Abstract

Reinforcement learning (RL) is increasingly being used in the healthcare domain, particularly for the development of personalized health adaptive interventions. Inspired by the success of Large Language Models (LLMs), we are interested in using LLMs to update the RL policy in real time, with the goal of accelerating personalization. We use the text-based user preference to influence the action selection on the fly, in order to immediately incorporate the user preference. We use the term "user preference" as a broad term to refer to a user personal preference, constraint, health status, or a statement expressing like or dislike, etc. Our novel approach is a hybrid method that combines the LLM response and the RL action selection to improve the RL policy. Given an LLM prompt that incorporates the user preference, the LLM acts as a filter in the typical RL action selection. We investigate different prompting strategies and action selection strategies. To evaluate our approach, we implement a simulation environment that generates the text-based user preferences and models the constraints that impact behavioral dynamics. We show that our approach is able to take into account the text-based user preferences, while improving the RL policy, thus improving personalization in adaptive intervention.

1 Introduction

Reinforcement learning (RL) is increasingly being used in the healthcare domain, particularly for the development of personalized health adaptive interventions [\[Coronato et al., 2020,](#page-9-0) [Yu et al., 2021,](#page-10-0) [Gönül et al., 2021,](#page-9-1) [Liao et al., 2020\]](#page-9-2). Inspired by the success of Large Language Models (LLMs), we are interested in using LLMs to update the RL policy in real time, with the goal of accelerating personalization. We use the text-based user preference to influence the selection of actions on the fly, in order to immediately incorporate the user preference. We use the term "user preference" as a broad term to refer to a user personal preference, constraint, health status, or a statement expressing like or dislike, etc.

We illustrate our motivation with an example from the behavioral domain, where researchers study the effectiveness of a mobile health app that encourages positive behavior change (i.e., exercise more or reduce smoking) by sending messages to the user, a.k.a participant [\[Nahum-Shani et al., 2018,](#page-10-1) [Hardeman et al., 2019\]](#page-9-3). Often, there can be too many messages sent to the user, or some issues in the decision rule or policy that result in incorrectly contextualized messages sent to the user (e.g., when the user preference does not align with the policy). These messages may annoy the user, or even cause the user to disengage from the study. Thus, it is critical to take into account the user preference before it becomes too late or irreversible (e.g. the user exits the study).

One solution is to allow the user to specify their preferences in the form of free-text descriptions, and immediately take them into account to influence the action selection. This is especially relevant in today's generation, where people use chats and social media to communicate. For example, the user preference can be: "I sprained my ankle", "I don't want messages during the weekend" or "I don't like to receive negative messages about smoking".

Our goal is to immediately incorporate the user preferences, by using LLMs, in order to improve the RL policy, and thus accelerate personalization in adaptive intervention.

However, implementing methods using LLMs comes with challenges: (1) how to construct effective LLM prompts to obtain the desired LLM response, (2) how to incorporate the LLM response in the RL system, in order to update the RL policy, and (3) how to evaluate the new method, since incorporating the user preference introduces additional constraints on the behavioral dynamics.

Thus, our problem statement is: "How can we use LLMs to update the RL policy to accelerate personalization in adaptive interventions?". We answer this question by introducing: (1) our novel hybrid method "LLM+TS", (2) a novel simulation environment "StepCountJITAI for LLM" that works with LLMs and allows for the evaluation of our new method, and (3) a solution framework for implementing a pipeline for personalized health adaptive interventions.

Our contributions are:

1. LLM+TS: combining LLM decision and RL action selection to improve RL policy. We introduce our novel hybrid method called "LLM+TS", that combines the LLM response and the RL action selection to improve the RL policy for adaptive intervention. We use Thompson Sampling (TS) as the RL agent, because it is an effective Bayesian approach that requires fewer iterations than typical deep RL methods [\[Agrawal and Goyal, 2013\]](#page-9-4).

Our approach incorporates prompting strategies and action selection strategies to accelerate personalization. For our approach, we implement two loops: (1) a simulation environment that generates text-based user preferences, which we describe below, and (2) the typical RL loop where the RL agent selects a candidate action at each time step. Then, based on the LLM prompt that includes the user preference and other information, the LLM decides whether to "not send" or "send" a message. The LLM acts as a filter in the typical RL action selection.

- 2. StepCountJITAI for LLM: novel simulation environment that generates user preferences and incorporates constraints to impact behavioral dynamics. We extend the base simulator for adaptive intervention, introduced in [Karine and Marlin](#page-9-5) [\[2024\]](#page-9-5), to create a new simulation environment that works with LLMs. StepCountJITAI for LLM is used to evaluate our new method. To construct it, we: (1) augment the user state with an auxiliary variable with dynamics that follow a Markov chain, (2) generate the text-based user preference based on the auxiliary variable value, (3) incorporate constraints that impact the behavioral dynamics implemented inside the simulation environment (e.g., if the user is in a "cannot walk" state, then the reward value drops to 0, the disengagement risk increases, and the habitual level increases). We note that our new process for generating the text-based user preference is separate from the RL loop, and is only included in the simulation environment. Our StepCountJITAI for LLM is an innovative simulation environment that has not been explored in prior work, and it offers significant potential for advancing the development of new RL algorithms for adaptive interventions using LLM. StepCountJITAI is available at: github.com/reml-lab/StepCountJITAI.
- 3. Practical method for accelerating personalization in adaptive intervention. We demonstrate how to frame a physical activity adaptive intervention as an RL system using LLMs. We show that our approach improves the RL policy while incorporating the user preference. Our method offers a promising solution framework for implementing a pipeline for personalized health adaptive intervention.

We provide an overview of our novel method in Figure [1,](#page-2-0) and details in Section [3.](#page-3-0)

Figure 1: Overview of LLM+TS method. LLM+TS is a hybrid method that combines LLM decision and RL action selection to improve the RL policy. The LLM prompt includes information such as a description of the behavioral dynamics, current user state and some past data, user preference (constraint) and a question asking the LLM to decide: "not send" or "send" a message (i.e., $\tilde{a} = 0$ or $\tilde{a} = a$). The LLM acts as a filter in the typical RL action selection.

2 Background

StepCountJITAI: simulation environment for adaptive intervention. There is limited prior work on simulation environments for adaptive intervention in the literature. In this work, we extend the base simulator for adaptive intervention introduced in [Karine and Marlin](#page-9-5) [\[2024\]](#page-9-5). This base simulator was specifically designed to be used for the development of new RL algorithms for adaptive intervention.

A physical activity adaptive intervention can be framed as an RL system, where the types of messages are the possible actions. In our simulation environment, we use the following values: $a = 0$ (do not send a message), $a = 1$ (send a generic message), $a = 2$ (send a message tailored to context 0), and $a = 3$ (send a message tailored to context 1).

The context can be, for example, a binary state of the participant: 'stressed / not stressed' or 'at home / at work' or 'smoker / not a smoker', etc. Note that the context can be extended to include multiple values.

The environment states include the participant behaviors: habituation level and disengagement risk.

For the notation, we use an uppercase letter for the variable name, and a lowercase letter for the variable value, for example: the context variable C has value $c_t = 0$ at time t.

Below we describe some of the simulation environment variables and parameters that are used in the behavioral dynamics: c_t is the true context, p_t is the probability of context 1, l_t is the inferred context, h_t is the habituation level, d_t is the disengagement risk, s_t is the step count (s_t is the participant's number of walking steps), and a_t is the action at time t. The base simulator also includes behavioral parameters: δ_d and ϵ_d are decay and increment parameters for the disengagement risk, and δ_h and ϵ_h are decay and increment parameters for the habituation level.

The goal is to increase the participant's walking step count. Thus, the walking step count is also the RL reward.

This base simulator implements complex behavioral dynamics. The behavioral dynamics can be summarized as follows: Sending a message causes the habituation level to increase. Not sending a message causes the habituation level to decrease. An incorrectly tailored message causes the disengagement risk to increase. A correctly tailored message causes the disengagement risk to decrease. When the disengagement risk exceeds a given threshold, the behavioral study ends. The reward is the surplus step count, beyond a baseline count, attenuated by the habituation level. These behavioral dynamics can be translated into equations, which we present below.

$$
c_{t+1} \sim Bernoulli(0.5), \quad x_{t+1} \sim \mathcal{N}(c_{t+1}, \sigma^2)
$$
 (1)

$$
p_{t+1} = P(C = 1|x_{t+1}), \quad l_{t+1} = p_{t+1} > 0.5 \tag{2}
$$

$$
h_{t+1} = \begin{cases} (1 - \delta_h) \cdot h_t & \text{if } a_t = 0\\ \min(1, h_t + \epsilon_h) & \text{otherwise} \end{cases}
$$
 (3)

$$
d_{t+1} = \begin{cases} d_t & \text{if } a_t = 0\\ (1 - \delta_d) \cdot d_t & \text{if } a_t \in \{1, c_t + 2\} \\ \min(1, d_t + \epsilon_d) & \text{otherwise} \end{cases}
$$
(4)

$$
s_{t+1} = \begin{cases} m_s + (1 - h_{t+1}) \cdot \rho_1 & \text{if } a_t = 1\\ m_s + (1 - h_{t+1}) \cdot \rho_2 & \text{if } a_t = c_t + 2\\ m_s & \text{otherwise} \end{cases}
$$
(5)

where σ is the context uncertainty, x_t is the context feature, σ , ρ_1 , ρ_2 , m_s are fixed parameters. We use the same default parameter values as the base simulator, which we summarize in Appendix [A.1.](#page-11-0)

However this base simulator does not support LLMs. Thus, we extend this base simulator to create our novel simulation environment that includes the support for LLMs and the constraints arising from inserting the user preference. We describe our novel simulation environment in Section [3.1.](#page-4-0)

Thompson Sampling. Thompson Sampling (TS) is a probabilistic method for decision-making under uncertainty. It can be used to address contextual multi-armed bandit problems [\[Russo et al., 2018,](#page-10-2) [Agrawal and Goyal, 2013,](#page-9-4) [Chu et al., 2011,](#page-9-6) [Thompson, 1933\]](#page-10-3). Typical TS for contextual bandit settings uses a reward model of the form $\mathcal{N}(r; \theta_a^T v_t, \sigma_{Ya}^2)$, where v_t is the state vector at time t, θ_a is a vector of weights, and σ_{Ya}^2 is the reward variance for action a. Thus, $\theta_a^{\top} v_t$ represents the mean reward for action a.

The reward model weights θ_a are random variables of the form $\mathcal{N}(\theta_a; \mu_{ta}, \Sigma_{ta})$. Actions are selected at each time t by sampling $\hat{\theta}_a$ from $\mathcal{N}(\theta_a; \mu_{ta}, \Sigma_{ta})$ and choosing the action with the largest value $\hat{\theta}_a^{\top} v_t$. The prior distribution for θ_a is of the form $\mathcal{N}(\theta_a; \mu_{0a}, \Sigma_{0a})$. The distribution over θ_a for the selected action is updated at time t based on the observed reward r_t and v_t using Bayesian inference. We provide the update equations for the mean and covariance matrix below.

$$
\Sigma_{(t+1)a} = \sigma_{Ya}^2 \left(v_t^\top v_t + \sigma_{Ya}^2 \Sigma_{ta}^{-1} \right)^{-1} \tag{6}
$$

$$
\mu_{(t+1)a} = \Sigma_{(t+1)a} \left((\sigma_{Ya}^2)^{-1} r_t v_t + \Sigma_{ta}^{-1} \mu_{ta} \right)
$$
\n(7)

Related work. Recent works use LLMs in RL, where the RL agent selects actions based on natural language inputs, and apply to games [\[Du et al., 2023\]](#page-9-7). Note that in our work we leverage LLMs as foundational models, and focus on online decision-making for episode-limited RL settings, thus while we combine LLMs and RL, our work differs from the recent research on RL from human feedback (RLHF) and from AI feedback (RLAIF), which typically require some form of reward modeling, and a large number of episodes to perform well. Other works have also explored using natural language inputs, but apply to recommender systems for items such as movies, or instructability of social media recommendation algorithms [\[Lyu et al., 2024,](#page-9-8) [Feng et al., 2024,](#page-9-9) [Mysore et al., 2023,](#page-9-10) [Sanner et al.,](#page-10-4) [2023\]](#page-10-4). However, these approaches also require a large number of iterations to work well. In contrast, we use TS which is a Bayesian approach that can perform well in a lower number of iterations than typical deep RL methods.

3 Methods

We start with an overview of our new method in Figure [1,](#page-2-0) and summarize below how to frame an adaptive intervention as an RL system using LLM. Then we provide the details.

- 1. Run a typical RL loop to select a candidate action a.
- 2. Extract LLM decision: given the user preference and previous data, we construct the prompt, send it to the LLM, then extract the LLM decision from the LLM response.
- 3. Update RL policy based on LLM decision: we choose to either select $\tilde{a} = 0$ (no message) or send $\tilde{a} = a$ (set the hybrid action \tilde{a} to the RL candidate action a).

Note: if the RL agent selects action $a > 0$ (indicating a candidate message to be sent) and a user preference is generated, then the LLM is prompted to decide if this message should actually be sent or not. If the RL agent selects action $a = 0$ (indicating no message) or if there is no user preference that was generated, then there is no need to call the LLM, so the typical RL loop continues as usual.

To evaluate our method, we run our new simulation environment that generates text-based user preferences.

Importantly, the RL loop and the user preference generation process are two separate loops. The text-based user preference is generated by the simulation environment, as described in Section [3.1.](#page-4-0) The user preference is inserted into the LLM prompt, when a call to the LLM is made.

3.1 StepCountJITAI for LLM

We extend the base simulator for adaptive intervention, introduced in [Karine and Marlin](#page-9-5) [\[2024\]](#page-9-5), to create StepCountJITAI for LLM, a novel simulation environment that works with LLMs. We describe the base simulator as well as the behavioral dynamics in Section [2.](#page-2-1)

Our simulation environment, StepCountJITAI for LLM, can generate text-based user preferences, and incorporates constraints that affect the behavioral dynamics. To illustrate how it works, we focus on the user preference "cannot walk". Other user preferences can be implemented in the same way as described in our work.

Below, we start with a summary of how to create StepCountJITAI for LLM, then provide details.

- 1. Augment the simulation environment states with a new binary auxiliary variable W , with values: 0 "cannot walk" or 1 "can walk". Note that this variable W is hidden for the RL agent (i.e., not observed by the RL agent).
- 2. Implement the dynamics for W using a Markov chain.
- 3. Generate a text-based user preference when $w = 0$, randomly chosen from a list of predefined user preferences.

Creating auxiliary variable W (cannot walk / can walk). We first augment the simulation environment with a new binary state variable W with value: 0 "cannot walk" or 1 "can walk". The variable W is not observed by the RL agent. It reflects a hidden state of the user, and is used to generate the user preference. We implement a Markov chain to simulate w_t , the values of W at time t. The Markov chain and transition function for W are shown in Figure [2](#page-4-1) and Table [1.](#page-4-2)

Figure 2: Markov chain sketch.

We define the new parameters: $p_{w_{01}}$ the probability of transitioning from $w_t = 0$ to $w_{t+1} = 1$, and $p_{w_{11}}$ the probability of remaining in the "can walk" state.

$$
p_{w_{01}} = P(w_{t+1} = 1|w_t = 0)
$$
\n(8)

$$
p_{w_{11}} = P(w_{t+1} = 1|w_t = 1)
$$
\n(9)

Setting $p_{w_{11}}$ to a lower (or higher) value allows for a lower (or higher) probability of remaining in the "can walk" state. Similarly, setting p_{w01} to a lower (or higher) value allows for a lower (or higher) probability of transitioning from $w_t = 0$ to $w_{t+1} = 1$.

We note that the parameters $p_{w_{01}}$ and $p_{w_{11}}$ can be used to simulate the user state "cannot walk" over a variety of ranges, from shorter to longer time intervals, and thus enabling a variety of scenarios for our experiments.

Generating a text-based user preference "cannot walk". Following the Markov chain and transition function in Figure [2](#page-4-1) and Table [1,](#page-4-2) the variable w_t can take values 0 "cannot walk" or 1 "can walk".

When transitioning from "cannot walk" to "can walk", the user preference is set to none, and the behavioral dynamics are not impacted by any constraints. The behavioral dynamics are the same as in the base simulator in [Karine and Marlin](#page-9-5) [\[2024\]](#page-9-5).

When transitioning from "can walk" to "cannot walk", a text-based user preference is randomly chosen from a list of pre-defined reasons for "cannot walk". This list was previously created by asking ChatGPT to give reasons why a user cannot walk.

We show 20 reasons for "cannot walk":

```
I am tired, I do not want to walk, I got an injury, my leg is sore, I have
a headache, the weather is bad, I have a cold, I feel unwell, I have a prior
commitment, I have a blister, I'm feeling dizzy, I twisted my ankle, I am recovering
from surgery, I need to rest, I have joint pain, I'm dealing with anxiety, I have a
family obligation, I forgot my shoes, I don't have anyone to walk with, I have to
finish my work first.
```
Incorporating "cannot walk" constraint that impacts behavioral dynamics.

When transitioning from "can walk" to "cannot walk", in addition to generating a user preference above, the additional "cannot walk" constraint affects the behavioral dynamics as below.

"cannot walk" constraint:

- disengagement risk d_t is increased by $\eta_d \times d_t$
- habituation level h_t is increased by $\eta_h \times h_t$
- reward is set to 0.

The reward is the walking step count. It is set to 0 since the user cannot walk. We introduce the constraint parameters η_d and η_h , with values $\in [0, 1]$. The base simulator variables and parameters are summarized in Appendix [A.1.](#page-11-0)

3.2 Construct LLM prompt

We construct the LLM prompt by including a description of the mobile health app, the behavioral dynamics, the user current state and previous data, the user preference, and a question asking the LLM to make a decision "send" or "not send" a message to the user.

Below, we provide an example of an LLM prompt.

Example of LLM prompt. The LLM prompt contains the following blocks of text (a chain of instructions).

```
A mobile health app can send a message to the user to encourage the user to walk.
...
Sending a message causes the habituation level to increase.
Not sending a message causes the habituation level to decrease.
An incorrectly tailored message causes the disengagement risk to increase.
A correctly tailored message causes the disengagement risk to decrease.
...
The user current state and previous data...
...
The user preference is "I twisted my ankle".
...
Should the mobile health app send a message to the user?
```
We detail the text in purple. The block of text contains the current user state and several previous rows of data (e.g., h_t , d_t , r_t , c_{t-1} , h_{t-1} ,...). We experimented with various windows of previous data, and chose to insert the 4 previous rows of data, since inserting more rows did not significantly impact the results. The block of text for the user preference (e.g., "I twisted my ankle") is chosen randomly from the list provided in Section [3.1.](#page-4-0)

3.3 Select hybrid action based on RL candidate action and LLM decision

Based on the given prompt, the LLM responds with a decision. The LLM decision is to either send a message to the user (i.e, $\tilde{a} = a$, where a is the RL candidate action) or not send any message to the user (i.e., $\tilde{a} = 0$). In other words, based on the prompt that includes the user preference and other data, the LLM can understand if a message should be sent or not, and thus can override the original candidate action selected by the RL agent. Note that the RL agent does not have knowledge of the user preference.

Example of LLM response. If the user preference is "I twisted my ankle", then the LLM will recognize that a message should not be sent to the user. Thus, the LLM response is "not send", then the hybrid action is $\tilde{a} = 0$ (the original RL candidate action is discarded). Otherwise the LLM may decide to answer "send", in which case the hybrid action is $\tilde{a} = a$ (\tilde{a} is set to the original RL candidate action).

4 Experiments

Below, we first describe how to validate the LLM response, then we describe our practical method for accelerating personalization in adaptive intervention.

4.1 Validating LLM response

We perform experiments to check if the LLM response is correct. For each experiment, we generate prompts for "cannot walk", along with the constraint to impact the behavioral dynamics. Ideally, the LLM response to these prompts should be "not send" a message. We also ask the LLM to provide a reason for its decision. Below are some examples.

Example 1:

The user preference is: $my \text{ leg}$ is sore.

The LLM correctly decides "not send" with the reason: The user has a sore leg, indicating they cannot walk. The app should not send a message.

The LLM manages to provide a valid reason. This shows how an LLM can be a useful tool.

Example 2:

The user preference is: I'm feeling dizzy.

The LLM correctly decides "not send" with the reason: The user is feeling dizzy, which means they cannot walk, so the mobile health app should not send a message.

Again, the LLM manages to provide a valid reason.

Example 3:

The user preference is I am dealing with anxiety.

The LLM incorrectly decides "send", with the reason: The user is expressing anxiety, and a tailored message could be helpful.

In a few cases, the LLM incorrectly decides to send a message, when the user cannot walk (i.e., the "cannot walk" constraint impacts the behavioral dynamics). Further investigation reveals that this occurs when the text-based user preference is ambiguous, thus does not clearly indicate if the user can or cannot walk. However, since these ambiguous text-based user preferences appear in less than 6% of the time steps during our experiment, and since sending the hybrid action falls back to sending the RL candidate action, LLM+TS still outperforms the standard TS agent.

Above, we have shown how to check if the LLM response is correct, thanks to our simulation environment, by tracking exactly where the LLM decision is incorrect. Future work would involve inserting additional insights into the LLM prompt to further improve the LLM response.

4.2 Practical method for accelerating personalization in adaptive intervention.

We conduct extensive experiments to compare our novel method LLM+TS to the standard TS. An experiment (a.k.a trial) corresponds to the behavioral study of one participant, where the maximum study length is 50 days, with daily data. We run our experiments for various combinations of the parameters $(p_{w_{11}}, p_{w_{00}})$, where $p_{w_{00}} = 1 - p_{w_{01}}$, to cover different scenarios. For example, the participant often sustains a light injury and thus often cannot walk for short periods, or the participant sometimes twists their ankle and thus sometimes cannot walk for longer periods. We repeat each experiment 10 times with different seeds.

For each experiment, we also run using various LLMs as foundational models, such as gemma and gemma 2, llama3 and llama 3.1, etc. [\[Gemma Team, 2024,](#page-9-11) [Llama Team, 2024\]](#page-9-12). When using different LLM versions, we found that the choice of LLM version did not impact the results.

For each experiment setting, we compute the total reward as the sum of the rewards over a study. We use $\eta_d = \eta_h = 0.1$. The other experiment parameter values are provided in Appendices [A.1](#page-11-0) and [A.2.](#page-11-1)

We present the results for two realistic scenarios: Scenario 1, where $p_{w_{11}} = 0.7$, and Scenario 2, where $p_{w_{11}} = 0.95$. In both scenarios, $p_{w_{00}}$ varies in the range [0.1, ..., 0.5]. Recall that $p_{w_{00}}$ is the probability of remaining in the "cannot walk" state, and $p_{w_{11}}$ is the probability of remaining in the "can walk" state.

In Figure [3,](#page-8-0) we plot the median total reward, along with the 25th and 75th percentiles, over all the trials. The plots show that LLM+TS, outperforms standard TS in most settings. For example, for $(p_{w_{11}}, p_{w_{00}}) = (0.7, 0.1)$, the median total reward for LLM+TS is 919.9 (25th percentile is 852.6 and 75th percentile is 990.4), whereas the median total reward for standard TS is 622.5 (25th percentile is 600.4 and 75th percentile is 699.4).

We compare the histograms of actions, taking into account all the selected actions across all the trials, for LLM+TS versus standard TS. We also compare the cumulative rewards. In Figure [4,](#page-8-1) we show the histogram of all the selected actions, and the median cumulative reward, along with the 25th and 75th percentiles, over all the trials. We show that LLM+TS is able to capture a larger number of actions 0, which indicates that the LLM has correctly decided to not send a message when the user cannot walk. This is further confirmed by the cumulative rewards for LLM+TS, which are higher than those for standard TS. Additional experiment results are provided in Appendix [A.3.](#page-11-2)

(a) Scenario 1: $p_{w_{11}} = 0.7$ (probability of staying in state "can walk") and various $p_{w_{00}}$ (probability of staying in state "cannot walk").

(b) Scenario 2: $p_{w_{11}} = 0.95$ (probability of staying in state "can walk") and various $p_{w_{00}}$ (probability of staying in state "cannot walk").

Figure 4: LLM+TS vs. standard TS. Example of histogram for all the selected actions, and plot of the cumulative rewards for $(p_{w_{11}}, p_{w_{00}}) = (0.7, 0.1)$. The histograms show that LLM+TS is able to capture a larger number of actions 0, which indicates that the LLM has correctly decided to not send a message when the user cannot walk. The cumulative reward plots show that LLM+TS outperforms standard TS.

5 Conclusion

We introduce LLM+TS, a novel hybrid method that combines the LLM decision and the RL action selection, to update the RL policy, and thus to accelerate personalization in health adaptive intervention. We also introduce StepCountJITAI for LLM, a novel simulation environment that can be used to develop new RL algorithms for adaptive interventions using LLMs. StepCountJITAI for LLM can generate text-based user preferences and incorporate constraints that affect the behavioral dynamics. Our results show that LLM+TS outperforms standard Thompson Sampling. Finally, we demonstrate how to frame a physical activity adaptive intervention as an RL system using LLM. Our method offers a promising solution framework for implementing a pipeline using LLM for personalized health adaptive interventions.

A Appendix

A.1 JITAI simulation environment specifications

The base simulator introduced in [\[Karine et al., 2023\]](#page-9-13) mimics a participant's behaviors in a mobile health study, where the interventions (actions) are the messages sent to the participant. We summarize the base simulator specifications in Tables [2](#page-11-3) and [3.](#page-11-4)

Action	Description
$a=0$	No message is sent to the participant.
$a=1$	A non-contextualized message is sent.
$a=2$	A message customized to context 0 is sent.
$a=3$	A message customized to context 1 is sent.

Table 2: Possible action values

Variable	Description	Values
c_t	true context	$\{0,1\}$
p_t l_t	probability of context 1 inferred context	[0,1] $\{0,1\}$
d_t	disengagement risk level	[0,1]
h_t	habituation level	[0, 1]
S_t	step count	

Table 3: State variables

We describe the behavioral dynamics in Section [2.](#page-2-1) We use the same default parameter values as in the base simulator: context uncertainty $\sigma = 0.4$, behavioral parameters $\delta_h = 0.1$, $\epsilon_h = 0.05$, $\delta_d = 0.1$, $\epsilon_d = 0.4, m_s = 0.1, \rho_1 = 50, \rho_2 = 200$. For our experiments, we set the disengagement threshold $D_{threshold} > 1$.. The maximum study length is 50 days with daily data.

A.2 Thompson Sampling configurations

Using the same notations as in Section [2,](#page-3-1) we set the TS prior parameters $\mu_{0a} = 0$ and $\Sigma_{0a} = 100I$ for each action a, and the reward noise variance $\sigma_{Ya}^2 = 25^2$ for each action a.

A.3 Additional experiment results

We run similar experiments as in Section [4](#page-6-0) for various combinations of $(p_{w_{11}}, p_{w_{00}})$. We show the histogram of all the selected actions, and the median cumulative reward, along with the 25th and 75th percentiles, over all the trials, in Figure [5.](#page-12-0) The histograms show that LLM+TS is able to capture a larger number of actions 0, which indicates that the LLM has correctly decided to not send a message when the user cannot walk. The cumulative reward plots show that LLM+TS outperforms standard TS.

Figure 5: LLM+TS vs. standard TS. Example of histogram for all the selected actions, and plot of the cumulative rewards for various $(p_{w_{11}}, p_{w_{00}})$ with fixed $p_{w_{11}} = 0.7$ and varying $p_{w_{00}}$, when using LLM+TS (blue) and standard TS (gray). The histograms show that LLM+TS is able to capture a larger number of actions 0, which indicates that the LLM has correctly decided to not send a message when the user cannot walk. The cumulative reward plots show that LLM+TS outperforms standard TS.
