When building dark matter (DM) models, one often imposes conserved discrete symmetries to stabilize DM candidates. The simplest choice is \mathbb{Z}_2 but models with larger stabilizing groups have also been explored. Can a conserved non-abelian group lead to a viable DM model? Here, we address this question within the three-Higgs-doublet model based on the group $\Sigma(36)$, in which DM stabilization by a non-abelian group is not only possible but inevitable. We show that the tight connections between the Higgs, fermion, and DM sectors repeatedly drive the model into conflict with the LHC results and DM observations, with the most recent LZ results playing a decisive role. We believe that the lessons learned from this study help chart the limits of what can be achieved within multi-Higgs-doublet DM models with large symmetry groups.

INTRODUCTION I.

Stabilizing dark matter: symmetry groups vs. individual symmetries А.

There exist several irrefutable pieces of evidence for dark matter (DM) filling the Universe [1]. The mainstream view is that DM consists of one or several sorts of heavy, stable, electrically neutral particles of non-baryonic nature, which are absent in the Standard Model (SM) and, therefore, require some form of New Physics beyond the SM. One popular idea is to assume that the scalar sector is not as minimal as in the SM but contains new scalar fields. Equipped with a new global symmetry that remains unbroken in the vacuum, this scalar sector leads to one or more scalar DM candidates.

A prototypical illustration of this scenario is the inert doublet model (IDM) [2–5]. This is a version of the two-Higgs-doublet model (2HDM) with an exact \mathbb{Z}_2 symmetry that acts trivially on the first Higgs doublet ϕ_1 and the SM fields and flips the sign of the second Higgs doublet ϕ_2 . If the vacuum expectation value (vev) of the second doublet is zero, $\langle \phi_2 \rangle = 0$, \mathbb{Z}_2 remains unbroken and stabilizes the lightest scalar from ϕ_2 against decay. As the model introduces very few free parameters and leads to numerous collider and cosmological predictions, it has become a popular playground, see for example [6–10] and references therein.

Using \mathbb{Z}_2 as a DM stabilizing group is not the only option.¹ One can easily construct multi-Higgs models in which DM candidates are protected by the unbroken \mathbb{Z}_n , n > 2, see [12–22] and references therein. Such models often contain additional processes that affect the DM evolution or feature several DM components with distinct interaction preferences. One can even build a 3HDM model in which a pair of mass-degenerate DM candidates is stabilized by an exotic CP symmetry of higher order rather than a Higgs family transformations [23, 24]. Another idea considered in literature is to replicate the IDM, that is, to consider a 3HDM with two independent \mathbb{Z}_2 symmetries flipping the signs of ϕ_2 and ϕ_3 , respectively. The model possesses two DM candidates coming come from the two inert doublets with much freedom to adjust the properties of the two dark sectors [25–29].

One may wonder what happens if scalar DM candidates are stabilized not by a single symmetry but by a non-abelian symmetry group. We stress that we talk about not a generic model whose lagrangian is invariant under a non-abelian global group G (which can be broken later by the vevs), but a special situation where a remnant non-abelian global symmetry group $G_v \subset G$ survives after the minimization of the scalar potential. If this is the case, the DM candidates h_i form a multiplet under G_v , with additional channels for relic density evolution, such as co-annihilation $h_i h_i \to SM$ or semi-annihilation $h_i h_i \to h_k + SM$. On the other hand, one expects that, due to many residual symmetries, these interactions are not fully arbitrary but correlated with other observables of the model.

This idea is not new. To our knowledge, the first—and the simplest—example based on the residual group $G_v = S_3$ was presented in [30]. In that work, a simplified DM model was constructed, which featured, in

¹ We mention in passing that there exist examples of scalar DM that are not based on any exact symmetry [11].

addition to the SM Higgs doublet, two electroweak (EW) singlet fields, the real η and the complex χ . The interaction potential was designed in such a way that the model possesses S_3 and that the vev alignment preserves this group, making χ and χ^* the two mass degenerate DM candidates. The model contained enough freedom to introduce new channels that affect the DM thermal evolution and to satisfy observational constraints. Another attempt to build a DM model based on a non-abelian group, the quaternion group Q_4 , was described in [31].

In this paper, we are interested in a different twist of the non-abelian DM scenario. In the above papers, as well as in many other DM models, one postulates a dark sector which, by construction, does not participate in the EW interactions and couples to the visible sector either through portal-like interactions or flavor physics connections. Since the visible and the dark sectors are governed by different lagrangians, it is no wonder that this scenario offers enough freedom to adjust the DM sector separately from the SM fields.

However, we want to explore the same scenario in the multi-Higgs-doublet models. Here, the scalar DM protected by a non-abelian group appears from the same self-interaction potential as the SM-like Higgs boson itself. As a result, the connections and constraints become much tighter, and it is not clear a priori whether such a DM scenario is tenable. What we want is not to simply construct yet another DM model but to chart the limits of what multi-Higgs-doublet models can in principle accommodate. Can they incorporate such a scenario? Does it require much fine-tuning or any additional assumptions? Does it run into immediate conflicts with collider and cosmological observations? Does it lead to specific predictions?

When addressing these questions, we make as few assumptions as possible and check where the analysis leads us. It may seem that a residual non-abelian symmetry group of a multi-Higgs-doublet model must hinge on several assumptions. This is not so. In fact, we start with only one assumption: we choose a multi-Higgsdoublet potential which is invariant under a large finite group G of global symmetries. Experience shows that if G is sufficiently large—and it of course depends on what "sufficiently" means—non-abelian DM follows automatically. Namely, it turns out that, for a sufficiently large G, any minimum of the scalar potential keeps unbroken some non-abelian subgroup $G_v \subset G$. Thus, DM stabilization by a non-abelian residual symmetry group is not only possible but inevitable in such models. It was this initial observation that motivated the present study.

In this work, we explore this phenomenon and its DM implications with the example of the three-Higgsdoublet model (3HDM) whose scalar sector is invariant under the global symmetry group $G = \Sigma(36)$. This option first appeared in the systematic classification of the finite realizable symmetry groups of the 3HDMs [32, 33]; the fact that all its global minima preserve a non-abelian subgroup $G_v = S_3 \subset \Sigma(36)$ was mentioned in [34]. Recently, it was shown in [35] that, with a softly broken $\Sigma(36)$, this model can accommodate cosmological phase transition scenarios, in which expanding bubbles of true vacuum are separated from the false vacuum background by charge-breaking bubble walls. The S_3 -stabilized DM evolution, which we study here, is another interesting feature of this model.

B. The objectives and the structure of the paper

The main objective of this paper is to explore the characteristic features of the DM in multi-Higgs-doublet models highly constrained by large global symmetry groups. We will see that it is not an easy task to arrange for stable DM candidates that could account for at least a part of the total relic density without running into conflict with direct detection and collider constraints. We believe that the $\Sigma(36)$ -based 3HDM offers us lessons about this general phenomenon.

The sequence of the steps we will take along these lines is the following. In the next section, we will review the scalar sector of the $\Sigma(36)$ 3HDM, list its minima and the physical scalars. We will also highlight the features that arise due to stabilization of DM candidates by a non-abelian group, as contrasted with stabilization by a single symmetry. Then, in Section III we attempt to complete the model with a suitable Yukawa sector. We first show in Section III A that $\Sigma(36)$ can be, in principle, extended to the quark sector but leads to unphysical quark properties. Even this situation would be acceptable as a toy model, had we been able to keep the DM candidates stable. But it turns out that all possible $\Sigma(36)$ -invariant Yukawa sectors unavoidable lead to scalar decays to quark pairs, precluding any stable DM scenario. This no-go result is the first lesson we learn.

We then relax our assumptions and, in Section IIIB, we construct a Yukawa sector that is invariant not under the full $\Sigma(36)$ but under its subgroup $G_v = S_3$, the residual symmetry group at a chosen minimum. This can be easily done in a fully realistic way. Moreover, since $\Sigma(36)$ is not the symmetry of the full lagrangian, we also take the liberty of introducing soft breaking terms respecting the same S_3 , which adds only one additional parameter. This is done in a consistent way, so that the minimum we initially selected becomes the unique global minimum of the resulting potential. We incorporate the model in micrOMEGAs [36] and present, in Section IV, the results of our study. First, we focus on the model without any soft breaking and explore how the relic density and direct detection signals depend on the free parameters. We compare our predictions with the Planck observations [37] and the upper limits from the direct detection experiments Xenon1T [38] and LZ [39], including the very recent LZ results [40]. We find that, due to a strong correlation among the signals, the $\Sigma(36)$ -symmetric scalar sector is unable to account even for a part of DM density. This strong conclusion is the second lesson emerging from our study.

We then proceed to the softly broken $\Sigma(36)$ 3HDM, complemented with the S_3 symmetric Yukawa sector, and discuss in Section IV C the DM relic density and direct detection signals. As the tight correlation between the scalar masses and couplings is now relaxed, we find it possible to match the DM abundance or to remain in the sub-dominant DM scenario without violating observational constraints. However, even with these relaxed assumptions, we see a serious clash between theoretical constraints and the LZ-2024 direct detection results, which is the third lesson of our study. We place a lower bound on the magnitude of the soft breaking terms that allow us to reach minimally viable models, and comment on the origin of these persistent conflict between different experimental constraints.

II. THE SCALAR SECTOR OF THE $\Sigma(36)$ 3HDM

A. Structural rigidity and its consequences

Structural rigidity is the central theme of the symmetry-based multi-Higgs model building activity. Here, "rigidity" means that, for a sufficiently large finite group, the phenomenological properties of the model follow robust patterns insensitive to the exact numerical values of the parameters. The key goal is then to identify which pattern seems to (approximately) fit the observables and which multi-Higgs models lend support to such a pattern.

We find it instructive to remind the reader of the situation in which the particle physics found itself at the end of the 1970s. With the third generation of fermions just discovered, and their masses and mixing parameters measured, the hierarchical structure of the fermion masses and the Cabibbo-Kobayashi-Maskawa (CKM) matrix V_{CKM} called for explanations. The problem was optimistically attacked by constructing N-Higgs-doublet models with several generations of Higgs doublets. The scalar doublets were assumed to couple to fermions and among themselves in such a way that the lagrangian stayed invariant under a group G of global transformations acting both on the scalar and fermions fields. In this early activity, several options for the group G were studied, such as the groups of sign flips, rephasing transformations, permutations, or their combinations; for a brief historical overview see [41]. For example, the early suggestion [42] was based on the group of $\Delta(27) \subset SU(3)$ generated by the following order-3 rephasing and permutation transformations:

$$a = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \omega & 0 \\ 0 & 0 & \omega^2 \end{pmatrix}, \quad b = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix}, \quad \text{where} \quad \omega = e^{2\pi i/3}, \ \omega^3 = 1.$$
(1)

The idea of Ref. [42] was to "naturally" explain the mass and mixing hierarchies by assuming that the three Higgs doublets acquire hierarchical vevs $|v_1| \ll |v_2| \ll |v_3|$. However, as it was pointed out already in [42], the $\Delta(27)$ invariant scalar potential, with its limited structures and very few free parameters, was unable to yield such a vev alignment.

The failure of the $\Delta(27)$ -invariant 3HDM to reproduce the desired vevs was later understood as a particular example of a general phenomenon. Multi-Higgs potentials based on large finite symmetry groups possess a rigid structure of their minima [34, 43] and even saddle points [35]. Their vevs scale as simple ratios such as 1 : 1 : 1 and remain stable against smooth variation of the coefficients. Another manifestation of a rigid vev structure is the so-called geometric *CP* violation, the calculable relative phase between vevs, which was first noticed in [44] for the same $\Delta(27)$ 3HDM and later used in other multi-Higgs models [45–47].

Structural rigidity has far-reaching consequences for the fermion sector of the model. As it was first pointed out in [48], structural rigidity may render the quark sector unphysical at any minimum of a symmetryconstrained potential. A no-go theorem was formulated in [48] and later refined in [49], which states that the only way to obtain a non-block-diagonal CKM mixing matrix and, simultaneously, non-degenerate and non-zero quark masses is to make sure that vev alignment breaks the group G completely, except possibly for a symmetry belonging to the baryon number or a symmetry located purely within the inert sector (i.e. for the doublets which do not couple to quarks). But in potentials with a large symmetry group, there are always residual symmetries left at each of the possible minima. One popular way out is to add soft breaking terms, which can in many cases provide enough freedom to adjust vevs at least within some limits. A nice illustration of the above situation was given for the A_4 -invariant 3HDM: while the model with an exact A_4 symmetry always leads to pathological fermion sectors [50], adding soft breaking terms was enough to remove the unwanted residual symmetries and render the model compatible with experiment [51]. For the $\Delta(27)$ symmetric 3HDM, numerous attempts were undertaken to incorporate it into realistic models [45, 52–54], but all of them had to resort to additional non-SM fields, going beyond the pure multi-Higgs-doublet models, or even had to accept the massless fermions as a viable option as in [54].

Stabilization of scalar DM candidates is another manifestation of structural rigidity, as certain vevs can remain exactly zero in broad regions of the parameter space. Thus, rigidity can be either a welcome feature, as in the case of DM candidates, or a nuisance factor, as for the fermion sector. Whether one can keep its positive features and avoid its downsides remains to be analyzed in specific models.

B. The $\Sigma(36)$ 3HDM potential

Let us now describe and analyze the $\Sigma(36)$ 3HDM scalar sector. First, a technical remark is in order. The group $\Sigma(36)$ derived in the 3HDM symmetry classification [32, 33, 55] was, by constructed, considered as a subgroup of $PSU(3) \simeq SU(3)/Z(SU(3))$, where $Z(SU(3)) \simeq \mathbb{Z}_3 = \{\mathbb{1}_3, \omega \cdot \mathbb{1}_3, \omega^2 \cdot \mathbb{1}_3\}$ is the center of SU(3), see more discussion in Appendix A. However, since it is convenient to work with unitary, not projective representations, we will work inside SU(3). In this group space, the finite symmetry group we deal with is denoted as $\Sigma(36\varphi)$, or $\Sigma(36 \times 3)$, see e.g. [56, 57], and is of order 108. Although we will occasionally write $\Sigma(36)$ as in " $\Sigma(36)$ -based 3HDM," we will actually deal with $\Sigma(36\varphi)$.

The group $\Sigma(36\varphi)$, which can also be represented as $\Delta(27) \rtimes \mathbb{Z}_4$, is generated by the same *a* and *b* as in Eq. (1) and a new transformation *d* of order four:

$$d = \frac{i}{\sqrt{3}} \begin{pmatrix} 1 & 1 & 1\\ 1 & \omega^2 & \omega\\ 1 & \omega & \omega^2 \end{pmatrix}, \text{ so that } d^2 = - \begin{pmatrix} 1 & 0 & 0\\ 0 & 0 & 1\\ 0 & 1 & 0 \end{pmatrix}.$$
 (2)

The 3HDM scalar potential invariant under this group is

$$V_{0} = -m^{2} \left(\phi_{1}^{\dagger} \phi_{1} + \phi_{2}^{\dagger} \phi_{2} + \phi_{3}^{\dagger} \phi_{3} \right) + \lambda_{1} \left(\phi_{1}^{\dagger} \phi_{1} + \phi_{2}^{\dagger} \phi_{2} + \phi_{3}^{\dagger} \phi_{3} \right)^{2} \\ -\lambda_{2} \left[|\phi_{1}^{\dagger} \phi_{2}|^{2} + |\phi_{2}^{\dagger} \phi_{3}|^{2} + |\phi_{3}^{\dagger} \phi_{1}|^{2} - (\phi_{1}^{\dagger} \phi_{1})(\phi_{2}^{\dagger} \phi_{2}) - (\phi_{2}^{\dagger} \phi_{2})(\phi_{3}^{\dagger} \phi_{3}) - (\phi_{3}^{\dagger} \phi_{3})(\phi_{1}^{\dagger} \phi_{1}) \right] \\ +\lambda_{3} \left(|\phi_{1}^{\dagger} \phi_{2} - \phi_{2}^{\dagger} \phi_{3}|^{2} + |\phi_{2}^{\dagger} \phi_{3} - \phi_{3}^{\dagger} \phi_{1}|^{2} + |\phi_{3}^{\dagger} \phi_{1} - \phi_{1}^{\dagger} \phi_{2}|^{2} \right).$$

$$(3)$$

Here, the first two lines are invariant under the entire SU(3) group of family rotations of the three Higgs doublets, while the λ_3 term selects the finite group $\Sigma(36\varphi)$. This potential is also *CP* invariant [34, 55]; in fact, the \mathbb{Z}_4 symmetry group within the 3HDM scalar sector automatically forbids any form of *CP* violation in the scalar sector, be it explicit or spontaneous.

The potential in Eq. (3) contains very few free parameters. The coefficients m^2 and λ_1 fix the overall scales of the vev v and the SM-like Higgs mass, while the locations of the global minima depend on λ_2 and λ_3 . The conditions for the potential to be bounded from below (BFB) were derived in [35]:

$$\lambda_1 > 0, \quad \lambda_1 + \lambda_3 > 0, \quad \lambda_1 + \frac{1}{4}\lambda_2 > 0, \quad \lambda_1 + \frac{1}{4}(\lambda_2 + \lambda_3) > 0.$$
 (4)

All these inequalities are strict, meaning we must impose the BFB conditions in the strong sense [58].

C. The global minima and residual symmetries

Depending on the values of the quartic coefficients, the global minimum of the $\Sigma(36)$ 3HDM can be either neutral or charge-breaking. The latter option must be avoided at zero temperature, although existence of a charge-breaking phase at intermediate temperatures is an interesting and insufficiently explored opportunity for the hot early Universe evolution [35, 59]. The regions on the (λ_2, λ_3) plane that guarantee the neutral minimum of the tree-level potential were established in [35] and are listed below. The vev alignment corresponding to a neutral global minimum can be written as

$$\langle \phi_1 \rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v_1 \end{pmatrix}, \quad \langle \phi_2 \rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v_2 \end{pmatrix}, \quad \langle \phi_3 \rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v_3 \end{pmatrix}, \tag{5}$$

with v_i being, in general, complex. To simplify the notation, we will take the overall scale out, implicitly assuming that $|v_1|^2 + |v_2|^2 + |v_3|^2 = v^2$, where v = 246 GeV, and indicate the ratios between the individual vevs. For example, if a minimum corresponds to $v_1 = v_2 = v_3$, we write

$$(\langle \phi_1^0 \rangle, \langle \phi_2^0 \rangle, \langle \phi_3^0 \rangle) = \left(\frac{v_C}{\sqrt{2}}, \frac{v_C}{\sqrt{2}}, \frac{v_C}{\sqrt{2}}\right) = \frac{v_C}{\sqrt{2}} (1, 1, 1) , \text{ with } v_C = \frac{v}{\sqrt{3}} ,$$
 (6)

and label this vev alignment as (1, 1, 1).

Depending on the free parameters, $\Sigma(36)$ 3HDM allows for two scenarios for neutral minima [34, 35].

• BC-scenario: if $\lambda_2 > 0$ and $\lambda_3 > 0$, then the global minima correspond to the following vev alignments:

alignment B:
$$B_1 = (1, 0, 0), \quad B_2 = (0, 1, 0), \quad B_3 = (0, 0, 1)$$
 (7)

alignment C:
$$C_1 = (1, 1, 1), \quad C_2 = (1, \omega, \omega^2), \quad C_3 = (1, \omega^2, \omega).$$
 (8)

Other configurations such as $(\omega, \omega^2, 1)$ can be reduced to those already listed by an overall phase rotation of the three doublets. For example, $(\omega, \omega^2, 1) = \omega(1, \omega, \omega^2)$ corresponds to the alignment C_2 .

• AA'-scenario: if $\lambda_3 < 0$, while λ_2 satisfies $\lambda_2 - 3\lambda_3 > 0$, then the global minima correspond to

alignment A:
$$A_1 = (\omega, 1, 1), \quad A_2 = (1, \omega, 1), \quad A_3 = (1, 1, \omega)$$
 (9)

alignment A':
$$A'_1 = (\omega^2, 1, 1), \quad A'_2 = (1, \omega^2, 1), \quad A'_3 = (1, 1, \omega^2)$$
 (10)

In either case, we observe a similar picture: there are six degenerate global minima, which are all linked by the transformations from the group $\Sigma(36)$ broken by the vev alignment. For example, the broken transformation d links B_i and C_i . Also, no higher-lying local minima exists for any of these cases [35].

For any choice of the global minimum, the symmetry group $G = \Sigma(36)$ is spontaneously broken to the residual subgroup $G_v = S_3$. It is well known that any S_3 can be generated by two generators g_2 and g_3 satisfying $g_2^2 = g_3^3 = e$, $g_2^{-1}g_3g_2 = g_3^{-1}$. The specific transformations g_2 and g_3 from $\Sigma(36)$ that remain unbroken and generate this residual S_3 differ for each minimum. Here are several examples of the residual symmetry generators:

alignment
$$B_1 = (1, 0, 0)$$
: $g_2 = d^2$, $g_3 = a$. (11)

alignment
$$C_1 = (1, 1, 1)$$
: $g_2 = d^2$, $g_3 = b$. (12)

dignment
$$C_2 = (1, \omega, \omega^2)$$
: $g_2 = d^2 a$, $g_3 = b$. (13)

alignment
$$A_1 = (\omega, 1, 1)$$
: $g_2 = d^2$, $g_3 = ba^2$. (14)

Besides, each vev alignment conserves CP, either the canonical $CP_0 : \phi_a \mapsto \phi_a^*$ or a generalized CP symmetry which combines CP_0 with a transformation from $\Sigma(36)$. For example, the alignment A_1 is invariant under CP_0 followed by d.

D. The physical scalars and DM candidates

Since any choice of the global minimum leads to residual symmetries, we expect scalar DM candidates stabilized by these symmetries. The fact that the residual symmetry group is S_3 hints at a two-dimensional space of mass-degenerate DM candidates. This is the feature which we want to explore with our choice of the symmetry group $\Sigma(36)$.

In this subsection, we give the spectrum of physical scalars and indicate their conserved quantum numbers which protect them against decay. We remind the reader that, at this stage, we are working with the bosonic degrees of freedom only.

Let us begin with the *BC*-scenario and choose the vev alignment B_1 as a representative case. We expand the Higgs doublets around the minimum as

$$\phi_1 = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{2}h_1^+ \\ v + h_1 + ia_1 \end{pmatrix}, \quad \phi_2 = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{2}h_2^+ \\ h_2 + ia_2 \end{pmatrix}, \quad \phi_3 = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{2}h_3^+ \\ h_3 + ia_3 \end{pmatrix}.$$
(15)

6

The fields h_1^+ and a_1 are the would-be Goldstone bosons which disappear in the unitary gauge. The remaining fields are physical scalars with the following masses:

$$h_{SM} = h_1: \qquad m_{SM}^2 = 2\lambda_1 v^2 = 2m^2,$$
 (16)

$$H_2^+ = h_2^+, \ H_3^+ = h_3^+: \qquad m_{H^+}^2 = \frac{\lambda_2 v^2}{2} \quad \text{(double degenerate)}, \qquad (17)$$

$$h = \frac{1}{\sqrt{2}}(h_2 + h_3), \quad a = \frac{1}{\sqrt{2}}(a_2 - a_3): \qquad m_h^2 = \frac{\lambda_3 v^2}{2} \quad \text{(double degenerate)}, \tag{18}$$

$$H = \frac{1}{\sqrt{2}}(h_2 - h_3), \quad A = \frac{1}{\sqrt{2}}(a_2 + a_3): \qquad m_H^2 = \frac{3\lambda_3 v^2}{2} \quad \text{(double degenerate)}. \tag{19}$$

Assuming $\lambda_2 > \lambda_3$, the neutral fields h and a indicated in the third line are the DM candidates. Since they are mass degenerate, one can alternatively choose any linear combination of h and a, which can also be considered as the DM candidate. Indeed, the residual symmetry group S_3 given in Eq. (11) acts on h and a by $2\pi/3$ rotations and reflections in the (h, a) plane. Thus, the pair (h, a) forms a real 2D irreducible representation of S_3 , and it is this 2D space of spaces which is stabilized by the residual group.

For the AA'-scenario, we choose the alignment $A_3 = (1, 1, \omega)$ and parametrize the doublets as

$$\phi_1 = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{2}h_1^+ \\ v_A + h_1 + ia_1 \end{pmatrix}, \quad \phi_2 = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{2}h_2^+ \\ v_A + h_2 + ia_2 \end{pmatrix}, \quad \phi_3 = \frac{\omega}{\sqrt{2}} \begin{pmatrix} \sqrt{2}h_3^+ \\ v_A + h_3 + ia_3 \end{pmatrix}, \quad (20)$$

where $v_A = v/\sqrt{3}$. Note that we took the phase factor ω out of the third doublet. The mass of the SM-like Higgs is again

$$h_{\rm SM} = \frac{1}{\sqrt{3}}(h_1 + h_2 + h_3): \quad m_{\rm SM}^2 = 2(\lambda_1 + \lambda_3)v^2 = 2m^2.$$
 (21)

The charged Goldstone is $G^+ = (h_1^+ + h_2^+ + h_3^+)/\sqrt{3}$, while the two charged Higgses orthogonal to it are again mass degenerate:

$$H_2^+, H_3^+ \perp G^+: \quad m_{H^+}^2 = \frac{v^2}{2}(\lambda_2 - 3\lambda_3).$$
 (22)

To find the remaining four neutral mass eigenstates, we define

$$h_{-} = \frac{1}{\sqrt{2}}(h_{1} - h_{2}), \quad h_{+} = \frac{1}{\sqrt{6}}(h_{1} + h_{2} - 2h_{3}), \quad a_{-} = \frac{1}{\sqrt{2}}(a_{1} - a_{2}), \quad a_{+} = \frac{1}{\sqrt{6}}(a_{1} + a_{2} - 2a_{3}), \quad (23)$$

and observe that the neutral mass matrix splits into two identical 2×2 blocks \mathcal{M}_2 acting within the spaces (h_-, a_-) and (h_+, a_+) :

$$\mathcal{M}_2 = -\frac{\lambda_3 v^2}{4} \begin{pmatrix} 5 & \sqrt{3} \\ \sqrt{3} & 3 \end{pmatrix}.$$
 (24)

Inside (h_{-}, a_{-}) , the eigenvectors and eigenvalues are

$$h = -\frac{1}{2}h_{-} + \frac{\sqrt{3}}{2}a_{-} : \qquad m_{h}^{2} = -\frac{\lambda_{3}v^{2}}{2}$$
$$H = \frac{\sqrt{3}}{2}h_{-} + \frac{1}{2}a_{-} : \qquad m_{H}^{2} = -\frac{3\lambda_{3}v^{2}}{2}.$$
 (25)

Note that A, A' can be the minima only for $\lambda_3 < 0$. We observe the same mass hierarchy $m_H^2 = 3m_h^2$ as in Eqs. (18), (19). The construction of the physical states in the space (h_+, a_+) proceeds in the same way, yielding a and A. Thus, we again have two mass degenerate DM candidates, h and a.

E. DM stabilization by a group vs. by a single symmetry

In the above discussion, we state that the DM candidates are stabilized by the residual symmetry group S_3 rather than by individual residual symmetries. This language may be somewhat unconventional but it is fully

$$\chi = \frac{1}{\sqrt{2}}(h+ia), \quad \chi^* = \frac{1}{\sqrt{2}}(h-ia)$$
(26)

and say that they are stabilized by the residual \mathbb{Z}_3 symmetry, under which they transform with the charges +1 and -1. Although such a representation may be useful to identify the semi-annihilation channel $\psi\psi \rightarrow \psi^* + SM$, it still does not capture the full picture. The full information on DM stabilization is provided by indicating that it is the group S_3 that protects the two real component scalar DM candidates.

Stabilization by a non-abelian group leads to another important feature, which prevents an immediate clash with experiment that other models with two mass-degenerate scalar DM candidates may possess. Consider again the IDM, the 2HDM with the residual symmetry group \mathbb{Z}_2 . In this model, H is the lightest DM candidate stabilized by \mathbb{Z}_2 , and A is a heavier state, which is also \mathbb{Z}_2 odd. Being members of the same doublet and possessing the opposite CP parities, the two scalars can interact through the ZHA interaction:

$$\mathcal{L} \supset i \frac{g}{2c_W} Z^{\mu} \left(H \partial_{\mu} A - A \partial_{\mu} H \right) \,. \tag{27}$$

Then, in the mass-degenerate limit of $m_A = m_H$, we find that the DM particles can elastically scatter off a nucleus via the transitions $H \to A$ and $A \to H$ mediated by the Z-exchange. This scattering would lead to an unacceptable large direct detection (DD) signal and is definitely ruled out by the negative results of DD searches.

One may wonder if the two degenerate DM candidates h and a, which our model contains, can also couple to the Z bosons in a similar way. Fortunately, they do not; we observe only the ZhA and ZHa vertices but not Zha. The reason is again group-theoretical. Since (h, a) form a doublet under S_3 , their hypothetical interaction terms with Z must be of the type $\mathbf{2} \otimes \mathbf{2} = \mathbf{1} \oplus \mathbf{1}' \oplus \mathbf{2}$. Since the conserved S_3 does not act on the Z, we must select the trivial singlet, which involves only the diagonal combinations. But the Zhh and Zaa couplings are impossible by construction, and the non-symmetric Zha does not enter the trivial S_3 singlet. We conclude that the residual group S_3 protects the model against the Zha interactions.

Finally, stabilization of DM by S_3 differs from the case of $\mathbb{Z}_2 \times \mathbb{Z}_2$ in that it allows for semi-annihilation channels such as $hh \to a + SM$. This is due to the fact that the S_3 decomposition of $\mathbf{2} \otimes \mathbf{2}$, which corresponds to the S_3 quantum numbers of the initial state, contains a $\mathbf{2}$, which matches the final state quantum numbers.

III. BUILDING REALISTIC $\Sigma(36)$ -BASED DARK MATTER MODELS

A. A toy model: exact $\Sigma(36)$ in the Yukawa sector

In order to track the freeze-out evolution of DM density and explore the interplay of two DM candidates, one must complement the scalar interactions with a minimally realistic Yukawa sector. In this section, we describe our attempt to extend the full symmetry group $\Sigma(36)$ to the quark Yukawa. The no-go theorem proved [48, 49] makes it clear that, even if such a sector can be constructed, the resulting quark properties cannot fully match the experimentally measured values and will unavoidably display pathologies such as massless quarks and insufficient mixing parameters. Nevertheless, since the main goal of our study is to check the evolution of scalar DM stabilized by a non-abelian residual group, we find it appropriate to embrace this situation, considering it as a toy model, provided the scalar DM candidates remain stable.

To set up notation, we write the quark Yukawa sector of the 3HDM as

$$-\mathcal{L}_Y = \overline{Q}_{Li}^0 \Gamma_{a,ij} \phi_a d_{Rj}^0 + \overline{Q}_{Li}^0 \Delta_{a,ij} \tilde{\phi}_a u_{Rj}^0 + h.c.$$
(28)

Here, the indices i, j = 1, 2, 3 refer to the quark generations, while a = 1, 2, 3 label the Higgs doublets. The superscript 0 for the quark fields indicates that these are the starting quark fields; when we pass to the physical quarks by diagonalizing their mass matrices, we will remove this superscript.

To construct the $\Sigma(36)$ -invariant quark Yukawa sector, we need to assign the quark fields Q_L , d_R , and u_R to specific group representations, follow the rules for decomposition of their products, and extract the trivial singlet. To do this, we first briefly review the irreducible representations (irreps) of $\Sigma(36\varphi)$, reproducing some of the results of [56, 57].

The finite group $\Sigma(36\varphi)$ has four 1D irreps labeled $\mathbf{1}^{(p)}$, p = 0, 1, 2, 3, which trivially represent the generators a and b, $\rho_{1^{(p)}}(a) = \rho_{1^{(p)}}(b) = 1$, and differ only by the representing value of the generator d: $\rho_{1^{(p)}}(d) = i^p$. For shorthand notation, we will denote the trivial representation $\mathbf{1}^{(0)}$ as $\mathbf{1}$. Next, it has four complex 3D irreps $\mathbf{3}^{(p)}$, whose $\rho_3(a)$ and $\rho_3(b)$ are given by Eq. (1) and whose $\rho_3(d)$ is as in Eq. (2) with the same extra factor i^p . These are complemented by the four conjugate triplets $(\mathbf{3}^{(p)})^*$. Finally, the group possesses two real 4D irreps, $\mathbf{4}$ and $\mathbf{4}'$, which we will not encounter in our construction. The squares of the irrep dimensions sum up to the group order as $\sum_i d_i^2 = 4 \times 1 + 8 \times 3^2 + 2 \times 4^2 = 108$.

In Appendix B, we collect the irrep decomposition rules for the products of a triplet with another triplet or an antitriplet. These rules follow a uniform pattern, which allows us, without losing generality, to assign the Higgs doublets to $\mathbf{3}^{(0)}$, which we shorten as $\mathbf{3}$. Then, the two most relevant decomposition rules are

$$\mathbf{3} \otimes \mathbf{3}^* = \mathbf{1} \oplus \mathbf{4} \oplus \mathbf{4}', \qquad \mathbf{3} \otimes \mathbf{3} = \mathbf{3}^* \oplus (\mathbf{3}^{(1)})^* \oplus (\mathbf{3}^{(3)})^*.$$
 (29)

It is instructive to compare this situation with the irreps of $\Delta(27)$ and their product decomposition, which can be found, for example, in [60]. The group $\Delta(27)$ has nine distinct 1D irreps $\mathbf{1}_{ij}$, which are labeled by the powers of ω in their $\rho_1(a)$ and $\rho_1(b)$, and two complex 3D irreps, **3** and **3**^{*}. As a result, **3** \otimes **3**^{*} decomposes into the sum of all nine distinct singlets. This feature makes the group convenient for flavor model building. Indeed, assuming that ϕ_a and Q_{Li} transform as **3**, one can assign each individual d_{Rj} to a different singlet, which introduces flexibility in building the Yukawa sector [54]. In the case of $\Sigma(36\varphi)$, this freedom is strongly reduced, because the product **3** \otimes **3**^{*} involves now only one singlet.

In Appendix B, we list all classes of irrep assignments for the quark fields. Although the Yukawa matrices Γ_a and Δ_a depend on cases, the consequences are similar: in each sector, we obtain massless or mass degenerate quarks and insufficient mixing. For example, in the case where Q_L are trivial singlets, d_R transform as $\mathbf{3}^*$, and u_R transform as $\mathbf{3}$, the three Yukawa matrices Γ_a take the following form:

$$\Gamma_1 = \begin{pmatrix} g_1 & \cdot & \cdot \\ g_2 & \cdot & \cdot \\ g_3 & \cdot & \cdot \end{pmatrix}, \quad \Gamma_2 = \begin{pmatrix} \cdot & g_1 & \cdot \\ \cdot & g_2 & \cdot \\ \cdot & g_3 & \cdot \end{pmatrix}, \quad \Gamma_3 = \begin{pmatrix} \cdot & \cdot & g_1 \\ \cdot & \cdot & g_2 \\ \cdot & \cdot & g_3 \end{pmatrix}, \quad (30)$$

where dots correspond to the zero entries. The three independent coefficients g_i are in general complex. In the up-quark sector, the matrices Δ_a have the same structure, bearing their own parameters d_i . The quark mass matrices become rank-1 matrices: $(M_d)_{ij} = g_i v_j / \sqrt{2}$, $(M_u)_{ij} = d_i v_j^* / \sqrt{2}$. Diagonalizing these matrices, we find two generations of massless quarks in the down and up-quark sectors and one generation of massive ones, with $m_b^2 = v^2 |\vec{g}|^2/2$ and $m_t^2 = v^2 |\vec{d}|^2/2$. These masses do not depend on the vev alignment.

Since the mass matrices can be diagonalized analytically, we write the quark rotation matrices explicitly, insert them back in the Yukawa lagrangian, and, for a each choice of the vev alignment, establish how physical scalars interact with quark pairs. Taking the vev alignment B_1 as a reference, we find the following interaction terms for the DM candidates h and a:

$$-\mathcal{L}_Y \supset \frac{m_b}{v} \bar{b}_L \left[(d_R + s_R)h + i(d_R - s_R)a \right] + \frac{m_t}{v} \bar{t}_L \left[(u_R + c_R)h - i(u_R - c_R)a \right] + h.c.$$
(31)

We arrive at a very concrete conclusion: the scalars h and a, which we considered as DM candidates in the previous section, cannot be stable as they unavoidable decay to quark pairs with unsuppressed couplings.

We checked that this key result remains valid for all other vev alignments as well as for all the irrep choices that can lead to $\Sigma(36)$ -symmetric Yukawa sectors, even though the patterns of the Yukawa matrices and the Higgs-quark couplings can be distinct. For completeness, in Appendix C we provide more details for each case.

In summary, when building an exactly $\Sigma(36)$ -invariant Yukawa sector, there is no way to avoid tree-level decays of the anticipated DM candidates to quark pairs. These scalars are intrinsically unstable and cannot play the role of dark matter. The main obstacle is that quarks also carry the conserved quantum numbers with respect to the same group S_3 that was used to stabilize the scalars h and a. Thus, these scalars are no longer forbidden to decay into quark pairs.

B. A realistic model: S_3 -symmetric Yukawa sector and softly broken $\Sigma(36)$

Since the exact $\Sigma(36)$ in the Yukawa sector leads not only to the pathological quark sector but also to unavoidable decays of the anticipated DM candidates, we need to relax our assumptions. We can construct a realistic model using the same $\Sigma(36)$ -invariant scalar potential (3) and complementing it with a Yukawa sector that is invariant not under the full $\Sigma(36)$ but under a S_3 subgroup. Moreover, we require this S_3 to be exactly the same residual S_3 that remains unbroken at the minimum.

The specific example we consider is the vev alignment $B_1 = (1, 0, 0)$, with the residual symmetry group S_3 given in Eq. (11). The doublet ϕ_1 is now the trivial singlet of S_3 , while ϕ_2 and ϕ_3 transform as a doublet irreducible representation. In the Yukawa sector, we assume that all quarks transform trivially under S_3 , so that they couple only to the first doublet with the SM Yukawa matrices. In this way, the doublets ϕ_2 and ϕ_3 become truly inert, and their lightest states are indeed stable.

Of course, the full $\Sigma(36)$ is no longer a conserved symmetry group of the entire lagrangian. As a result, $\Sigma(36)$ -breaking terms will leak, via quark loops, from the Yukawa sector back into the scalar sector. Instead of calculating these terms, we take a different strategy and add soft breaking terms to the scalar potential that violate the full $\Sigma(36)$ but preserve S_3 . Various soft breaking options for the $\Sigma(36)$ 3HDM were discussed in [35, 61]. If we fix v and m_h , then there is only one type of S_3 -preserving soft breaking terms,

$$V_{\rm soft} = \mu^2 (\phi_2^{\dagger} \phi_2 + \phi_3^{\dagger} \phi_3), \qquad (32)$$

which must be added to the potential V_0 given in Eq. (3). The requirement that the vev alignment B_1 is the global minimum corresponds to $\mu^2 > 0$. Since the symmetry group S_3 is unbroken, we still have the two DM candidates h and a with the bosonic interactions coming from the scalar potential and the kinetic terms. Compared to Eqs. (17)–(19), the soft breaking term leads to a uniform shift of the masses of all the scalars from the second and third doublets keeping the physical scalar doublet degenerate:

$$(H_2^+, H_3^+): \quad m_{H^+}^2 = \mu^2 + \frac{\lambda_2 v^2}{2}, \qquad (h, a): \quad m_h^2 = \mu^2 + \frac{\lambda_3 v^2}{2}, \qquad (H, A): \quad m_H^2 = \mu^2 + \frac{3\lambda_3 v^2}{2}.$$
(33)

We then choose m_h , $m_{H^+} > m_h$, and μ^2 as the three independent free parameters² and express the quartic couplings λ_2 and λ_3 by inverting the first two relations from Eq. (33), while the heavy inert Higgs mass is given by $m_H^2 = 3m_h^2 - 2\mu^2$. Note that all three quantities μ^2 , λ_2 , λ_3 must be positive for the global minimum to reside at B_1 . Also, due to the present of μ^2 , the model now has a well-defined decoupling limit.

We still call this model the $\Sigma(36)$ -based DM model. Although the exact symmetry group is S_3 , the quartic potential is the same as in the $\Sigma(36)$ -symmetric 3HDM, which constrains in a significant way the types of interactions and imposes correlations among the couplings. This model "inherits" certain features from the $\Sigma(36)$ -symmetric 3HDM [61], and this is why we distinguish it from a generic S_3 -based 3HDM DM models [62, 63].

IV. DARK MATTER PROPERTIES IN THE $\Sigma(36)$ -BASED 3HDM

A. Constraints on the model and comparison with the IDM

We implemented the $\Sigma(36)$ -based DM model just described in micrOMEGAs [36], which allowed us to explore the relic density and direct detection (DD) signals as functions of the free parameters of the model. Note that the model features an exact scalar alignment limit, which allows us to evade most of the phenomenological constrains on the SM-like Higgs measurements. We must, however, take into account the important constraint on the model coming from the SM-like Higgs decay to the DM candidates, which exists for sufficiently light hand a. The negative results of the LHC searches for an invisible Higgs decay [64] lead to the upper limit on its branching ratio, $B_{inv} < 0.107$, which translates into $\Gamma(h_{SM} \to inv.) < 0.42$ MeV.

To discuss the resulting constraints on the free parameters of our model, we find it instructive to compare it with the IDM in the notation of [7–9]. The scalar potential of the IDM contains seven free parameters. After fixing v and $m_{\rm SM}$, we still have five real parameters to adjust, which affect the IDM phenomenology. Among them, the key role is played by the trilinear $h_{\rm SM}$ -DM-DM coupling divided by v, which is traditionally labeled as λ_{345} . This coefficient sets the magnitude of several important processes, such as DM annihilation through the s-channel Higgs resonance and the invisible Higgs decay to light DM candidates. It also contributes to the quartic vertices $hhW_L^+W_L^-$ and hhZ_LZ_L to be discussed below. The key feature is that, within the IDM, this all-important λ_{345} is an independent parameter, not directly related to the scalar masses. It can be chosen

² Another possible choice of the three free parameters is m_h , m_H , and $m_{H^+} > m_h$.

sufficiently small, $|\lambda_{345}| \leq 0.04$, so that, for the light DM candidates, the Higgs invisible decay width stays suppressed.

However, in our model, the coefficient in the vertices $h_{\rm SM}hh$ and $h_{\rm SM}aa$ is not an independent parameter but is expressed via masses of the $h_{\rm SM}$ and the SM candidates:

$$h_{\rm SM}hh, \ h_{\rm SM}aa: \quad \bar{\lambda}v \equiv (2\lambda_1 + \lambda_3)v = \frac{m_{\rm SM}^2 + m_H^2 - m_h^2}{v} = \frac{m_{\rm SM}^2 + 2m_h^2 - 2\mu^2}{v},$$
 (34)

which is never too small. It is at least as large as v/4 and grows further as the inert sector mass splitting increases. This coefficient leads to a huge invisible decay width of the SM-like Higgs

$$\Gamma(h_{\rm SM} \to hh, aa) = \frac{(m_{\rm SM}^2 + 2m_h^2 - 2\mu^2)^2}{16\pi m_{\rm SM} v^2} \beta, \quad \text{where } \beta = \sqrt{1 - \frac{4m_h^2}{m_{\rm SM}^2}}.$$
(35)

For $m_h^2 = \mu^2$, it yields 640 MeV $\cdot \beta$ and exceeds the experimental upper limit by orders of magnitude. Even the nominal threshold $m_{\rm SM} = 2m_h$ is excluded: a slightly off-shell Higgs boson with the invariant mass exceeding the nominal value $m_{\rm SM}$ by a few $\Gamma_{\rm SM}$ would already generate an unacceptably large signal. This analysis implies that in our model, unlike in the IDM, the light DM region $m_h \leq m_{\rm SM}/2$ is altogether ruled out.

FIG. 1. The ratio $R_{\gamma\gamma}$ defined in Eq. (36) as a function of he charged Higgs mass for several values of μ^2 compared with the LHC results for the 2σ and 3σ bands around the central value.

The presence of inert scalars also modifies the loop-induced decays of the SM-like Higgs, in particular, $h_{\rm SM} \rightarrow \gamma \gamma$. Let us denote the modification of this decay width with respect to the SM prediction as

$$R_{\gamma\gamma} = \frac{\Gamma(h_{\rm SM} \to \gamma\gamma)}{\Gamma(h_{\rm SM} \to \gamma\gamma)^{\rm SM}} \,. \tag{36}$$

The expression for this decay width can be recovered from the generic 2HDM result [65]:

$$\Gamma(h_{\rm SM} \to \gamma \gamma) = \frac{G_F \alpha^2 m_{\rm SM}^3}{128\sqrt{2}\pi^3} \left| \sum_f N_c Q_f^2 A_{1/2}(\tau_f) + A_1(\tau_W) + 2 \times \frac{m_{\rm SM}^2 + 2m_{H^+}^2 - 2\mu^2}{2m_{H^+}^2} A_0(\tau_+) \right|^2, \quad (37)$$

while for the SM expression we simply omit the last contribution. The factor 2 in the last term shows that both H_2^+ and H_3^+ give equal contributions. Following [65], for a particle with mass m_i , we define the mass ratio as $\tau_i = m_{\rm SM}^2/(4m_i^2)$ and use the formfactors

$$A_0(\tau) = -\frac{\tau - f(\tau)}{\tau^2}, \quad A_{1/2}(\tau) = 2\frac{\tau + (\tau - 1)f(\tau)}{\tau^2}, \quad A_1(\tau) = -\frac{2\tau^2 + 3\tau + 3(2\tau - 1)f(\tau)}{\tau^2}, \tag{38}$$

where

$$f(\tau) = \left\{ \arcsin^2 \sqrt{\tau} \ \text{for } \tau \le 1, \quad -\frac{1}{4} \left[\log \left(\frac{1 + \sqrt{1 - \tau^{-1}}}{1 - \sqrt{1 - \tau^{-1}}} \right) - i\pi \right]^2 \ \text{for } \tau > 1 \right\}.$$
(39)

The structure of the charged Higgs contribution closely resembles the IDM counterpart [66–69]. However, unlike in the IDM, the sign of the coefficient is fixed, which leads to $R_{\gamma\gamma} < 1$ for a heavy charged Higgs.

The coefficient in the last term of Eq. (37) makes it clear that, without the soft breaking terms, the contribution of the charged Higgses is not negligible. We find that, for $\mu^2 = 0$ and heavy charged Higgses, $R_{\gamma\gamma}$ is as low as 0.8, which is already ruled out by the LHC measurements [70]: $R_{\gamma\gamma}^{exp.} = 1.10 \pm 0.06$. However, a non-zero μ^2 reduces the tension, provided the charged Higgs mass stays close to μ . In Fig. 1, we show the behavior of $R_{\gamma\gamma}$ as a function of $m_{H^+}^2$ for several values of μ^2 . As we can see, the $R_{\gamma\gamma}$ curves can reach 0.92, which lies within 3σ of the central experimental value, only for $\mu^2 > (150 \text{ GeV})^2$, and can exceed 0.98 (2σ band) only for $\mu^2 > (350 \text{ GeV})^2$.

We arrive at the conclusion that the charged Higgs contributions to $h_{\rm SM} \to \gamma \gamma$ are very sizable and, in the absence of any additional contribution to compensate their effect, rule out the $\Sigma(36)$ symmetric scalar sector. The only way to bring $h_{\rm SM} \to \gamma \gamma$ back within experimental limits is to assume a sufficiently large soft breaking term.

B. DM properties: no soft breaking

FIG. 2. Combined relic density of h and a in the 3HDM with an exact $\Sigma(36)$. Left: the relic density encoded in color on the parameter plane (m_h, m_{H^+}) . Right: the relic density as a function of m_h for several values of m_{H^+} .

Keeping the above results in mind, we turn now to the study of the relic density as a function of the free parameters. We begin the presentation of our results with the case of the $\Sigma(36)$ -symmetric scalar sector, that is, the model without soft breaking terms, $\mu^2 = 0$. Although the measurements of the two photon decay width effectively rule out this scenario, we still want to see whether additional problems arise from the DM sector alone.

When exploring the relic density evolution, we always observe that h and a give equal contributions. This is of course expected due to the symmetry that links h and a, the two components of the S_3 doublet. Thus, when showing the values for Ωh^2 , we will always present the sum of their contributions.

In Fig. 2, we show the resulting relic density Ωh^2 as a function of the two remaining free parameters m_h and m_{H^+} . The left plot shows the results of a general scan, with the relic density encoded in color, while the left plot reveals finer details of Ωh^2 as a function of m_h for several representative values of m_{H^+} that go up to 1 TeV. The shaded region in the right plot corresponds to $m_h < m_{\rm SM}/2$ and is excluded by the invisible decay width.

A salient feature of these plots is that, for $m_h > 45$ GeV, the relic density is always below the Planck result [37]: $(\Omega h^2)_{\text{Planck}} = 0.1200 \pm 0.0012$. This is due to the rather large annihilation, coannihilation, and semi-annihilation cross sections. The only region where the predicted relic density matches the Planck result is the narrow band around $m_h \approx 40$ GeV, but this low mass region is already excluded by the invisible Higgs decay constraint.

The low relic density in the high-mass region can also be understood by comparing our model with the IDM. In the IDM with heavy DM candidates, annihilation mainly proceeds into the longitudinally polarized

 W^+W^- and ZZ pairs [8], which are dominated by the quartic vertices

$$hhW_L^+W_L^-(\text{IDM}): \quad \lambda_{345} + \frac{2(m_H^2 - m_h^2)}{v^2}, \qquad hhZ_LZ_L(\text{IDM}): \quad \lambda_{345} + \frac{2(m_{H^+}^2 - m_h^2)}{v^2}.$$
 (40)

As mentioned earlier, λ_{345} is an independent parameter and can be chosen small. If the mass splitting in the inert sector is also small, the annihilation cross section is suppressed, and the relic density can match the observed value. This is the mechanism behind the high-mass region of the IDM, which still remains viable.

However, in the $\Sigma(36)$ model, these couplings are

$$hhZ_LZ_L: \quad 2\lambda_1 + 3\lambda_3 = \bar{\lambda} + \frac{2(m_H^2 - m_h^2)}{v^2}, \qquad hhW_L^+W_L^-: \quad 2\lambda_1 + \lambda_2 = \bar{\lambda} + \frac{2(m_{H^+}^2 - m_h^2)}{v^2}, \qquad (41)$$

where $\bar{\lambda}$ is given in Eq. (34). Both expressions are never small. The minimal value for the hhZ_LZ_L coupling in the exactly $\Sigma(36)$ -symmetric scalar sector is $5m_{\rm SM}^2/2v^2 \approx 0.6$ and further grows approximately as m_h^2 . This explains why, for large DM masses, we always obtain the relic density significantly below the observed value.

We conclude that the model can account only for a small fraction of total dark matter. Although it still leaves open the question of the origin of the dominant DM component, this sub-dominant DM scenario is, in principle, viable.

Next, we confront this model with the direct detection limits. Let us denote by $\xi_{\Omega} = \Omega/\Omega_{\text{Planck}}$ the fraction of the total relic density constituted by h and a. Then, we can compute the DD signal expected in this case, taking into account the sub-dominant DM scenario we work in, and compare it with the experimental upper limits on the spin-independent cross section σ_{SI} established by the DD searches. Instead of up-scaling the published upper limits on σ_{SI} for such a comparison, we downscale our predicted cross section by defining

$$\hat{\sigma}_{SI} = \sigma_{SI} \cdot \xi_{\Omega} \,, \tag{42}$$

and directly compare it with the published results.

FIG. 3. The rescaled cross section for the direct detection signal $\hat{\sigma}_{SI} = \sigma_{SI} \cdot \xi_{\Omega}$ obtained in our model, compared with the upper limits from recent DD experiments.

In Fig. 3 we present this comparison. Even with the scaling down taken into account, the model predicts rather large DD signals. This is unavoidable because the DM-Higgs interaction is governed by the same coupling $\overline{\lambda}$ as in Eq. (34). Still, there remains a sizable part of the random scan which passes the limits obtained by the Xenon1T experiment. However, these predictions are in a clear conflict with the upper limits announced by the LZ experiment both in 2022 [39] and especially in 2024 [40], definitely ruling out the model we consider.

The bottom line is: with the latest LZ-2024 result, the scenario featuring two DM candidates arising within the 3HDM with an exact $\Sigma(36)$ symmetry in the scalar sector is ruled out.

C. DM properties with soft breaking terms

Next, we introduce the soft breaking terms (32) and explore the consequences for the DM observables. In Fig. 4, left, we show how the DM relic density depends on $\mu^2 > 0$. The light and dark shaded green

FIG. 4. Left: The total relic density in the 3HDM for three values of the soft breaking parameter μ^2 and several options for $m_{H^+} - m_h$, see the main text. Right: The region in the $(m_{H^+} - m_h, m_h)$ parameter space in which the relic density computed with a suitable μ^2 can match the Planck results.

points correspond to the exactly $\Sigma(36)$ -symmetric scalar sector with $m_{H^+} - m_h = 10 \text{ GeV}$ and 100 GeV; they agree with Fig. 2, right. The red and blue families of points correspond to $\mu^2 = (250 \text{ GeV})^2$ and $(460 \text{ GeV})^2$, respectively. In both cases, the three sequences of points, from top to bottom, refer to $m_{H^+} - m_h = 0.1 \text{ GeV}$, 10 GeV, and 100 GeV. As expected, if m_h is fixed but μ increases, the annihilation cross section goes down, and as a result the relic density rises.

Fig. 4, left, indicates that, for $\mu^2 > (460 \text{ GeV})^2$ and with a small mass splitting, a region of parameters opens up, in which the calculated relic density matches the Planck measurements. For a better visualization, we show this region in Fig. 4, right, on the plane of the mass splitting $m_{H^+} - m_h$ vs. m_h . For any choice of masses m_{H^+} and m_h that fall inside the blue region, it is possible to find a suitable μ^2 that leads to the total relic density that matches the Planck result. For masses m_{H^+} and m_h outside this region, one always obtains subdominant scalar DM for any choice of μ^2 . It is interesting to note that this borderline value of μ is very similar to the value of the DM mass in the IDM, $m_{DM} \sim 500$ GeV, above which the so-called heavy mass region with a matching relic density opens up [6–8].

FIG. 5. The rescaled cross section for the direct detection signal $\hat{\sigma}_{SI} = \sigma_{SI} \cdot \xi_{\Omega}$ for $\mu^2 = (250 \text{ GeV})^2$ and $(460 \text{ GeV})^2$, compared with the experimental upper limits.

In Fig. 5, we show how the rescaled cross section for the direct detection signal $\hat{\sigma}_{SI}$ changes as μ^2 grows. We show the predictions for the same soft breaking parameter values: $\mu^2 = (250 \text{ GeV})^2$ and $(460 \text{ GeV})^2$. For DM mass well above μ , the rescaled DD signals still hover above the upper limits from LZ, similarly to the case $\mu^2 = 0$, and are not significantly suppressed with μ^2 variation. This behavior can be understood by noticing once more that the same $\bar{\lambda}$, which is never too small, both sets the DM scattering process as in Eq. (34) and drives the annihilation cross section, Eq. (41). If we fix a large m_h and increase μ^2 , the DD cross section goes down, but the relic density fraction goes up, and the two effects approximately compensate each other in the rescaled DD signal.

The only way to keep DD cross section low and, at the same time, further suppress relic density is to keep $\bar{\lambda}$ small and increase the charged Higgs mass. This is what we observe for m_h very close to μ . In particular,

we find that the model with $\mu^2 = (460 \text{ GeV})^2$ is, in principle, capable of bringing the DD signal below not only LZ-2022 but also the latest LZ-2024 upper limits [40]. However, this is done at the expense of a large λ_2 ; we checked that the lowest lying points in Fig. (5), right, correspond to $m_{H^+} > 720$ GeV, which translates into λ_2 above 10. Also, the large mass splitting between H, A and $H_{2,3}^+$, which arises in this case, drives the electroweak precision observables far beyond the experimental limits.

We conclude that the tight correlations arising in our model even in the softly broken regime, once more, lead the predictions to severe clashes with theoretical and experimental constraints. It may prove useful to extend the parameter μ^2 to even larger values in a quest for a fully viable DM model. But we believe that the present study clearly indicates the persistent problems that arise in this and other similar DM models based on a multi-Higgs-doublet with very large finite symmetry groups.

V. DISCUSSION AND CONCLUSIONS

In this paper we addressed the question whether scalar DM candidates stabilized by a non-abelian residual group is a viable option within multi-Higgs-doublet models. A conserved non-abelian group not only protects the multiplet of DM candidates against decay but also gives rise to additional DM evolution channels. In contrast to previous works, in which a non-abelian group protected dark sector, by construction, was nearly decoupled from the SM fields, we considered a multiplet of DM candidates emerging from additional inert electroweak scalar doublets that enter the same Higgs potential that leads to the SM-like Higgs boson. As the benchmark example, we used the $\Sigma(36)$ -based 3HDM [32, 33] and took the advantage of its property that, for any choice of its free parameters, the global minimum of the potential always preserves a non-abelian subgroup $S_3 \subset \Sigma(36)$ and therefore always stabilizes a pair of mass degenerate DM candidates [34].

Due to very tight symmetry-based relations between the SM-like Higgs, the quark sector, and the dark sector, we found that this idea repeatedly runs into conflict with observations.

- The 3HDM Yukawa sector invariant under the exact $\Sigma(36)$ not only leads to non-physical quark properties but also destabilizes all the scalars, rendering a realistic quark sector incompatible with DM candidates. To avoid this problem, we relaxed our assumptions and built the Yukawa sector invariant not under the full $\Sigma(36)$ but under S_3 , the same subgroup that remains unbroken after minimization.
- The extra charged Higgses significantly reduce the $h_{\rm SM} \rightarrow \gamma \gamma$ decay width, which conflicts the LHC measurements. As the $h_{\rm SM}$ coupling with DM is never suppressed, the unsuppressed invisible Higgs decay rules out this model for $m_h < m_{\rm SM}/2$.
- If the scalar sector respects the full $\Sigma(36)$ symmetry, the scalar DM is unavoidably subdominant and, at the same time, enters in conflict with the direct detection results from the LZ experiment [40]. The bottom line is that the model with an exactly $\Sigma(36)$ -symmetric scalar sector complemented with S_3 invariant Yukawa interactions is ruled out.
- The soft breaking terms governed by the single new free parameter μ² can relax the tension. These soft breaking terms violate Σ(36) but preserve the same S₃ that remains as a residual symmetry group at the minimum, thus, supporting the same pair of DM candidates stabilized by the residual non-abelian group. Still, the quartic potential inherits many features of the exact Σ(36) 3HDM and remains very constrained. A moderately large μ > 350 GeV can bring the h_{SM} → γγ within the experimental limits. For μ > 460 GeV, a high-mass, compressed-spectrum region opens up, in which the relic density predictions can match the Planck result. However, the DD signals in this region are way too high, above not only LZ [39, 40] but even Xenon-1T [38] results.
- Alternatively, there is a region for $\mu > 460$ GeV with a very sub-dominant DM scenario, in which the DD signal dives below the latest LZ limits [40]. However, it requires a large charged vs. neutral Higgs mass splitting, and an extreme value of λ_2 , violating experimental and theoretical constraints.

The origin of these repeated conflicts is clear. Our starting idea of a large finite global symmetry group strongly constraints the shape of the scalar sector. Looking back at the Higgs potential (3), we see that it is the term $\lambda_1(\phi_1^{\dagger}\phi_1 + \phi_2^{\dagger}\phi_2 + \phi_3^{\dagger}\phi_3)^2$ that forces the effective DM-SM coupling $\bar{\lambda}$ in Eq. (34) to always remain unsuppressed. It is this unsuppressed coupling that drives the large invisible Higgs decay for light DM, the large contribution of the charged Higgs loops to $h_{\rm SM} \to \gamma \gamma$ for heavy DM, as well as the large DD signal. Thus, the large DM effects are tightly connected with our starting assumption of a large symmetry group. It may happen that extending our study to μ^2 in excess of 1 TeV^2 would reveal a model that would be technically within the existing limits. But judging from the present experience, it will always be at the brink of exclusion and never be a natural candidate. But the main goal of this work was not to construct yet another DM model but to explore the limits of what multi-Higgs-doublet models can in principle accommodate. We met this objective: through a concrete example, we learned several lessons that further highlight the conflicts between symmetry assumptions, the LHC results, and DM properties that arise if we try to derive a DM multiplet stabilized by a non-abelian group from the multi-Higgs-doublet model potential. We believe that these lessons are of interest to the community and help clarify what can and what cannot be achieved with several Higgs doublets alone, without additional New Physics assumptions.

Appendix A: SU(3) vs. PSU(3)

When we discuss three-family global symmetries either of the Higgs doublets or of fermion generations, we usually think of a symmetry group $G \subset SU(3)$. However, SU(3) contains a non-trivial center: $Z(SU(3)) \simeq \mathbb{Z}_3 = \{\mathbb{1}_3, \omega \cdot \mathbb{1}_3, \omega^2 \cdot \mathbb{1}_3\}$. Of course, this center is always a symmetry of the entire lagrangian of any 3HDM, just because it is a very particular subgroup of the hypercharge gauge transformations $U(1)_Y$. Since we are looking for symmetry groups G in addition to the electroweak gauge group, we should not include this \mathbb{Z}_3 in our search for global symmetry groups. This can be done by considering the factor group $SU(3)/\mathbb{Z}_3$, which is called PSU(3), the projective SU(3). Thus, if we aim to establish all distinct symmetry-based situations in the 3HDM, we should look for subgroups of PSU(3), not SU(3).

Let us show how it works for the group $\Delta(27)$ mentioned above. The two generators in Eq. (1) do not commute inside SU(3), as their commutator gives

$$[a,b] = aba^{-1}b^{-1} = \omega^2 \cdot \mathbb{1}_3.$$
(A1)

However, if we now view a and b as representative elements of the cosets $a\mathbb{Z}_3$ and $b\mathbb{Z}_3$, which belong to PSU(3), then they do commute: their commutator is just the coset \mathbb{Z}_3 itself, the trivial element of PSU(3). So, by applying the homomorphism $f: SU(3) \to PSU(3)$ to the group $\Delta(27) \subset SU(3)$, we obtain the abelian group $\Delta(27)/\mathbb{Z}_3 = \mathbb{Z}_3 \times \mathbb{Z}_3 \subset PSU(3)$. Similarly, if we start with $\Delta(54) = \Delta(54) \rtimes \mathbb{Z}_2 \subset SU(3)$, we arrive at $\Delta(27)/\mathbb{Z}_3 = (\mathbb{Z}_3 \times \mathbb{Z}_3) \rtimes \mathbb{Z}_2 \subset PSU(3)$. This is why the classification of the finite symmetry groups of the 3HDM scalar sector [32, 33, 55], dealt with $(\mathbb{Z}_3 \times \mathbb{Z}_3) \rtimes \mathbb{Z}_2$, not $\Delta(54)$.

However, working directly inside PSU(3) is less convenient. We are used to exploring complex spaces, not projective spaces, and to dealing with matrices as in Eq. (1), not cosets of matrices. Moreover, we have much information on unitary irreducible representations (irreps) of finite groups, not projective irreps. Therefore, in practical calculations, it is advisable to work inside SU(3)—remembering about the center when appropriate.

The group $\Sigma(36)$ of order 36 was identified in [32, 33, 55] as the largest finite symmetry group of the 3HDM scalar sector. This is a subgroup of PSU(3), and it can be written as $(\mathbb{Z}_3 \times \mathbb{Z}_3) \rtimes \mathbb{Z}_4$, with the already familiar $\mathbb{Z}_3 \times \mathbb{Z}_3$ "core" and the new transformation which acts on it by automorphisms. Back within SU(3), this group is denoted as $\Sigma(36\varphi)$, or $\Sigma(36 \times 3)$, see e.g. [56, 57], and is of order 108.

Appendix B: Representations of the group $\Sigma(36\varphi)$

Irreducible representations of the group $\Sigma(36\varphi)$ together with the character table were listed in [56, 57]. They include four 1D irreps $\mathbf{1}^{(p)}$, which differ by the representing value of $\rho_1(d) = i^p$, four complex 3D irreps $\mathbf{3}^{(p)}$, whose $\rho_3(a)$ and $\rho_3(b)$ are given in Eq. (1) and $\rho_3(d)$ is the same as in Eq. (2) with an extra factor i^p , four conjugate triplets $(\mathbf{3}^{(p)})^*$, and finally two real 4D irreps. As in the main text, we shorten $\mathbf{3}^{(0)}$ to just $\mathbf{3}$. The sum of the squares of the irrep dimensions is $\sum_i d_i^2 = 4 \times 1 + 8 \times 3^2 + 2 \times 4^2 = 108$, which is the order of $\Sigma(36\varphi)$.

The decomposition of various products of irreps were derived in [56], Appendix C. We are interested in products of **3**, which is how the Higgs doublets transform, with $\mathbf{3}^{(p)}$ or $(\mathbf{3}^{(p)})^*$. First,

$$\mathbf{3} \otimes \mathbf{3}^* = \mathbf{1}^{(0)} \oplus \mathbf{4} \oplus \mathbf{4}' \,. \tag{B1}$$

If $a \sim \mathbf{3}$ and $b^* \sim \mathbf{3}^*$, then the trivial singlet is obtained as

$$[ab^*]_1 = a_1b_1^* + a_2b_2^* + a_3b_3^*.$$
(B2)

Eq. (B1) can be generalized to other triplets-antitriplet products as

$$\mathbf{3}^{(p)} \otimes (\mathbf{3}^{(p')})^* = \mathbf{1}^{(p-p')} \oplus \mathbf{4} \oplus \mathbf{4}', \tag{B3}$$

where p - p' is understood as taken mod 4.

Next, the product of two triplets is decomposed as

$$\mathbf{3} \otimes \mathbf{3} = \mathbf{3}^* \oplus (\mathbf{3}^{(1)})^* \oplus (\mathbf{3}^{(3)})^*.$$
 (B4)

If $a \sim 3$ and $b \sim 3$, then the explicit expression for the antitriplet 3^* , which is antisymmetric under $a \leftrightarrow b$, is inherited from the SU(3) irrep products:

$$\frac{1}{\sqrt{2}}\epsilon_{ijk}a_jb_k = \frac{1}{\sqrt{2}} \begin{pmatrix} a_2b_3 - a_3b_2\\a_3b_1 - a_1b_3\\a_1b_2 - a_2b_1 \end{pmatrix} \sim \mathbf{3}^* \,. \tag{B5}$$

The six-dimensional symmetric subspace splits into the two invariant subspaces:

$$\frac{1}{\sqrt{24}} \begin{pmatrix} \sqrt{2} \tau_{-}a_{1}b_{1} - \tau_{+}(a_{2}b_{3} + a_{3}b_{2}) \\ \sqrt{2} \tau_{-}a_{2}b_{2} - \tau_{+}(a_{3}b_{1} + a_{1}b_{3}) \\ \sqrt{2} \tau_{-}a_{3}b_{3} - \tau_{+}(a_{1}b_{2} + a_{2}b_{1}) \end{pmatrix} \sim (\mathbf{3}^{(1)})^{*}, \quad \frac{1}{\sqrt{24}} \begin{pmatrix} \sqrt{2} \tau_{+}a_{1}b_{1} + \tau_{-}(a_{2}b_{3} + a_{3}b_{2}) \\ \sqrt{2} \tau_{+}a_{2}b_{2} + \tau_{-}(a_{3}b_{1} + a_{1}b_{3}) \\ \sqrt{2} \tau_{+}a_{3}b_{3} + \tau_{-}(a_{1}b_{2} + a_{2}b_{1}) \end{pmatrix} \sim (\mathbf{3}^{(3)})^{*}.$$
(B6)

Here, we used the shorthand notation

$$\tau_{-} = \sqrt{2(3-\sqrt{3})}, \quad \tau_{+} = \sqrt{2(3+\sqrt{3})}, \quad \tau_{-}\tau_{+} = \sqrt{24}.$$
(B7)

Again, the decomposition Eq. (B4) can be generalized to the product of any two triplets:

$$\mathbf{3}^{(p)} \otimes \mathbf{3}^{(p')} = (\mathbf{3}^{(-p-p')})^* \oplus (\mathbf{3}^{(1-p-p')})^* \oplus (\mathbf{3}^{(3-p-p')})^*,$$
(B8)

where all indices are computed mod 4. However, the decomposition rules remain the same as in Eqs. (B5) and (B6).

Appendix C: Yukawa sectors for the exact $\Sigma(36)$ symmetry

We present here the details of extending the symmetry group $\Sigma(36)$ to the quark Yukawa sector. With the list of irreps of the group $\Sigma(36\varphi)$ and their product composition rules, we present in Table I the main options for the irrep assignments in a $\Sigma(36\varphi)$ -invariant quark sector. In principle, one can also choose different triplets; for example, in the second line, $\overline{Q_L}$ could be chosen to transform as $\mathbf{3}^{(1)}$. But with a simultaneous relabeling the irrep assignments for d_R and u_R , this choice would still lead to the same Yukawa structures. Let us now build the Yukawa matrices for each of the cases listed in Table I.

Case 1-3-3-3: Q_L are trivial singlets, $d_R \sim \mathbf{3}^*$, $u_R \sim \mathbf{3}$, the first line of Table I. The three Yukawa matrices Γ_a were given in Eq. (30), and similar matrices Δ_a with their own parameters d_i arise for the up sector. Starting from the mass matrices $(M_d)_{ij} = g_i v_j / \sqrt{2}$ and $(M_u)_{ij} = d_i v_j^* / \sqrt{2}$, we define, as usual, their hermitean squares $H_d = M_d M_d^{\dagger}$ and $H_u = M_u M_u^{\dagger}$:

$$(H_d)_{ij} = \frac{v^2}{2} g_i g_j^*, \quad (H_u)_{ij} = \frac{v^2}{2} d_i d_j^*.$$
 (C1)

label	$\overline{Q_L}$	ϕ	d_R	u_R
case 1-3-3-3	1	3	3^*	3
case $3-3-1-3$	3^*	3	1	3^* or $(3^{(1)})^*$ or $(3^{(3)})^*$
case 3-3-3-1	3	3	3 or $3^{(1)}$ or $3^{(3)}$	1

TABLE I. The main options for $\Sigma(36\varphi)$ -invariant Yukawa sector.

Both in the down and up-quark sectors, we have two generations of massless quarks and one generation of massive ones, with $m_b^2 = v^2 |\vec{g}|^2/2$ and $m_t^2 = v^2 |\vec{d}|^2/2$.

In general, the mass matrices are diagonalized through the rotations

$$d_L^0 = V_{dL} d_L , \quad d_R^0 = V_{dR} d_R , \quad u_L^0 = V_{uL} u_L , \quad u_R^0 = V_{uR} u_R .$$
(C2)

which lead to the CKM matrix $V_{CKM} = V_{uL}^{\dagger}V_{dL}$ and the diagonal matrices $D_d = V_{dL}^{\dagger}M_dV_{dR}$ and $D_u = V_{uL}^{\dagger}M_uV_{uR}$. Let us assume that the non-zero masses correspond to the third eigenvector. Then the matrices V_{dL} and V_{uL} take the following generic form:

$$V_{dL} = \frac{1}{\sqrt{|\vec{g}|^2}} \begin{pmatrix} \uparrow & \uparrow & \uparrow \\ \vec{x}_1 & \vec{x}_2 & \vec{g} \\ \downarrow & \downarrow & \downarrow \end{pmatrix}, \quad V_{uL} = \frac{1}{\sqrt{|\vec{d}|^2}} \begin{pmatrix} \uparrow & \uparrow & \uparrow \\ \vec{y}_1 & \vec{y}_2 & \vec{d} \\ \downarrow & \downarrow & \downarrow \end{pmatrix}.$$
(C3)

Here, for the down-quark sector, $\vec{g} = (g_1, g_2, g_3)$ and \vec{x}_1, \vec{x}_2 are the other two eigenvectors corresponding to zero eigenvalue, which cannot be uniquely defined. The same construction holds for the up-sector in terms of the vectors $\vec{d} = (d_1, d_2, d_3)$ and \vec{y}_1, \vec{y}_2 .

Proceeding in a similar way with $G_d = M_d^{\dagger} M_d$ and $G_u = M_u^{\dagger} M_u$, one finds $(G_d)_{ij} = |\vec{g}|^2 v_i^* v_j$ and $(G_u)_{ij} = |\vec{d}|^2 v_i v_j^*$. One can then find the rotation matrices V_{dR} and V_{uR} , inserting them back in the Yukawa lagrangian and obtain the interaction patterns of the neutral scalar fields $\phi_a^0 = (h_a + ia_a)/\sqrt{2}$ with quark pairs:

$$-\mathcal{L}_{Y} \supset \frac{\sqrt{2}m_{b}}{v^{2}} \bar{d}_{L} \begin{pmatrix} 0 & 0 & 0\\ 0 & 0 & 0\\ \vec{\phi^{0}} \cdot \vec{u_{1}} & \vec{\phi^{0}} \cdot \vec{u_{2}} & \vec{\phi^{0}} \cdot \vec{v} \end{pmatrix} d_{R} + h.c.,$$
(C4)

and a similar matrix for the up-quark sector. Here, the two vectors \vec{u}_1 and \vec{u}_2 , of norm v, are orthogonal to \vec{v} and with each other. Although the three vectors \vec{u}_1 , \vec{u}_2 , \vec{v} are different for different vev alignments, they all share the key properties: the SM-like Higgs couples only to $\bar{b}b$, while all the additional neutral Higgses couple to $b\bar{d}$ and $b\bar{s}$. In particular, for the vev alignment B_1 we recover the coupling patterns given in Eq. (31).

Case 3-3-1-3: d_R are trivial singlets, $Q_L \sim \mathbf{3}$, $u_R \sim \mathbf{3}^*$. The Yukawa matrices Γ_a again come from the simple product of $\mathbf{3}^* \otimes \mathbf{3}$, which is then coupled to the three singlets d_R , each with its own coefficient:

$$\Gamma_1 = \begin{pmatrix} g_1 & g_2 & g_3 \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \end{pmatrix}, \quad \Gamma_2 = \begin{pmatrix} \cdot & \cdot & \cdot \\ g_1 & g_2 & g_3 \\ \cdot & \cdot & \cdot \end{pmatrix}, \quad \Gamma_3 = \begin{pmatrix} \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ g_1 & g_2 & g_3 \end{pmatrix}.$$
(C5)

We arrive at $(H_d)_{ij} = |\vec{g}|^2 v_i v_j^*/2$. again yielding two massless generations and a massive *b*-quark, with the same mass squared as before: $m_b^2 = v^2 |\vec{g}|^2/2$. However, the quark rotation matrix is now governed by the vector of vevs rather than the coefficients:

$$V_{dL} = \frac{1}{v} \begin{pmatrix} \uparrow & \uparrow & \uparrow \\ \vec{u}_1 & \vec{u}_2 & \vec{v} \\ \downarrow & \downarrow & \downarrow \end{pmatrix} , \qquad (C6)$$

while V_{dR} takes the form similar to Eq. (C3). The interactions of the neutral Higgses with quark pairs is now described by the matrix

$$-\mathcal{L}_{Y} \supset \frac{\sqrt{2}m_{b}}{v^{2}} \bar{d}_{L} \begin{pmatrix} 0 & 0 & \vec{\phi^{0}} \cdot \vec{u}_{1} \\ 0 & 0 & \vec{\phi^{0}} \cdot \vec{u}_{2} \\ 0 & 0 & \vec{\phi^{0}} \cdot \vec{v} \end{pmatrix} d_{R} + h.c., \qquad (C7)$$

We again observe that the decays of h and a to $\bar{b}d$ and $\bar{b}s$ are unavoidable.

In the up-quark sector, we encounter the product $\mathbf{3}^* \otimes \mathbf{3}^* \otimes \mathbf{3}^*$, which contains only one singlet. As a result, the entire up-quark sector now involves only one free parameters d. Using the representation product rules listed in Appendix B, we obtain the following Yukawa matrices:

$$\Delta_1 = d \begin{pmatrix} \cdot & \cdot & \cdot \\ \cdot & \cdot & -1 \\ \cdot & 1 & \cdot \end{pmatrix}, \quad \Delta_2 = d \begin{pmatrix} \cdot & \cdot & 1 \\ \cdot & \cdot & \cdot \\ -1 & \cdot & \cdot \end{pmatrix}, \quad \Delta_3 = d \begin{pmatrix} \cdot & -1 & \cdot \\ 1 & \cdot & \cdot \\ \cdot & \cdot & \cdot \end{pmatrix}.$$
(C8)

The mass matrix and its hermitean square are

$$(M_u)_{ij} = -\frac{d}{\sqrt{2}} \epsilon_{ijk} v_k^*, \quad (H_u)_{ij} = \frac{|d|^2}{2} \left(v^2 \delta_{ij} - v_i^* v_j \right).$$
 (C9)

The mass spectrum is now different: one zero eigenvalue, with the eigenvector (v_1^*, v_2^*, v_3^*) and two non-zero degenerate eigenvalues $m^2 = |d|^2 v^2/2$. The Higgs-quark couplings now show a different pattern but the overall conclusion remains unchanged: h and a unavoidably decay to the quark pairs.

Case 3-3-3-1, with u_R being trivial singlets, while $Q_L \sim \mathbf{3}^*$, $d_R \sim \mathbf{3}$, is similar to the previous one, with the structures in the up and down-quark sectors swapped. Finally, **case 3-3-1-3**⁽¹⁾ and **case 3-3-1-3**⁽³⁾, with $Q_L \sim \mathbf{3}$ and $u_R \sim (\mathbf{3}^{(1)})^*$ or $u_R \sim (\mathbf{3}^{(3)})^*$, involve new

Finally, case 3-3-1-3⁽¹⁾ and case 3-3-1-3⁽³⁾, with $Q_L \sim 3$ and $u_R \sim (3^{(1)})^*$ or $u_R \sim (3^{(3)})^*$, involve new structures. The down sector remains the same as in case 3-3-1-3, while the up sector is now constructed from a different contraction of triplets:

$$\Delta_1 = d \begin{pmatrix} \sqrt{2}\tau_{\mp} & \cdot & \cdot \\ \cdot & \cdot & \mp \tau_{\pm} \\ \cdot & \mp \tau_{\pm} & \cdot \end{pmatrix}, \quad \Delta_2 = d \begin{pmatrix} \cdot & \cdot & \mp \tau_{\pm} \\ \cdot & \sqrt{2}\tau_{\mp} & \cdot \\ \mp \tau_{\pm} & \cdot & \cdot \end{pmatrix}, \quad \Delta_3 = d \begin{pmatrix} \cdot & \mp \tau_{\pm} & \cdot \\ \mp \tau_{\pm} & \cdot & \cdot \\ \cdot & \cdot & \sqrt{2}\tau_{\mp} \end{pmatrix}, \quad (C10)$$

where $\tau_{-} = \sqrt{2(3-\sqrt{3})}$, $\tau_{+} = \sqrt{2(3+\sqrt{3})}$, so that $\tau_{-}\tau_{+} = \sqrt{24}$. We now obtain a mass matrix with three non-zero masses, two of them being degenerate. Although the analytic diagonalization for a generic vev alignment is cumbersome, it is easily done for the alignments which are possible for the $\Sigma(36)$ potential. The bottom line is the same: all new neutral Higgses couple to quark pairs, leading to decays of h and a.
