} B_{l,0}^2$ has full rank K with

$$\sigma_{\min}(\sum_{l=1}^{L} B_{l,0}^2) \ge cL,$$

where $\sigma_{min}(\cdot)$ denotes the minimum eigenvalue of a matrix.

Assumption 1 requires that the communities are balanced, which is a common assumption for notational simplicity in the derived misclassification rate. Assumption 2 requires the linear growth of the aggregated squared block probability matrices in terms of its minimum eigenvalue; similar conditions are also imposed in Lei and Lin (2023). Note that when B_l 's are identical and positive-definite across layers with two parameters (i.e., all the diagonal and non-diagonal entries are the same, respectively), Assumption 2 holds naturally. For analytical simplicity, we assume that $\sum_{l=1}^{L} B_{l,0}^2$ is of full rank, this condition can be relaxed to a rank-deficient scenario, where only a linear growth of the minimum non-zero eigenvalue of the aggregated squared block probability matrices is required (Su et al., 2024).

The next theorem provides the bound for the misclassification rate of RSC under two sparsity regimes.

Theorem 1 Suppose Assumptions 1 and 2 hold and the power parameter $q \approx \log n$, the following results hold respectively for two sparsity regimes.

(i) If
$$\frac{\log(L+n)}{pnL^{1/2}} \lesssim \rho \lesssim \frac{1}{pn},$$
 (8)

then with probability larger than $1-O((L+n)^{-c_1})-2e^{-c_2K}$ for some positive constants c_1 and c_2 ,

$$\mathcal{L}(\Theta, \widehat{\Theta}) \lesssim \max\{\frac{\log^2(L+n)}{p^3 L n^2 \rho^2}, \frac{1}{n^2}\}. \tag{9}$$

(ii) If
$$\rho \gtrsim \frac{\log(L+n)}{pn},\tag{10}$$

then with probability larger than $1-O((L+n)^{-c_3})-2e^{-c_4K}$ for some positive constants c_3 and c_4 ,

$$\mathcal{L}(\Theta, \widehat{\Theta}) \lesssim \max\{\frac{\log(L+n)}{pLn\rho}, \frac{1}{n^2}\}.$$
 (11)

Remark 3 In the regime (8), the lower bound of ρ depends on $L^{-1/2}$, which means that the sparsity level ρ in each single layer can be small provided that the number of layers L is large, indicating the benefit of combining L layers. This situation (i.e., lower bound of ρ inversely proportional to L) is generally more challenging in the statistical estimation of multi-layer SBMs (e.g., Lei and Lin (2023); Jing et al. (2021)). In this work, we address not only the statistical estimation but also the computational challenges associated with large-scale SBMs. Therefore, we also examine the regime (10) with a higher sparsity level, which is more challenging than (8) from the computational aspect.

Remark 4 Under the regime that $\log^{1/2}(L+n)/(L^{1/2}n) \lesssim \rho \lesssim 1/n$, which corresponds to our regime (8) for fixed p up to log terms, Lei and Lin (2023) derived the bound $\max\{\log(L+n)/(Ln^2\rho^2), n^{-2}\}$ for misclassification rate. Hence, (9) is of the same order with their bound for fixed p up to log terms, though (9) is generally not better than theirs due to the information loss of random sampling.

Under the regime $n\rho \gtrsim \log n$, which corresponds to our regime (10) for fixed p up to log terms, Arroyo et al. (2021) derived the bound $\max\{1/(Ln\rho), n^{-2}\rho^{-2}\}$ for misclassification rate. Under $Ln\rho \gtrsim \log^4 n$, Jing et al. (2021) derived the bound $\log n/(Ln\rho)$. Hence, our bound under the regime (10) is of the same order as their bounds (under the sparsity regime (10)) for a fixed p up to logarithmic terms. Note that Jing et al. (2021) utilized tensor-based methods for clustering, which yields tighter bounds compared to (9) obtained with the summary statistics-based approach in this work.

Remark 5 We make use of the randomization results (Musco and Musco, 2015) and decoupling techniques (de la Peña and Montgomery-Smith, 1995) to derive the bound in Theorem

1. Note that due to randomization, directly applying the concentration tools developed in Lei and Lin (2023) does not yield a sharp bound in the sparse regime.

It is worth mentioning that the method and theory can be extended to the co-clustering of multi-layer directed networks under the multi-layer Stochastic co-Block Models (ScBMs); see the Appendix for details. For simplicity, we will still refer to the randomized spectral co-clustering for multi-layer ScBMs as RSC.

5 Simulations

In this section, we compare the finite sample performance of the proposed algorithm RSC with that of the original spectral clustering (SC) through simulations, to show that the accuracy of RSC is not much worse than SC. We consider four model set-ups for the multi-layer networks: the first three models are based on the multi-layer SBM under three different scenarios; the fourth model corresponds to the multi-layer ScBM.

Model 1. Consider the *n*-node multi-layer SBM with K=3 communities. The proportions of nodes in three communities are (0.3, 0.4, 0.3). We set $B_l = \rho B^{(1)}$ for $l \in \{1, \ldots, L/2\}$ and $B_l = \rho B^{(2)}$ for $l \in \{L/2 + 1, \ldots, L\}$, with

$$B^{(1)} = U \begin{bmatrix} 1.5 & 0 & 0 \\ 0 & 0.2 & 0 \\ 0 & 0 & 0.4 \end{bmatrix} U^{T} \approx \begin{bmatrix} 0.62 & 0.22 & 0.46 \\ 0.22 & 0.62 & 0.46 \\ 0.46 & 0.46 & 0.85 \end{bmatrix}$$

and

$$B^{(2)} = U \begin{bmatrix} 1.5 & 0 & 0 \\ 0 & 0.2 & 0 \\ 0 & 0 & -0.4 \end{bmatrix} U^{T} \approx \begin{bmatrix} 0.22 & 0.62 & 0.46 \\ 0.62 & 0.12 & 0.46 \\ 0.46 & 0.46 & 0.85 \end{bmatrix},$$

where

$$U = \begin{bmatrix} 1/2 & 1/2 & -\sqrt{2}/2 \\ 1/2 & 1/2 & \sqrt{2}/2 \\ \sqrt{2}/2 & -\sqrt{2}/2 & 0 \end{bmatrix}.$$
 (12)

It is easy to see that $\sum_{l=1}^{L} B_l^2$ is of full rank. The networks are then generated from the multi-layer SBM given in (1). This model was also studied in Lei and Lin (2023).

Model 2. In this model, we consider the case where $\sum_{l=1}^{L} B_l^2$ is rank-deficient. The basic set-up is identical to Model 1 except that we use the following matrix to define the block probability matrices.

$$B^{(1)} = U \begin{bmatrix} 1.5 & 0 & 0 \\ 0 & 0.4 & 0 \\ 0 & 0 & 0 \end{bmatrix} U^{T} \approx \begin{bmatrix} 0.66 & 0.22 & 0.44 \\ 0.22 & 0.46 & 0.58 \\ 0.44 & 0.58 & 0.78 \end{bmatrix}$$

and

$$B^{(2)} = U \begin{bmatrix} 1.5 & 0 & 0 \\ 0 & -0.4 & 0 \\ 0 & 0 & 0 \end{bmatrix} U^{T} \approx \begin{bmatrix} 0.09 & 0.53 & 0.62 \\ 0.53 & 0.29 & 0.48 \\ 0.62 & 0.48 & 0.72 \end{bmatrix},$$

where

$$U = \begin{bmatrix} 0.5 & 0.84 & -0.19 \\ 0.5 & -0.46 & -0.73 \\ 0.71 & -0.27 & 0.65 \end{bmatrix}.$$

It is easy to see that $\sum_{l=1}^{L} B_l^2$ is rank-deficient and the rank is 2. We generate the adjacency matrices using the multi-layer SBM defined in (1).

Model 3. In previous models, we considered scenarios where direct summation of B_l matrices would lead to the cancellation of some communities. We now consider a multi-layer SBM without this constraint. The model set-up is identical to Model 1, with the exception of

$$B^{(2)} = U \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0.4 & 0 \\ 0 & 0 & 0.2 \end{bmatrix} U^{T} \approx \begin{bmatrix} 0.45 & 0.25 & 0.21 \\ 0.25 & 0.45 & 0.21 \\ 0.21 & 0.21 & 0.7 \end{bmatrix}.$$

The matrices $B^{(1)}$ and U remain the same as those specified in Model 1. In this set-up, the direct sum does not lead to community cancellation.

Model 4. In this model, we consider the multi-layer ScBM (see Appendix A), which is used for generating multi-layer directed networks. We set $B_l = \rho B^{(1)}$ for $l \in \{1, ..., L/2\}$, and $B_l = \rho B^{(2)}$ for $l \in \{L/2 + 1, ..., L\}$, with

$$B^{(1)} = U \begin{bmatrix} 1.5 & 0 & 0 \\ 0 & 0.2 & 0 \\ 0 & 0 & 0.4 \end{bmatrix} V^T \approx \begin{bmatrix} 0.46 & 0.625 & 0.225 \\ 0.46 & 0.225 & 0.625 \\ 0.85 & 0.46 & 0.46 \end{bmatrix}$$

and

$$B^{(2)} = U \begin{bmatrix} 1.5 & 0 & 0 \\ 0 & 0.2 & 0 \\ 0 & 0 & -0.4 \end{bmatrix} V^{T} \approx \begin{bmatrix} 0.46 & 0.225 & 0.625 \\ 0.46 & 0.625 & 0.225 \\ 0.85 & 0.46 & 0.46 \end{bmatrix},$$

where U is as defined in (12) and

$$V = \begin{bmatrix} \sqrt{2}/2 & -\sqrt{2}/2 & 0\\ 1/2 & 1/2 & -\sqrt{2}/2\\ 1/2 & 1/2 & \sqrt{2}/2 \end{bmatrix}.$$

We consider the *n*-node ScBM with $K_y = 3$ row communities and $K_z = 3$ column communities. The proportions of nodes in three row (resp. column) communities are (0.3, 0.4, 0.3) (resp. (0.4, 0.3, 0.3).

Results. For each model, we examine the misclassification rates as the number of nodes n, the number of layers L, and the sparsity ρ vary, respectively, as shown below.

- (i) Effect of n. L=20, $\rho=0.1$ and n ranges from 200 to 2000.
- (ii) Effect of L. $n=1000,\,\rho=0.1$ and L ranges from 2 to 50.
- (iii) Effect of ρ . n = 1000, L = 20 and ρ ranges from 0.02 to 0.18.

For each of the above three set-ups, we test different combinations of the sampling rate $p \in \{0.5, 0.7, 0.9\}$ and the power parameter $q \in \{2, 4, 6\}$.

The average results over 50 replications corresponding to Models 1 to 4 are shown in Figures 1 to 4, respectively. It is evident that for all parameter settings, the proposed RSC performs closely to the performance of the SC as n, L and ρ increase, which is consistent with the theoretical results. Moreover, as expected, the performance of RSC improves with increasing the sampling rate and the power parameter. The above observation, along with the significantly reduced computational complexity achieved by RSC, demonstrates its effectiveness in handling large-scale multi-layer networks.

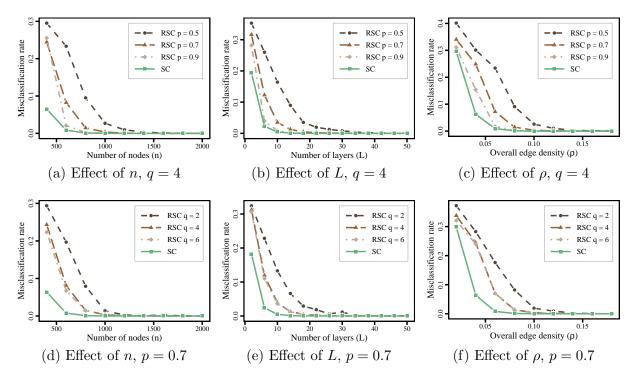

Figure 1: The misclassification rates of two methods under Model 1 with different parameters and hyperparameters.

6 Real data analysis

In this section, we evaluate the proposed algorithm RSC on seven real datasets in terms of the computational efficiency and clustering accuracy.

The seven datasets consist of both directed and undirected multi-layer networks, with the number of nodes ranging from one thousand to three million. The detailed information is as follows.

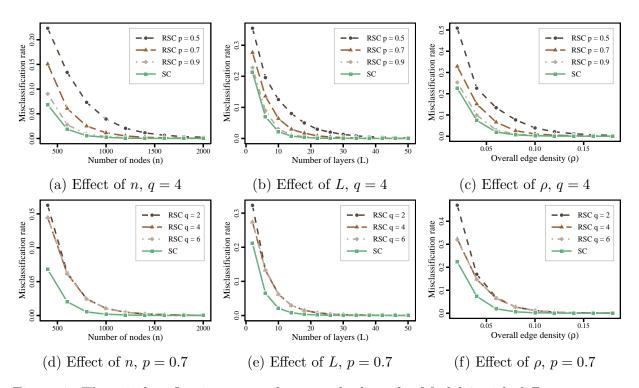

Figure 2: The misclassification rates of two methods under Model 2 with different parameters and hyperparameters.

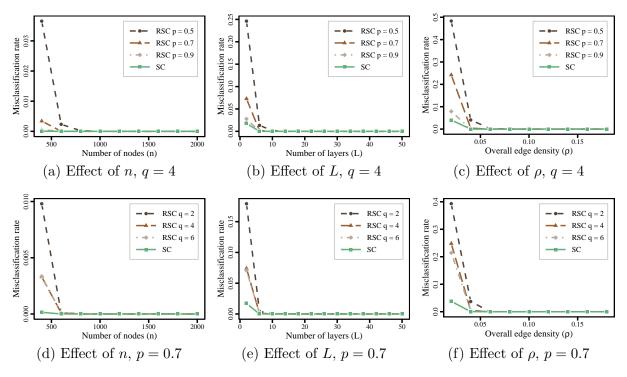

Figure 3: The misclassification rates of two methods under Model 3 with different parameters and hyperparameters.

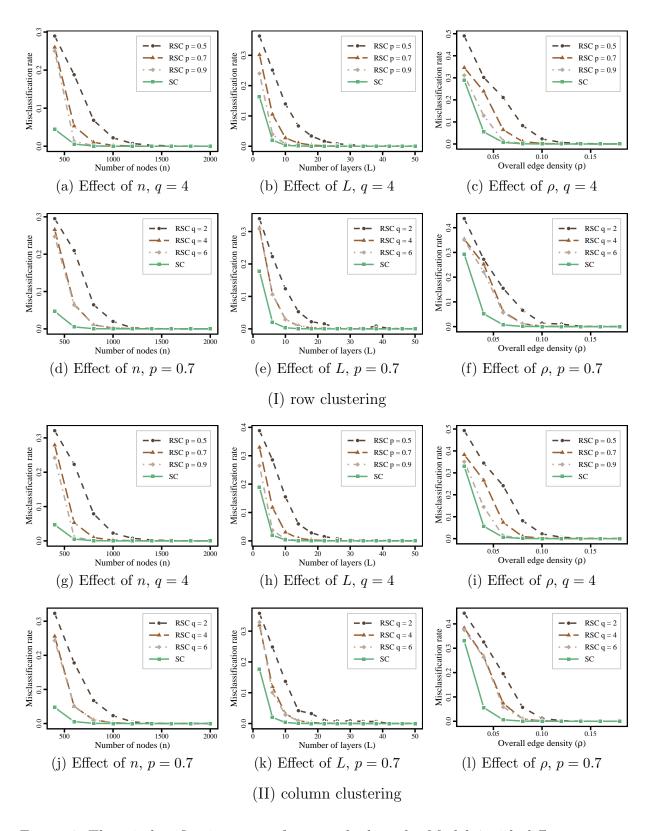

Figure 4: The misclassification rates of two methods under Model 4 with different parameters and hyperparameters.

- (i) European email network (Paranjape et al., 2017). A collection of emails exchanged among members of a European research institution, with layers representing different time periods.
- (ii) Yeast landscape network (Costanzo et al., 2010). The multilayer genetic interaction of the Saccharomyces Cerevisiae, a species of yeast.
- (iii) Home genetic network (Stark et al., 2006). The multilayer genetic and protein interactions of the Homo Sapiens.
- (iv) MoscowAthletics 2013 social network (Omodei et al., 2015). Various types of social relationships among Twitter users during 2013 World Championships in Athletics, with layers corresponding to retweet, mentions, and replies observed between.
- (v) Cannes2013 social network (Omodei et al., 2015). Similar to the previous network, this dataset focuses on social interactions during the 2013 Cannes Film Festival.
- (vi) YouTube social network (Mislove et al., 2007). A social network of YouTube users and their friendship connections, with layers representing different time periods.
- (vii) Stack overflow network (Paranjape et al., 2017). A network of interactions on the stack exchange website Stack Overflow, with layers representing different types of interactions.

The basic statistics of these real multi-layer networks are presented in Table 1.

To examine the computational efficiency of our method, we run RSC on all seven real multi-layer networks and report the computational times. Table 2 presents the average computational time (seconds) of our method over 50 replications, where all computations are performed on a machine with an Apple M2 processor and 16GB of memory, using R version 4.2.0. For comparison, we include the computational time of the original spectral clustering algorithm (denoted by SC), namely, the non-randomized counterpart of RSC, on two small-scale multi-layer networks, the European email network and the Yeast landscape network. The number of clusters in Table 2 is determined by the scree plot of the approximated eigenvalues of the aggregated matrix M for undirected networks, and M^R and M^C

Table 1: Basis statistics of the seven real multi-layer networks, including the number of nodes, the number of layers, the number of edges and the directness.

Networks	Nodes	Layers	Edges	Directness
European email network	986	6	56,440	Directed
Yeast landscape network	$4,\!458$	4	8,450,408	Undirected
Home genetic network	18,222	7	170,899	Directed
MoscowAthletics 2013 social network	88,804	3	210,250	Directed
Cannes 2013 social network	438,537	3	991,854	Directed
Youtube social network	3,223,589	6	20,621,018	Undirected
Stack overflow network	2,601,977	3	37,619,132	Undirected

for directed networks. When the number of nodes is four thousand, our RSC proved to be nearly thirty times faster than SC. As the number of nodes increased to ten thousand, SC failed due to memory constraints, while RSC continued to perform rapid clustering, efficiently handling networks with up to millions of nodes. This demonstrates the robust efficiency of our randomized algorithm across various network sizes and types.

Table 2: Average time (seconds) for clustering seven real multi-layer networks using RSC and SC. A dash '-' indicates that the clustering could not proceed due to memory overflow.

Networks	Clusters	Time of RSC	Time of SC
European email network	2, 2	0.092	0.112
Yeast landscape network	5	1.4	38
Home genetic network	3, 2	0.363	-
MoscowAthletics 2013 social network	3, 2	0.886	-
Cannes 2013 social network	5, 3	7.425	-
Youtube social network	4	53.523	-
Stack overflow network	5	51.225	-

To evaluate the clustering accuracy of the proposed algorithm RSC, we compare RSC with SC. We use the Adjusted Rand Index (ARI) and Adjusted Mutual Information (AMI) to measure the similarity between the clusters obtained by two methods. A higher ARI or AMI indicates greater similarity, with both metrics reaching a value of 1 when the clusters are identical. The numbers of clusters for both methods are determined by the scree plot of the approximated eigenvalues (in absolute value) of the aggregated matrix M

for undirected networks, and M^R and M^C for directed networks. The scree plot typically shows an eigen-gap between the eigenvalues corresponding to the target clusters and the subsequent smaller eigenvalues, which suggests the number of clusters. We set the sampling rate p=0.7 and the power parameter q=2 in RSC. We only compare the two methods on two relatively smaller-scale networks, the European email network and the Yeast landscape network, which is because when the number of nodes reaches tens of thousands, SC becomes impractical due to the high memory demands required for directly computing the square of the adjacency matrix, which can lead to memory exhaustion. The average results over 50 replications are presented in Table 3. It is evident from the results that the proposed algorithm performs similarly with the non-randomized counterpart in clustering, indicated by the large ARI and AMI.

Table 3: The similarity of the clustering results between RSC and SC is measured by ARI and AMI. Larger ARI and AMI indicate more similarity.

Networks	ARI	AMI
European email network (row)	0.965	0.904
European email network (column)	0.974	0.924
Yeast landscape network	0.929	0.902

7 Conclusion

In this paper, our goal was to develop an efficient algorithm for community detection of large-scale multi-layer networks. To this end, we proposed a randomized spectral clustering algorithm, where we utilized the random sampling to reduce the time complexity of squaring the adjacency matrices and used the random projection to accelerate the eigendecomposition of the sum of squared sparsified adjacency matrices. The algorithm reduces both the time complexity and space complexity. In theory, we studied the misclassification error rates of the proposed algorithm under the multi-layer SBMs. The results showed that under certain conditions, the randomization did not substantially deteriorate the clustering accuracy. Finally, we conducted extensive experiments to show the efficiency of proposed

algorithm on multi-layer networks with millions of nodes. In the future, it would be interesting to generalize the methodology and theory to other community detection methods, say the tensor-based methods, for multi-layer networks.

Appendix

Appendix A extends the method to multi-layer ScBMs and presents the corresponding theoretical results. Appendix B provides the technical theorem and lemmas that are needed to prove the misclassification rates. Appendix C includes the proof of the theorem in the main text. Appendix D contains auxiliary lemmas.

A Extension to multi-layer ScBMs

We extend the RSC algorithm to the spectral co-clustering of multi-layer directed networks, which are assumed to follow the ScBMs.

Compared to standard clustering, where only one set of clusters is obtained, co-clustering aims to obtain two sets of clusters (i.e., co-clusters), one for the row clusters containing nodes with similar sending patterns, and the other for the column clusters containing nodes with similar receiving patterns.

The multi-layer ScBM is designed to capture the co-clusters in multi-layer directed networks. Suppose there are L layers and n nodes. For each layer $l \in [L]$, the multi-layer ScBM assumes that the network adjacency matrix A_l is independently generated as follows,

$$A_{l,ij} \sim_{i.i.d.} \text{Bernoulli}(B_{l,g_i^y g_i^z}) \text{ if } i \neq j \quad \text{and} \quad A_{l,ij} = 0 \text{ if } i = j,$$
 (13)

where $g_i^y \in \{1, ..., K_y\}$ and $g_i^z \in \{1, ..., K_z\}$ denote the row and column community assignments of node i, for all $i \in [n]$. The matrix $B_l \in [0, 1]^{K_y \times K_z}$ represents the block probability matrix for layer l. Here, K_y and K_z , representing the numbers of row and column communities respectively, which can differ. The population of A_l can be formulated as $P_l := YB_lZ^T$, where $Y \in \{0, 1\}^{n \times K_y}$ and $Z \in \{0, 1\}^{n \times K_z}$ represent the row and column membership matrices, respectively.

As discussed in Section 2, to circumvent the potential clustering cancellation caused by directly summing the matrices A_l , utilizing the squared sum of adjacency matrices is more reasonable. We consider the spectral co-clustering method in Su et al. (2024) as the basis of our randomized algorithm. Specifically, define

$$M^R := \frac{1}{Ln} \sum_{l=1}^{L} (A_l A_l^T - D_l^{\text{out}})$$
 and $M^C := \frac{1}{Ln} \sum_{l=1}^{L} (A_l^T A^l - D_l^{\text{in}}),$

where D_l^{out} is a diagonal matrix consisting of the out-degree of A_l with $D_{l,ii}^{\text{out}} = \sum_j A_{l,ij}$ and D_l^{in} is a diagonal matrix consisting of the in-degree of A_l with $D_{l,ii}^{\text{in}} = \sum_j A_{l,ji}$. The spectral co-clustering obtains the row and column communities partition by applying k-means on the rows of the leading eigenvectors of M^R and the leading eigenvectors of M^C , respectively.

Similar to the undirected multi-layer networks set-up, we utilize the randomized sketching techniques to accelerate the spectral co-clustering algorithm for directed multi-layer networks. The algorithm is similar to Algorithm 1 with two main modifications: First, the random sampling step in (4) is independently performed for each pair $1 \leq i \neq j \leq n$. Second, both the bias-correction step in (7) and the subsequent random-projection-based eigen-decomposition are performed on both row and column communities. Specifically, \bar{M}_l should be replaced with \bar{M}_l^R and \bar{M}_l^C , where $\bar{M}_l^R := \frac{\tilde{A}_l \tilde{A}_l^T}{n} - \frac{\tilde{D}_l^{\text{out}}}{np^2}$ and $\bar{M}_l^C := \frac{\tilde{A}_l^T \tilde{A}_l}{n} - \frac{\tilde{D}_l^{\text{in}}}{np^2}$. For simplicity, we will still refer to the randomized spectral co-clustering for multi-layer ScBMs as RSC.

Let \widehat{Y} and \widehat{Z} be the estimated row and column membership matrices obtained from the RSC algorithm for multi-layer ScBMs. Analogous to Theorem 1, we can also provide error bounds for the misclassification rates $\mathcal{L}(Y,\widehat{Y})$ and $\mathcal{L}(Z,\widehat{Z})$. We begin by presenting some assumptions for multi-layer ScBMs, which are counterparts of Assumptions 1 and 2 for multi-layer SBMs.

Assumption E1 For $k \in [K_y]$ $(k \in [K_z])$, n_k^y (n_k^z) denotes the number of nodes within the k-th row (column) community. The community sizes are balanced such that for any $k \in [K_y]$, $cn/K_y \le n_k^y \le Cn/K_y$, and for any $k \in [K_z]$, $cn/K_z \le n_k^z \le Cn/K_z$, where c

and C are constants.

Assumption E2 $\sum_{l=1}^{L} B_{l,0} B_{l,0}^{T}$ has full rank K_{y} with $\sigma_{\min}(\sum_{l=1}^{L} B_{l,0} B_{l,0}^{T}) \geq cL$ and $\sum_{l=1}^{L} B_{l,0}^{T} B_{l,0}$ has full rank K_{z} with $\sigma_{\min}(\sum_{l=1}^{L} B_{l,0}^{T} B_{l,0}) \geq cL$, where σ_{\min} denotes the minimum eigenvalue of a matrix.

The following corollary provides upper bounds on the proportion of misclustered nodes for the multi-layer ScBM. The proof is similar to that in Theorem 1, and is therefore omitted.

Corollary 1 Suppose Assumptions E1 and E2 hold, the following results hold respectively for two sparsity regimes.

(i) In regime (8), we have

$$\max\{\mathcal{L}(Y,\widehat{Y}), \mathcal{L}(Z,\widehat{Z})\} \lesssim \max\{\frac{\log^2(L+n)}{p^3Ln^2\rho^2}, \frac{1}{n^2}\}$$

with probability larger than $1 - O((L+n)^{-c_1}) - 2e^{-c_2K}$ for some positive constants c_1 and c_2 .

(ii) In regime (10), we have

$$\max\{\mathcal{L}(Y,\widehat{Y}), \mathcal{L}(Z,\widehat{Z})\} \lesssim \max\{\frac{\log(L+n)}{pLn\rho}, \frac{1}{n^2}\}$$

with probability larger than $1 - O((L+n)^{-c_3}) - 2e^{-c_4K}$ for some positive constants c_3 and c_4 .

B Technical lemmas and theorem

In this subsection, we provide the lemmas and theorem that will be used in the proof of the main theorem.

Lemma 1 Let A_l be the independent adjacency matrices generated by a multi-layer SBM satisfying the sparsity condition (8) for all $1 \le l \le L$, and let \tilde{A}_l represent the sparsified

matrices with sampling probability p. Then, the following statements hold simultaneously with probability larger than $1 - O((L+n)^{-c})$ for some positive constant c:

- (i) $\max_{l,i} \tilde{d}_{l,i} \lesssim \log(L+n)$.
- (ii) $\max_{i} \sum_{l=1}^{L} \tilde{d}_{l,i} \lesssim Ln\rho p$.

(iii)
$$\|\sum_{l=1}^{L} \tilde{A}_l^2\| \lesssim Ln\rho/p$$
.

Proof. Recall the definition of \tilde{A}_l in (4), where $\tilde{A}_{l,ij}$'s are independent and bounded. The first two statements are derived through a direct application of the standard Bernstein's inequality and the union bound.

The proof of the last part follows that of Lemma 8 in Lei and Lin (2023), with the main difference being the tail conditions of the entries of \tilde{A}_l . We omit it here for brevity.

Lemma 2 Under the same conditions as Lemma 1, let $X_l := \tilde{A}_l - \bar{P}_l$ be the noise matrices for all $1 \le l \le L$. Then N_1 , the off-diagonal part of $\frac{1}{L} \sum_{l=1}^{L} X_l^2$, satisfies

$$||N_1||_2 \lesssim \frac{n\rho\log(L+n)}{p^{3/2}L^{1/2}}$$

with probability at least $1 - O((L+n)^{-c})$ for some constant c > 0.

Proof. We use the decoupling techniques outlined in Lei and Lin (2023) and Su et al. (2024) to establish the proof. To use the decoupling argument, define

$$\widetilde{N}_{1} = \frac{1}{L} \sum_{l=1}^{L} \sum_{(i, j) \neq (i', j')} X_{l,ij} X_{l,ij}^{\text{ic}} X_{l,i'j'}^{\text{e}} e_{i} e_{i'}^{T} I_{\{j=j'\}},$$

$$\widetilde{N}_{2} = \frac{1}{L} \sum_{l=1}^{L} \sum_{(i, j)} X_{l,ij} X_{l,ij}^{\text{ic}} e_{i} e_{i}^{T},$$

and

$$\widetilde{N} = \frac{1}{L} \sum_{l=1}^{L} X_l X_l^{\text{ic}} = \widetilde{N}_1 + \widetilde{N}_2.$$

where \widetilde{N}_1 is the zero mean off-diagonal part and \widetilde{N}_2 is the diagonal part. Here, e_i is the standard basis vector in \mathbb{R}^n and pairs $(i,j), (i',j') \in \{1,2,\ldots,n\}^2$. X_l^{ic} is an independent

copy of X_l for all $1 \leq l \leq L$. Note that $\|\widetilde{N}_1\|_2 \leq \|\widetilde{N}\|_2 + \|\widetilde{N}_2\|_2$, we separately control the spectral norms of \widetilde{N} and \widetilde{N}_2 .

Recall that $X_l^{\text{ic}} = \tilde{A}_l^{\text{ic}} - \bar{P}_l$, where \tilde{A}_l^{ic} is an independent copy of \tilde{A}_l , we reformulate \tilde{N} as

$$L\widetilde{N} = \sum_{l=1}^{L} X_{l} X_{l}^{\text{ic}} = \sum_{l=1}^{L} X_{l} \widetilde{A}_{l}^{\text{ic}} - \sum_{l=1}^{L} X_{l} \bar{P}_{l}.$$

We first apply Lemma 1 and 3 to control $\|\sum_{l=1}^L X_l \tilde{A}_l^{\text{ic}}\|_2$ conditioning on $\tilde{A}_1^{\text{ic}}, \dots, \tilde{A}_L^{\text{ic}}$. Note that $\max_l \|\tilde{A}_l^{\text{ic}}\|_{2,\infty} \leq \max_{l,i} \tilde{d}_{l,i}/p \lesssim \log(L+n)/p$ and $n\|\sum_{l=1}^L \tilde{A}_l^{\text{ic}} \tilde{A}_l^{\text{ic}}\|_2 \lesssim Ln^2\rho/p$ with high probability, we have

$$\left\| \sum_{l=1}^{L} X_l \tilde{A}_l^{\text{ic}} \right\|_2 \le cL^{1/2} n\rho \log(L+n)/p^2$$

with probability larger than $1 - O((L+n)^{-c})$ for some constant c > 0. Combining this with (16), it follows that with probability at least $1 - O((L+n)^{-c})$,

$$\|\widetilde{N}\|_2 \lesssim \frac{n\rho \log(L+n)}{L^{1/2}p^{3/2}}.$$

Recall that \widetilde{N}_2 is a diagonal matrix whose *i*th diagonal element is $\frac{1}{L} \sum_{l=1}^{L} \sum_{j=1}^{n} X_{l,ij} X_{l,ij}^{\text{ic}}$. Using standard Bernstein's inequality and the union bound, we have with probability at least $1 - O((L+n)^{-c})$,

$$\|\widetilde{N}_2\|_2 \lesssim \frac{n^{1/2}\rho \log^{1/2}(L+n)}{L^{1/2}n^{3/2}}.$$

The claim follows by combining the bounds on $\|\widetilde{N}\|_2$ and $\|\widetilde{N}_2\|_2$ together with the decoupling inequality (Theorem 1 in de la Peña and Montgomery-Smith (1995)).

Theorem 2 The following results hold respectively for two sparsity regimes.

(i) In regime (8), we have

$$\|\overline{M} - \Pi\|_2 \lesssim \max\{\frac{\rho \log(L+n)}{p^{3/2}L^{1/2}}, \ \rho^2\}$$

with probability larger than $1 - O((L+n)^{-c_1})$ for some constant $c_1 > 0$.

(ii) In regime (10), we have

$$\|\overline{M} - \Pi\|_2 \lesssim \max\{\frac{n^{1/2}\rho^{3/2}\log^{1/2}(L+n)}{p^{1/2}L^{1/2}}, \ \rho^2\}$$

with probability larger than $1 - O((L+n)^{-c_2})$ for some constant $c_2 > 0$.

Proof. We utilize the concentration tools developed in Lei and Lin (2023) to prove. Recalling the decomposition outlined in Section 3.2, we obtain the following decomposition,

$$n\overline{M} - n\Pi = \frac{1}{L} \sum_{l=1}^{L} (n\overline{M}_l - n\Pi_l) := E_0 + E_1 + E_2 + E_3 - \frac{1}{L} \sum_{l=1}^{L} \frac{\tilde{D}_l}{p^2},$$

with $E_i := \frac{1}{L} \sum_{l=1}^{L} E_{l,i}$, where $E_{l,i}$ is the same as those in (5). We proceed to bound these error terms, respectively.

For
$$E_0 := \frac{1}{L} \sum_{l=1}^{L} (-P_l \cdot \operatorname{diag}(P_l) - \operatorname{diag}(P_l) \cdot P_l + (\operatorname{diag}(P_l))^2)$$
, it is easy to see that

$$||E_0||_2 \le 2 \max_l ||\operatorname{diag}(P_l)||_2 \max_l ||P_l||_F + \max_l ||\operatorname{diag}(P_l)||_2^2 \le Cn\rho^2.$$

For $E_1 := \frac{1}{L} \sum_{l=1}^{L} (X_l(P_l - \operatorname{diag}(P_l)) + (P_l - \operatorname{diag}(P_l))X_l)$, we will make use of the concentration inequality of Lei and Lin (2023) (see also Lemma 3). For that, we now show that each entry of pX_l satisfies the Bernstein condition (see Definition 1). With a slight abuse of notation, for $i \neq j$, we define $F_l := pX_{l,ij} = p(\tilde{A}_{l,ij} - P_{l,ij})$. Specifically,

$$F_{l} = \begin{cases} 1 - pP_{l,ij}, & \text{with probability } pP_{l,ij}, \\ -pP_{l,ij}, & \text{with probability } 1 - pP_{l,ij}, \end{cases}$$

and for $\alpha \geq 2$, we have

$$\mathbb{E}|F_{l}^{\alpha}| \leq |1 - pP_{l,ij}|^{\alpha} pP_{l,ij} + |pP_{l,ij}|^{\alpha} (1 - pP_{l,ij})$$

$$\leq (1 - pP_{l,ij}) pP_{l,ij} + pP_{l,ij} (1 - pP_{l,ij})$$

$$\leq 2pP_{l,ij} \leq \frac{v_{1}}{2} \alpha! R_{1}^{\alpha-2}, \tag{14}$$

where $v_1 := 4p\rho$ and $R_1 := 1$. Thus, $pX_{l,ij}$'s are (v_1, R_1) -Bernstein. We also have $\|\sum_{l=1}^{L} (P_l - \operatorname{diag}(P_l))^2\|_2 \le \sum_{l=1}^{L} \|P_l - \operatorname{diag}(P_l)\|_F^2 \le Ln^2\rho^2$ and $\max_l \|P_l - \operatorname{diag}(P_l)\|_{2,\infty} \le \sqrt{n}\rho$. By using Lemma 3, we have

$$\mathbb{P}(pL||E_1||_2 \ge t) \le 4n \cdot \exp\left\{\frac{-t^2/2}{4pLn^3\rho^3 + \sqrt{n\rho}t}\right\}.$$
 (15)

Choosing $t = p^{1/2} \rho^{3/2} n^{3/2} L^{1/2} \log^{1/2} (L+n)$, it follows that

$$\sqrt{n}\rho t \lesssim pLn^3\rho^3$$

which requires $\rho \gtrsim \log^{1/2}(L+n)/(pn^2L)$ and the latter is automatically met for both of our regimes (8) and (10). As a result, (15) implies that

$$||E_1||_2 \lesssim \frac{n^{3/2} \rho^{3/2} \log^{1/2} (L+n)}{p^{1/2} L^{1/2}}$$
 (16)

with probability larger than $1 - O((L+n)^{-c})$ for some constant c > 0.

For $E_2 := \frac{1}{L} \sum_{l=1}^{L} (X_l^2 - \operatorname{diag}(X_l^2))$, we discuss the upper bounds respectively under the sparse regime (8) and dense regime (10).

Under the sparse regime (8), Lemma 2 implies that

$$||E_2||_2 \lesssim \frac{n\rho \log(L+n)}{p^{3/2}L^{1/2}}$$
 (17)

with probability at least $1 - O((L+n)^{-c})$ for some constant c > 0.

Under the dense regime (10), we will make use of Lemma 4. Given an independent copy pX_l^{ic} of pX_l , and similar to the derivation of (14), we can show that $p^2X_{l,ij}X_{l,ij}^{\text{ic}}$ is (v'_2, R'_2) Bernstein with $v'_2 = 8p^2\rho^2$ and $R'_2 = 1$. Then by Lemma 4, we obtain with probability larger than $1 - O((L+n)^{-c})$ that

$$||Lp^2E_2||_2 \le p\rho n \log(L+n)\sqrt{L} + \sqrt{p\rho}\sqrt{Ln} \log^{3/2}(L+n) + p\rho\sqrt{Ln} \log(L+n) + \log^2(L+n).$$

Under (10), we have with probability at least $1 - O((L+n)^{-c})$ for some constant c > 0,

$$||E_2||_2 \lesssim \frac{n\rho \log(L+n)}{\sqrt{Lp}}.$$
 (18)

For $E_3 - \frac{1}{L} \sum_{l=1}^{L} \frac{\tilde{D}_l}{p^2}$, we have derived in (6) that

$$||E_3 - \frac{1}{L} \sum_{l} \frac{\tilde{D}_l}{p^2}||_2 \le Cn\rho^2.$$

Finally, we need to compare the three terms E_1 , E_2 and E_3 (E_0 is of the same order with E_3). The following results can be observed.

(i) Under the regime (8), the bound for E_1 is smaller than the bound (17) for E_2 and thus

$$\|\overline{M} - \Pi\|_2 \lesssim \max\{\frac{\rho \log(L+n)}{p^{3/2}L^{1/2}}, \ \rho^2\}.$$

(ii) Under the regime (10), the bound (18) for E_2 is smaller than that for E_1 and thus

$$\|\overline{M} - \Pi\|_2 \lesssim \max\{\frac{n^{1/2}\rho^{3/2}\log^{1/2}(L+n)}{p^{1/2}L^{1/2}}, \ \rho^2\}.$$

C Proof of main theorem

Proof of Theorem 1

Consider that the approximated eigenspace \hat{U} used for k-means clustering in Algorithm 1 is actually the eigenvector of $\hat{M} := QQ^T \bar{M} QQ^T$. We first use the concentration bound of \bar{M} around the population matrix Π and the argument about the low-rank randomized approximation in Musco and Musco (2015) to bound the deviation of \hat{M} from Π , recalling

the definition of Π in (3). We begin by noting that

$$\|\hat{M} - \Pi\|_{2} = \|QQ^{T}\overline{M}QQ^{T} - \Pi\|_{2}$$

$$\leq \|\overline{M} - \Pi\|_{2} + \|QQ^{T}\overline{M}QQ^{T} - \overline{M}\|_{2}$$

$$\leq \|\overline{M} - \Pi\|_{2} + \|QQ^{T}\overline{M}(QQ^{T} - \overline{M})\|_{2} + \|QQ^{T}\overline{M} - \overline{M}\|_{2}$$

$$\leq \|\overline{M} - \Pi\|_{2} + 2\|\overline{M} - QQ^{T}\overline{M}\|_{2}.$$
(19)

For the second term $\|\overline{M} - QQ^T\overline{M}\|_2$, by the Theorem 1 of Musco and Musco (2015), when $q \approx \log n/\sqrt{\varepsilon}$, the following inequality holds with probability at least $1 - 2e^{-cK}$,

$$\|\overline{M} - QQ^T \overline{M}\|_2 \le (1 + \varepsilon) \|\overline{M} - \overline{M}_K\|_2,$$

where \overline{M}_K is \overline{M} projected onto the space spanned by its top K singular vectors, $\epsilon \in (0,1)$ is the error, and c is some positive constant. Note that $\|\overline{M} - \overline{M}_K\|_2 = \sigma_{K+1}(\overline{M})$ and Π is of rank K, then we have

$$\|\overline{M} - QQ^T \overline{M}\|_2 \le (1+\varepsilon)\sigma_{K+1}(\overline{M}) = (1+\varepsilon)\left(\sigma_{K+1}(\overline{M}) - \sigma_{K+1}(\Pi)\right) \le (1+\varepsilon)\|\overline{M} - \Pi\|_2$$

where $\sigma_{K+1}(\cdot)$ denotes the K+1th largest eigenvalue of a symmetric matrix.

As a result, we have with high probability

$$\|\hat{M} - \Pi\|_2 \le (3 + 2\varepsilon) \|\overline{M} - \Pi\|_2$$

The upper bound of $\|\overline{M} - \Pi\|_2$ is provided in Theorem 2.

Then, by the Davis-Kahan $\sin\Theta$ theorem (Lemma 5), there exists a $K \times K$ orthogonal matrix O such that

$$\|\hat{U} - UO\|_{F} \le \frac{2\sqrt{2K}\|\overline{M} - \Pi\|_{2}}{\sigma_{K}(\Pi)} \le \frac{2\sqrt{2K}\|\overline{M} - \Pi\|_{2}}{cn\rho^{2}}.$$

Here, the last inequality comes from the given assumptions that the community sizes are balanced and the minimum eigenvalue of $\sum_{l=1}^{L} B_{l,0}^2$ is at least cL, ensuring that $\sigma_K(\Pi) \ge$

 $cn\rho^2$ for some constant c>0. Finally, by using Lemmas 6 and 7, we are able to obtain the desired bound for the misclassification rate.

D Auxiliary lemmas

This subsection includes the auxiliary lemmas used to prove the theorems in the paper.

Definition 1 (Bernstein condition) A zero-mean random variable X with Var(X) = v is said to be (v, R)-Bernstein if there exists a constant R such that for all $\alpha \geq 2$, the α -th moment satisfies $\mathbb{E}[|X|^{\alpha}] \leq \frac{1}{2}v\alpha!R^{\alpha-2}$.

Lemma 3 (Theorem 3 in Lei and Lin (2023)) Let $X_1, ..., X_L$ be a sequence of independent $n \times r$ random matrices with zero-mean independent entries being (v_1, R_1) -Bernstein. Let $H_1, ... H_L$ be any sequence of $r \times n$ non-random matrices. Then for all t > 0,

$$\mathbb{P}(\|\sum_{l=1}^{L} X_l H_l\|_2 \ge t) \le 4n \exp\left(-\frac{t^2/2}{v_1 n \|\sum_{l=1}^{L} H_l^T H_l\|_2 + R_1 \max_l \|H_l\|_{2,\infty} t}\right).$$

Lemma 4 (Theorem 4 in Lei and Lin (2023)) Let $X_1, X_2, ..., X_L$ be independent $n \times n$ random symmetric matrices with independent diagonal and upper diagonal entries. For any $l \in [L]$ and any pair (i,j) where $i \leq j$, $X_{l,ij}$ is (v_1, R_1) -Bernstein, and $X_{l,ij}\tilde{X}_{l,ij}$ is (v'_2, R'_2) -Bernstein where $\tilde{X}_{l,ij}$ is an independent copy of $X_{l,ij}$. Then with probability larger than $1 - O((n + L)^{-1})$,

$$\|\sum_{l=1}^{L} X_{l}^{2} - \operatorname{diag}(\sum_{l=1}^{L} X_{l}^{2})\|_{2} \leq C \left[v_{1} n \log(L+n) \sqrt{L} + \sqrt{v_{1}} R_{1} \sqrt{Ln} \log^{3/2}(L+n) + \sqrt{v_{2}'} \sqrt{Ln} \log(L+n) + (R_{1}^{2} + R_{2}') \log^{2}(L+n)\right].$$

Moreover, if the squared entry $X_{l,ij}^2$ is (v_2, R_2) -Bernstein, then with probability larger than $1 - O((n+L)^{-1})$,

$$\|\operatorname{diag}(\sum_{l=1}^{L} X_{l}^{2}) - \mathbb{E}(\operatorname{diag}(\sum_{l=1}^{L} X_{l}^{2}))\|_{2} \le C \left[\sqrt{v_{2}} \log(L+n)\sqrt{Ln} + R_{2} \log(L+n)\right].$$

Lemma 5 (Davis-Kahan theorem) Let $Q \in \mathbb{R}^{n \times n}$ be a rank K symmetric matrix with the smallest nonzero singular value γ_n . Let M be any symmetric matrix and $\hat{U}, U \in \mathbb{R}^{n \times K}$ be the K leading eigenvectors of M and Q, respectively. Then there exists a $K \times K$ orthogonal matrix O such that

$$\|\hat{U} - UO\|_{F} \le \frac{2\sqrt{2K}\|M - Q\|_{2}}{\gamma_{n}}.$$

Proof. See Lei and Rinaldo (2015); Chen et al. (2021), among others.

Lemma 6 (Lemma 5.3 in Lei and Rinaldo (2015)) Let U be an $n \times d$ matrix with K distinct rows with minimum pairwise Euclidean norm separation $\gamma > 0$. Let \widehat{U} be another $n \times d$ matrix and $\widehat{\Theta}$ be a solution to k-means problem with input \widehat{U} , then the number of errors in $\widehat{\Theta}$ as an estimate of the row clusters of U is no larger than $c\|\widehat{U} - U\|_F^2 \gamma^{-2}$ for some constant c > 0.

Lemma 7 Define the population matrix $Q = \Theta \bar{B} \Theta^{\mathsf{T}}$. Suppose \bar{B} is of full rank and denote the eigen-decomposition of Q by $V_{n \times K} \Sigma_{K \times K} V_{K \times n}^{\mathsf{T}}$. Then, $V = \Theta X$ for some given matrix X. Specifically, for $\Theta_{i*} = \Theta_{j*}$, we have $V_{i*} = V_{j*}$; while for $\Theta_{i*} \neq \Theta_{j*}$, we have $||V_{i*} - V_{j*}||_2 = \sqrt{(n_{g_i})^{-1} + (n_{g_j})^{-1}}$.

Proof. See Lei and Rinaldo (2015); Guo et al. (2023); Zhang et al. (2022), among others.
