# Reducing Latency by Eliminating CSIT Feedback: FDD Downlink MIMO Precoding Without CSIT Feedback for Internet-of-Things Communications

Juntaek Han, Namhyun Kim, and Jeonghun Park

*Abstract*—This paper presents a novel framework for lowlatency frequency division duplex (FDD) multi-input multioutput (MIMO) transmission with Internet of Things (IoT) communications. Our key idea is eliminating feedback associated with downlink channel state information at the transmitter (CSIT) acquisition. Instead, we propose to reconstruct downlink CSIT from uplink reference signals by exploiting the frequency invariance property on channel parameters. Nonetheless, the frequency disparity between the uplink and downlink makes it impossible to get perfect downlink CSIT, resulting in substantial interference. To address this, we formulate a max-min fairness problem and propose a rate-splitting multiple access (RSMA)-aided efficient precoding method. In particular, to fully harness the potential benefits of RSMA, we propose a method that approximates the error covariance matrix and incorporates it into the precoder optimization process. This approach effectively accounts for the impact of imperfect CSIT, enabling the design of a robust precoder that efficiently handles CSIT inaccuracies. Simulation results demonstrate that our framework outperforms other baseline methods in terms of the minimum spectral efficiency when no direct CSI feedback is used. Moreover, we show that our framework significantly reduces communication latency compared to conventional CSI feedback-based methods, underscoring its effectiveness in enhancing latency performance for IoT communications.

*Index Terms*—Rate-splitting multiple access, max-min fairness, beamformer design, generalized power iteration, imperfect CSIT.

#### I. INTRODUCTION

A key distinguishable characteristic of Internet of Things (IoT) communications is the demand for extremely low latency and high reliability, often referred to as Ultra-Reliable Low Latency Communications (URLLC) [\[1\]](#page-11-0), [\[2\]](#page-11-1). For reducing communication latency, one promising approach that has been actively studied in the literature is decreasing size of blocklength. As the blocklength decreases, communication systems enter the finite blocklength regime, where the block error rate does not vanish, and the classical Shannon capacity no longer accurately reflects the communication performance metric. To address this, the finite blocklength capacity was revealed in [\[3\]](#page-11-2). Compared to the classical Shannon capacity, the finite blocklength capacity accounts for the non-negligible block error rate. This block error rate, along with the blocklength, determines a back-off factor for the achievable rate, in which the interplay between the rate, the blocklength, and the error rate is properly captured [\[4\]](#page-11-3).

1

Harnessing the finite blocklength capacity result, abundant prior work has been presented to develop efficient design for URLLC IoT communications. In [\[5\]](#page-11-4), the multiple-input multiple-output (MIMO) capacity in the finite blocklength regime was characterized. In [\[6\]](#page-11-5), a joint resource allocation algorithm was developed exploiting semi-definite programming for maximizing the sum spectral efficiency. In [\[7\]](#page-11-6), [\[8\]](#page-11-7), the downlink communication latency performance was analyzed using tools of network calculus. Later, this was extended by incorporating uplink and non-orthogonal multiple access (NOMA) in [\[9\]](#page-11-8). In [\[4\]](#page-11-3), a MIMO precoding method for jointly optimizing the achievable rate and the error probability was developed. In a similar vein, [\[10\]](#page-11-9) developed a MIMO precoding design strategy for scenarios where delay-constrained IoT devices coexist with delaytolerant devices. In [\[11\]](#page-11-10)–[\[13\]](#page-11-11), a rate-splitting multiple access (RSMA) strategy was studied in the finite blocklength regime. Considering that the gap between the classical Shannon capacity and the finite blocklength capacity is noticeable when the number of information bits is approximately less than 20000 [\[5\]](#page-11-4) (for  $> 20000$ , the rate back-off factor is less than 0.1 at the signal-to-noise ratio (SNR) of 10 dB and the error probability of  $10^{-8}$  [\[4\]](#page-11-3)), the prior work is useful to design IoT communications with relatively small payloads, particularly when the payload size is less than 2.5 KB (kilobytes). According to [\[14\]](#page-11-12), this payload size corresponds to haptic messages in teleoperations or missioncritical messages in automotive applications.

In [\[14\]](#page-11-12), relatively heavy payload IoT communications were also discussed, including immersive virtual reality or video message for automotive applications and Internet-of-Drones (IoD), wherein the payload size ranges from  $2.5 \sim 20$ KB. In this case, decreasing blocklength is not effective, while latency is primarily determined by spectral efficiency performance and communication overhead. For this reason, minimizing communication overhead while maintaining high spectral efficiency is crucial for enabling URLLC for these

This work was supported by Institute of Information & communications Technology Planning & Evaluation (IITP) grant funded by the Korea government(MSIT) (No. RS-2024-00395824, Development of Cloud virtualized RAN (vRAN) system supporting upper-midband and No. RS-2024- 00434743, YKCS Open RAN Global Collaboration Center).

heavy payload IoT communications. Especially, the amount of overhead significantly increases when it comes with downlink MIMO systems using frequency division duplex (FDD). This is because i) in downlink MIMO, channel state information at the transmitter (CSIT) is essential for enabling multiplexing [\[15\]](#page-11-13); and ii) unlike in time division duplex (TDD) wherein full channel reciprocity holds, in FDD, the CSIT for the uplink and downlink bands is different [\[16\]](#page-11-14). Consequently, to obtain CSIT in FDD MIMO, the transmitter must first send a downlink pilot to each user, who then computes the CSI and sends it back to the transmitter. This CSIT acquisition process incurs significant communication latency, which poses a challenge for supporting URLLC.

Due to this obstacle, one may be tempted to consider alternatives to FDD MIMO, such as single-user transmission or TDD MIMO. Nonetheless, these solutions are not suitable for IoT communications. For example, with single-user transmission, spatial degrees of freedom (DoF) cannot be leveraged, resulting in significant latency when serving a large number of IoT devices. Furthermore, FDD is more suitable for achieving low latency, as it supports simultaneous uplink and downlink communications [\[17\]](#page-11-15). Additionally, it is well known that FDD provides better uplink coverage by allocating favorable low-frequency bands to IoT devices with limited transmit power [\[18\]](#page-11-16), [\[19\]](#page-11-17). This is especially critical in IoT communications, where the transmit power of IoT device is significantly limited. For this reason, enabling FDD MIMO transmission without incurring significant overhead is essential for URLLC.

There exists several prior work to reduce the overhead associated with CSIT acquisition in FDD MIMO. In [\[20\]](#page-11-18), a distributed CSIT compression strategy was proposed by leveraging shared geometry of scatterers for each user. In [\[21\]](#page-11-19), [\[22\]](#page-11-20), a deep learning technique was used for designing a mapping function to extrapolate the CSI to different sets of antennas and frequency. In [\[23\]](#page-11-21), a novel approach to reconstruct downlink CSI from uplink pilot signals was proposed, allowing the CSI feedback process to be omitted. This is feasible thanks to the frequency-invariant characteristics between the uplink and the downlink channels. For instance, even though full channel reciprocity does not hold, some key channel parameters, e.g., number of paths, angle of departure (AoD), delay, and path gains, can be assumed to be identical between the uplink and the downlink bands. This idea has served as the foundation for numerous other researches, such as [\[24\]](#page-11-22)–[\[27\]](#page-11-23). In particular, [\[28\]](#page-11-24) presented measurement campaigns to support the frequency invariant properties.

Nonetheless, the existing work primarily focused on efficient downlink CSIT acquisition, without providing a comprehensive framework that encompasses CSI acquisition, the effects of erroneous CSI, a robust multiple-access technique, and precoder optimization. To address this, in [\[27\]](#page-11-23), it was shown that when the downlink CSI is reconstructed from the uplink pilot signals without relying on direct CSI feedback in FDD massive MIMO systems, the robust spectral efficiency

gains are only achievable if the CSI reconstruction error is properly incorporated into the precoder optimization.

In this paper, we consider a IoT communication system using FDD MIMO. In such a system, we formulate a max-min fairness (MMF) problem whose main aim is to maximize the minimum spectral efficiency among the IoT devices. By solving this, we can guarantee the worst-case latency for the IoT communications. For instance, in [\[29\]](#page-11-25), [\[30\]](#page-11-26), the similar max-min fairness problem was tackled in the context of IoT communications, focusing on optimizing resource allocation to ensure fair performance among devices. Furthermore, some other prior work also tackled the max-min fairness problem, but it typically relied on direct CSI feedback to obtain downlink CSI [\[31\]](#page-11-27), [\[32\]](#page-11-28), resulting in significant latency overhead. This approach is not suitable for IoT communications, where achieving low latency is critical.

To resolve the above-mentioned issue, we put forth a novel framework for enabling low-latency FDD MIMO transmission. Specifically, to avoid significant latency overhead associated with downlink CSIT acquisition, we reconstruct the downlink CSI from the uplink pilot signals; thereby eliminating the need for direct CSI feedback. To this end, upon the received uplink reference signals, we use the 2D-Newtonized orthogonal matching pursuit (2D-NOMP) algorithm [\[33\]](#page-11-29) to extract the key channel parameters from the uplink CSI estimation. Then, leveraging the frequency invariant property [\[23\]](#page-11-21), [\[26\]](#page-11-30), [\[27\]](#page-11-23), [\[34\]](#page-11-31), we rebuild the downlink CSI. Unfortunately, this downlink CSI reconstruction approach cannot be perfect due to the uplink and downlink frequency difference; resulting in the remaining interference [\[26\]](#page-11-30), [\[27\]](#page-11-23). To mitigate this, we employ a rate-splitting multiple access (RSMA) technique [\[31\]](#page-11-27), [\[35\]](#page-11-32), [\[36\]](#page-11-33), wherein each user's message is split into a common and a private part; then each common part is jointly encoded to make a common message. Each private part is individually encoded to make a private message. Based on this message construction, each user decodes the common message, by which successive interference cancellation (SIC) gains are achieved. Following this, the user decodes the private message with reduced interference. RSMA is known to achieve robust spectral efficiency performance in the presence of imperfect CSIT [\[35\]](#page-11-32), [\[36\]](#page-11-33). Accordingly, we use RSMA to effectively manage the interference resulting from imperfect CSIT.

Nonetheless, it is not feasible to directly apply RSMA into our setup. This is because, in the precoder optimization, the CSIT error covariance is required to account for the impact of CSI inaccuracies on the spectral efficiency performance of RSMA. However, it is challenging to compute in our case due to the absence of CSI feedback. To deal with this, we devise a CSI error covariance approximation strategy based on observed Fisher information matrix (O-FIM), which is interpreted as a sampled version of Fisher information matrix (FIM). Accordingly, O-FIM is closely connected to Cramér-Rao lower bound (CRLB), which corresponds to a lowerbound on the mean squared error (MSE) performance. Lever-

aging the approximated CSI error covariance, we develop a low-complexity precoder design algorithm based on a generalized power iteration (GPI) approach [\[35\]](#page-11-32).

The proposed framework significantly reduces communication latency in three specific aspects, as detailed below.

- Downlink CSIT reconstruction: Since we reconstruct the CSI from the uplink reference signals, it is possible to omit the downlink CSI training and CSI feedback processes. In 5G-NR, these processes involve with CSI-RS, i.e., downlink pilot signals, and CSI feedback including PMI, RI, and SINR. In general, the whole processes take up to  $6 \sim 10$  ms [\[37\]](#page-11-34).
- Robust spectral efficiency: Even though downlink CSI can be obtained without CSI feedback, using the reconstructed CSI in transmission design can degrade the achievable spectral efficiency due to the inevitable CSI error arising from the uplink and downlink frequency differences. We compensate this by applying the CSI error covariance approximation and the RSMA-aided precoder optimization method.
- Low complexity precoder: Typically, the precoder optimization becomes very complicated with RSMA [\[32\]](#page-11-28), as the common message rate must be carefully determined to ensure decodability. As a result, the latency gains achieved by using RSMA can be negated by the high complexity precoder design. The proposed precoding method avoids the high computational complexity, by which efficiently manages the common message rate constraint using the LogSumExp approximation technique.

Via simulations, we demonstrate that our framework achieves significant minimum spectral efficiency gains when no direct CSI feedback is used. Particularly, the proposed method achieves 12.5% higher minimum spectral efficiency compared to that of the state-of-the-art RSMA precoder using the weighted minimum mean squared error (WMMSE) method [\[38\]](#page-11-35). These gains mainly come from the proposed error covariance matrix approximation technique, which suitably captures the impacts on remaining interference caused by CSI reconstruction error. Furthermore, we also analyze the latency performance of each method. We also consider the conventional CSI acquisition framework that relies on downlink training and feedback. In this comparison, we observe that the benefits of our method become more pronounced in terms of latency. Specifically, although the conventional CSI acquisition framework can obtain precise downlink CSI, it incurs approximately 6 ms of latency, which significantly undermines the overall latency performance. Our framework reduces the latency associated with CSI acquisition by reconstructing it based on uplink pilots. Notwithstanding the fact that this approach inevitably introduces additional interference due to CSI reconstruction errors, we address this challenge by employing a robust multiple access (i.e., RSMA) and leveraging the error covariance matrix approximation technique. As a result, the proposed framework achieves significantly reduced latency, demonstrating its suitability for URLLC IoT communications.

#### II. SYSTEM MODEL

<span id="page-2-3"></span>We focus on IoT communications using FDD MIMO. We are particularly interested in a large payload case, typically ranging from 2.5 to 20KB [\[14\]](#page-11-12). In such a scenario, we explain our system model as follows.

#### *A. Channel Model*

We consider that a base station (BS) equipped with  $N$  antennas serves  $K$  single-antenna devices. We denote a device set as  $K$ . Based on this scenario, we first introduce the uplink channel model. Assuming that orthogonal frequency division multiplexing (OFDM) is used, the uplink channel consists of *M* sub-carriers, each spaced by  $\Delta f$ . Then, following a widely-adopted multi-path signal model [\[28\]](#page-11-24), [\[34\]](#page-11-31), [\[39\]](#page-11-36), [\[40\]](#page-11-37) the uplink channel for device  $k \in \mathcal{K}$  on the *m*-th sub-carrier is given by

<span id="page-2-0"></span>
$$
\mathbf{h}_{k}^{\text{ul}}[m] = \sum_{\ell=1}^{L_{k}^{\text{ul}}} \alpha_{k,\ell}^{\text{ul}} \mathbf{a}\left(\theta_{k,\ell}^{\text{ul}}; \lambda^{\text{ul}}\right) e^{-j2\pi m \Delta f \tau_{k,\ell}^{\text{ul}}} \in \mathbb{C}^{N \times 1}, \quad (1)
$$

where the number of channel paths and the complex path gain are  $L_k^{\text{ul}}$  and  $\alpha_{k,\ell}^{\text{ul}}$ , respectively. The index  $m \in \mathbb{Z}$ ranges from  $\left[-M/2\right]$  to  $\left\lfloor M/2\right\rfloor$  - 1. Assuming uniform linear array (ULA) is used at the BS, the array response vector **a**  $(\theta_{k,\ell}^{\text{ul}}; \lambda^{\text{ul}})$  is constructed as

$$
\mathbf{a}\left(\theta_{k,\ell}^{\text{ul}};\lambda^{\text{ul}}\right) = \left[1, e^{j2\pi \frac{d}{\lambda^{\text{ul}}}\sin\theta_{k,\ell}^{\text{ul}}}, \cdots, e^{j2\pi(N-1)\frac{d}{\lambda^{\text{ul}}}\sin\theta_{k,\ell}^{\text{ul}}}\right]^{\mathsf{T}},\tag{2}
$$

where  $\theta_{k,\ell}^{\text{ul}}$  represents the angle-of-arrival (AoA) corresponding to  $\ell$ -th path in the channel for device k.  $\lambda$ <sup>ul</sup> is the uplink channel's carrier wavelength, and  $d$  is the antenna spacing, which is  $\lambda^{ul}/2$ . We note that the wavelength variations over the uplink sub-carriers are relatively small, so that we assume that the AoA  $\theta_{k,\ell}^{\text{ul}}$  is constant over all the subcarriers. We clarify that this assumption was justified in [\[34\]](#page-11-31), [\[41\]](#page-11-38). In addition,  $\tau_{k,\ell}^{\text{ul}}$  is the propagation delay for the  $\ell$ -th path of device k, which lies within  $0 \leq \tau_{k,\ell}^{\text{ul}} \leq 1/\Delta f$ . For generality and practicality, we assume no prior distribution on the channel parameters.

To simplify notation, we omit the sub-carrier index  $m$ and replace  $m\Delta f$  with generic  $f<sup>ul</sup>$ . Consequently, the uplink channel [\(1\)](#page-2-0) is rewritten as

<span id="page-2-1"></span>
$$
\mathbf{h}_{k}^{\text{ul}} = \sum_{\ell=1}^{L_{k}^{\text{ul}}} \alpha_{k,\ell}^{\text{ul}} \mathbf{a}\left(\theta_{k,\ell}^{\text{ul}}; \lambda^{\text{ul}}\right) e^{-j2\pi f^{\text{ul}} \tau_{k,\ell}^{\text{ul}}} \in \mathbb{C}^{N \times 1}.
$$
 (3)

Based on [\(3\)](#page-2-1), we define the downlink channel model. Letting the carrier frequency difference between the uplink and downlink be  $f$ , the downlink channel is represented as

<span id="page-2-2"></span>
$$
\mathbf{h}_{k}^{\mathrm{dl}}(f) = \sum_{\ell=1}^{L_{k}^{\mathrm{dl}}} \alpha_{k,\ell}^{\mathrm{dl}} \mathbf{a}\left(\theta_{k,\ell}^{\mathrm{dl}}; \lambda^{\mathrm{dl}}\right) e^{-j2\pi f \tau_{k,\ell}^{\mathrm{dl}}} \in \mathbb{C}^{N \times 1}.
$$
 (4)

Fig. 1: Comparison of the conventional CSI-RS based transmission and the proposed UL-SRS based transmission

Now we explain the frequency invariance property on channel parameters. As long as the propagation geometry remains unchanged between the uplink and downlink, the channel parameters are frequency invariant, i.e.,  $L_k^{\text{dl}} = L_k^{\text{ul}}$  $L_k$ ,  $\theta_{k,\ell}^{\text{dl}} = \theta_{k,\ell}^{\text{ul}}$ , and  $\tau_{k,\ell}^{\text{dl}} = \tau_{k,\ell}^{\text{ul}}$  as demonstrated in [\[26\]](#page-11-30), [\[28\]](#page-11-24),  $\hat{34}$ ],  $\hat{40}$ ]. However, this does not mean that the uplink channel  $\mathbf{h}_k^{\text{ul}}$  is same with the downlink channel  $\mathbf{h}_k^{\text{dl}}(f)$ . This is because the array response vectors  $\mathbf{a}\left(\theta_{k,\ell}^{\text{ul}};\lambda^{\text{ul}}\right)$ and  $\mathbf{a} \left( \theta_{k,\ell}^{\text{dl}}; \lambda^{\text{dl}} \right)$  are different even with  $\theta_{k,\ell}^{\text{dl}} = \theta_{k,\ell}^{\text{ul}}$  since  $\lambda^{\text{ul}} \neq \lambda^{\text{dl}}$ . Also, the delay terms are also different, i.e.,  $e^{-j2\pi f^{\text{ul}}\tau_{k,\ell}^{\text{ul}}}\neq e^{-j2\pi f\tau_{k,\ell}^{\text{dl}}}$  since the carrier frequencies are different.

In addition to above, the complex path gains  $\alpha_{k,\ell}^{\text{dl}}$  and  $\alpha_{k,\ell}^{\text{ul}}$ may be different since the path-loss is typically determined depending on the carrier frequency. To reflect this, we model these as

$$
\alpha_{k,\ell}^{\text{dl}} = \eta_{k,\ell} \alpha_{k,\ell}^{\text{ul}} + \sqrt{1 - \eta_{k,\ell}^2} g, g \sim \mathcal{CN}(0, \sigma_{\text{path},k}^2), \qquad (5)
$$

where  $\eta_{k,\ell}$  indicates the correlation factor of the  $\ell$ -th path between the downlink and uplink path gains of device k. The correlation factor  $\eta_{k,\ell}$  ranges from 0 to 1, where  $\eta_{k,\ell} = 1, \forall (k,\ell)$  indicates the perfect reciprocity of the complex path gain between uplink and downlink, while  $\eta_{k,\ell} = 0$ ,  $\forall (k,\ell)$  indicates that the complex path gains are totally independent. In this sense, our model [\(5\)](#page-3-0) encompasses several previous assumptions as special cases. For example, the assumptions in [\[26\]](#page-11-30), [\[42\]](#page-12-0) correspond to  $\eta_{k,\ell} = 1, \forall (k,\ell)$ in our model.

## *B. RSMA Signal Model*

To mitigate the interference caused from the imperfect downlink CSIT reconstruction, we employ the 1-layer RSMA approach [\[35\]](#page-11-32), [\[36\]](#page-11-33). In this approach, the message  $m_k, \forall k \in \mathcal{K}$ , which is intended to device k, is split into a common part  $m_{c,k}$  and a private part  $m_{p,k}$ . The common parts of all devices  $m_{c,l}$ ,  $\cdots$ ,  $m_{c,K}$  are combined and jointly encoded into the common symbol  $s_c$ . For  $s_c$ , a public codebook, shared by all the devices in the considered network, is used; so that every device is able to decode  $s_c$ . On the contrary to this, each private part  $m_{p,k}$  is independently encoded into the private symbol  $s_{p,k}$  using an individual codebook. We assume that the symbols  $s_c$ ,  $s_{p,k}$  are assumed to be drawn from an independent Gaussian codebook, i.e.,  $s_c, s_k \sim \mathcal{CN}(0, P).$ 

For decoding, each device first decodes the common symbol first while treating the private symbols as noise. After that, the common symbol is removed using successive interference cancellation (SIC), thereafter each private symbol of device  $k$  is decoded with a reduced amount of interference.

For signal transmission, we employ linear beamforming, wherein each symbol is superimposed and linearly combined with the beamforming vectors  $\mathbf{F} \triangleq [\mathbf{f}_c, \mathbf{f}_1, \cdots, \mathbf{f}_K] \in$  $\mathbb{C}^{N\times (K+1)}$ . Denoting  $\mathbf{s} \triangleq [s_c, s_{p,1}, \cdots, s_{p,K}]^{\mathsf{T}} \in \mathbb{C}^{(K+1)\times 1}$ , the transmit signal  $\mathbf{x} \in \mathbb{C}^{N \times 1}$  is given by

<span id="page-3-1"></span>
$$
\mathbf{x} = \mathbf{F}\mathbf{s} = \mathbf{f}_c s_c + \sum_{i=1}^K \mathbf{f}_i s_{p,i}.
$$
 (6)

<span id="page-3-0"></span>The transmit power constraint is tr( $\mathbf{FF}^H$ )  $\leq 1$ , ensuring that the total transmit power constraint is  $P$ . The received signal at device  $k$  is given by

$$
y_k = \mathbf{h}_k^{\mathrm{dl}}(f)^{\mathsf{H}}(\mathbf{f}_c s_c + \mathbf{f}_k s_{p,k}) + \sum_{i=1, i \neq k}^{K} \mathbf{h}_k^{\mathrm{dl}}(f)^{\mathsf{H}} \mathbf{f}_i s_{p,i} + z_k,
$$
\n(7)

where  $z_k \sim \mathcal{CN}(0, \sigma^2)$  is the additive white Gaussian noise (AWGN).

# III. DOWNLINK CHANNEL RECONSTRUCTION AND PERFORMANCE CHARACTERIZATION

## *A. Downlink Channel Reconstruction*

Recall that we do not use direct feedback to acquire downlink CSIT. Instead, we first estimate the uplink CSI, then extract the key channel parameters. Then, leveraging the frequency-invariance property of the uplink and downlink channels, we rebuild the downlink CSI. To this end, we first denote a stacked uplink channel vector  $\mathbf{u}(\tau, \theta)$  as

$$
\mathbf{u}(\tau,\theta) = [\mathbf{p}_0^{\mathsf{T}}, \mathbf{p}_1^{\mathsf{T}}, \cdots, \mathbf{p}_{M-1}^{\mathsf{T}}]^{\mathsf{T}} \in \mathbb{C}^{MN \times 1},\tag{8}
$$

where each sub-vector is

$$
\mathbf{p}_i = \mathbf{a}\left(\theta; \lambda^{\text{ul}}\right) e^{-j2\pi \left( \lfloor -\frac{M}{2} \rfloor + i \right) \Delta f \tau} \in \mathbb{C}^{N \times 1}.
$$
 (9)

Using this, assuming that all-ones uplink reference signal is used without loss of generality, the uplink reference signal of device  $k$  across all the sub-carriers and antennas is represented as

$$
\mathbf{y}_{k}^{\text{ul}} = \sum_{\ell=1}^{L_{k}} \alpha_{k,\ell}^{\text{ul}} \mathbf{u}(\tau_{k,\ell}^{\text{ul}}, \theta_{k,\ell}^{\text{ul}}) + \mathbf{w}_{k} \in \mathbb{C}^{MN \times 1}, \qquad (10)
$$

where  $\mathbf{w}_k \sim \mathcal{CN}(0, \sigma_{est}^2 \mathbf{I}_{MN})$  is an additive Gaussian noise in the uplink estimation phase.

From [\(10\)](#page-4-0), we extract the uplink channel parameters  $\{\alpha_{k,\ell}^{\text{ul}}, \tau_{k,\ell}^{\text{ul}}\}$ ,  $\forall_{k,\ell}$  from  $\mathbf{y}_{k}^{\text{ul}}$ . Note that this parameter extraction requires a much complicated process compared to the typical uplink channel estimation [\[43\]](#page-12-1). For this purpose, we exploit the 2D-NOMP algorithm [\[33\]](#page-11-29). In the 2D-NOMP algorithm, we interpret the parameter extraction problem based on [\(10\)](#page-4-0) as a spectral compressive sensing problem [\[44\]](#page-12-2). Specifically, assuming a grid-based dictionary matrix

$$
\tilde{\mathbf{U}} = \begin{bmatrix} \mathbf{u}(\tau_1, \theta_1) & \mathbf{u}(\tau_2, \theta_2) & \cdots & \mathbf{u}(\tau_Q, \theta_Q) \end{bmatrix}, \qquad (11)
$$

we regard [\(10\)](#page-4-0) as a product between the dictionary matrix  $\mathbf{\hat{U}}$  and a  $L_k$  sparse vector. Based on this viewpoint, the OMP algorithm [\[45\]](#page-12-3) can be applied to find the sparse vector. Nonetheless, this approach is not sufficient since the true  $\mathbf{u}(\tau_{k,\ell}^{\text{ul}}, \theta_{k,\ell}^{\text{ul}})$  may not be on a predefined grid in  $\tilde{\mathbf{U}}$  [\(11\)](#page-4-1). To address this, the 2D-NOMP additionally refines the detected signal through Newton step. For the sake of completeness, we briefly outline the process of the 2D-NOMP algorithm in Algorithm [1.](#page-4-2) For more detailed explanations regarding the 2D-NOMP algorithm, we refer readers to [\[33\]](#page-11-29).

After we obtain the estimated channel parameters  $\{\hat{\alpha}_{k,\ell}^{\text{ul}}, \hat{\tau}_{k,\ell}^{\text{ul}}\}$   $\forall k,\ell$  using the 2D-NOMP algorithm, we get the downlink channel parameters as

$$
(\hat{\tau}_{k,\ell}^{\text{dl}}, \hat{\theta}_{k,\ell}^{\text{dl}}) = (\hat{\tau}_{k,\ell}^{\text{ul}}, \hat{\theta}_{k,\ell}^{\text{ul}})
$$

$$
\hat{\alpha}_{k,\ell}^{\text{dl}} = \eta_{k,\ell} \hat{\alpha}_{k,\ell}^{\text{ul}}, \tag{12}
$$

where  $\hat{\alpha}_{k,i}^{\text{dl}}$  is derived from [\(5\)](#page-3-0). Finally, using  $\{\hat{\alpha}_{k,\ell}^{\text{dl}}, \hat{\tau}_{k,\ell}^{\text{dl}}, \hat{\theta}_{k,\ell}^{\text{dl}}\}$   $\forall k,\ell$ , we rebuild the downlink CSI as

$$
\hat{\mathbf{h}}_{k}(f) = \sum_{\ell=1}^{L_{k}} \hat{\alpha}_{k,\ell}^{\text{dl}} \mathbf{a}\left(\hat{\theta}_{k,\ell}^{\text{dl}}; \lambda^{\text{dl}}\right) e^{-j2\pi f \hat{\tau}_{k,\ell}^{\text{dl}}}.
$$
 (13)

We exploit  $\hat{\mathbf{h}}_k(f)$  to characterize the performance and design the precoders.

### *B. Performance Characterization*

Hereafter, we drop the notation of f from  $\hat{\mathbf{h}}_k(f)$  for simplicity so that we denote  $\hat{\mathbf{h}}_k$  as the downlink CSI of device  $k$ . It is worthwhile to note that the estimated downlink CSI  $\hat{\mathbf{h}}_k$  cannot be perfect due to the inherent reconstruction error caused from the carrier frequency difference and the performance limitations of the 2D-NOMP algorithm [\[34\]](#page-11-31), [\[41\]](#page-11-38). Incorporating this, we present the estimated downlink CSI as follows.

$$
\mathbf{h}_k = \hat{\mathbf{h}}_k + \mathbf{e}_k, \ \mathbf{e}_k \neq \mathbf{0}, \tag{14}
$$

Algorithm 1: 2D-NOMP Algorithm

<span id="page-4-2"></span><span id="page-4-0"></span>Output:  $\{\hat{\alpha}_{k,\ell}^{\text{ul}}, \hat{\tau}_{k,\ell}^{\text{ul}}, \hat{\theta}_{k,\ell}^{\text{ul}}\}_{\forall k,\ell}$ 1 for  $k \in \mathcal{K}$  do  $\mathbf{r}_k \leftarrow \mathbf{y}_k^{\text{ul}}, j \leftarrow 1$ 3 repeat

4 *Step 1: New Detection*

<span id="page-4-3"></span>
$$
(\tau_k^{(j)}, \theta_k^{(j)}) \leftarrow \underset{(\tau_k, \theta_k)}{\arg \max} \frac{|\mathbf{u}^{\mathsf{H}}(\tau_k, \theta_k)\mathbf{r}_k|^2}{\|\mathbf{u}(\tau_k, \theta_k)\|^2},
$$

$$
\alpha_k^{(j)} \leftarrow \frac{\mathbf{u}^{\mathsf{H}}(\tau_k^{(j)}, \theta_k^{(j)})\mathbf{r}_k}{\|\mathbf{u}(\tau_k^{(j)}, \theta_k^{(j)})\|^2}.
$$
 (\*)

<span id="page-4-1"></span>5 *Step 2: Refinement using Newton step* 6 | Newton Step  $s(\alpha, \tau, \theta)$ 

$$
\mathbf{s}(\alpha, \tau, \theta) = -J''(\alpha, \tau, \theta)^{-1} J'(\alpha, \tau, \theta)
$$

$$
\begin{bmatrix} \tau_k^{(j)} \\ \theta_k^{(j)} \end{bmatrix} \leftarrow \begin{bmatrix} \tau_k^{(j)} \\ \theta_k^{(j)} \end{bmatrix} + \mathbf{s}(\alpha_k^{(j)}, \tau_k^{(j)}, \theta_k^{(j)})
$$

7 | Update  $\alpha_k^{(j)}$  using (\*). 8 | Cyclical refinement using Newton step to get  $\{\alpha_k^{(i)}, \tau_k^{(i)}, \theta_k^{(i)}\}_{i=1,\cdots,j}$ <sup>9</sup> *Step 3: Update gains using LS estimation* 10  $\mathbf{U} = [\mathbf{u}(\tau_k^{(1)}, \theta_k^{(1)}), \cdots, \mathbf{u}(\tau_k^{(j)}, \theta_k^{(j)})]$  $[\alpha_k^{(1)}, \cdots, \alpha_k^{(j)}]^\mathsf{T} \leftarrow \mathbf{U}^\dagger \mathbf{y}_k^{\mathrm{ul}}$  $\mathbf{r}_k \leftarrow \mathbf{y}_{k_{\text{c}}}, \sum_{j}^{N} \sum_{k}^{j} \mathbf{u}(\tau_k^{(j)} \mathbf{u}(\tau_k^{(j)}, \theta_k^{(j)}), j \leftarrow j+1$ 12 until  $\|\mathbf{u}^{\mathsf{H}}(\tau_k^{(j)}, \theta_k^{(j)})\mathbf{r}_k\|^2 < \kappa;$ 

13 end

where  $e_k$  is the estimation error. With this, we rewrite the received signal [\(7\)](#page-3-1) as

$$
y_k = \mathbf{h}_k^{\mathsf{H}} \mathbf{f}_c s_c + \sum_{\ell=1}^K \mathbf{h}_k^{\mathsf{H}} \mathbf{f}_\ell s_{p,\ell} + z_k
$$
(15)  

$$
= \hat{\mathbf{h}}_k^{\mathsf{H}} \mathbf{f}_c s_c + \sum_{\ell=1}^K \hat{\mathbf{h}}_k^{\mathsf{H}} \mathbf{f}_\ell s_{p,\ell} + \mathbf{e}_k^{\mathsf{H}} \mathbf{f}_c s_c + \sum_{i=1}^K \mathbf{e}_k^{\mathsf{H}} \mathbf{f}_i s_{p,i} + z_k.
$$
(16)

For tractability, we treat  $e_k$  as an independent Gaussian noise, which leads to the worst case of mutual information [\[35\]](#page-11-32). Then we reach a lower bound on the spectral efficiency of the common symbol  $s_c$  achieved at device k

$$
R_{c,k}
$$
\n
$$
\geq^{(a)} \mathbb{E}_{\{\mathbf{e}_{k}\}}\left[\log_{2}\left(1+\frac{|\hat{\mathbf{h}}_{k}^{\mathsf{H}}\mathbf{f}_{c}|^{2}}{\left\{\sum_{\ell=1}^{K}|\hat{\mathbf{h}}_{k}^{\mathsf{H}}\mathbf{f}_{\ell}|^{2}+|\mathbf{e}_{k}^{\mathsf{H}}\mathbf{f}_{c}|^{2}}\right\}\right)\right]
$$
\n
$$
\geq^{(b)} \log_{2}\left(1+\frac{|\hat{\mathbf{h}}_{k}^{\mathsf{H}}\mathbf{f}_{\ell}|^{2}+|\mathbf{e}_{k}^{\mathsf{H}}\mathbf{f}_{c}|^{2}}{\left\{\sum_{\ell=1}^{K}|\hat{\mathbf{h}}_{k}^{\mathsf{H}}\mathbf{f}_{\ell}|^{2}+\mathbf{f}_{c}^{\mathsf{H}}\mathbf{g}_{\ell}|\mathbf{f}_{c}\right\}}\right)
$$
\n
$$
=^{(c)} \log_{2}\left(1+\frac{|\hat{\mathbf{h}}_{k}^{\mathsf{H}}\mathbf{f}_{c}|^{2}}{\sum_{\ell=1}^{K}|\hat{\mathbf{h}}_{k}^{\mathsf{H}}\mathbf{f}_{\ell}|^{2}+\mathbf{f}_{c}^{\mathsf{H}}\mathbf{g}_{\ell}\mathbf{e}_{k}\mathbf{e}_{k}^{\mathsf{H}}\mathbf{f}_{\ell}+\frac{\sigma^{2}}{P}}\right)
$$
\n
$$
=R_{c,k},\tag{17}
$$

where (a) results from treating the CSI estimation error as independent Gaussian noise, (b) follows Jensen's inequality, and (c) comes from

$$
\mathbb{E}[\mathbf{e}_k \mathbf{e}_k^{\mathsf{H}}] = \mathbf{\Phi}_k,\tag{18}
$$

where  $\Phi_k$  is the error covariance matrix.

After SIC, the common symbol is removed; and we also get a lower bound on the spectral efficiency of the private symbol  $s_{p,k}$  at device k

$$
R_{p,k}
$$
\n
$$
\geq \mathbb{E}_{\{\mathbf{e}_k\}} \left[ \log_2 \left( \frac{|\hat{\mathbf{h}}_k \mathbf{f}_k|^2}{\sum_{\ell=1,\ell \neq k}^K |\hat{\mathbf{h}}_k \mathbf{f}_\ell|^2 + \sum_{\ell=1}^K |\mathbf{e}_k^H \mathbf{f}_\ell|^2 + \frac{\sigma^2}{p} } \right) \right]
$$
\n
$$
\geq \log_2 \left( 1 + \frac{|\hat{\mathbf{h}}_k \mathbf{f}_k|^2}{\sum_{\ell=1,\ell \neq k}^K |\hat{\mathbf{h}}_k \mathbf{f}_\ell|^2 + \sum_{\ell=1}^K \mathbf{f}_\ell^H \mathbb{E}[\mathbf{e}_k \mathbf{e}_k^H] \mathbf{f}_\ell + \frac{\sigma^2}{p} } \right)
$$
\n
$$
= \log_2 \left( 1 + \frac{|\hat{\mathbf{h}}_k \mathbf{f}_\ell|^2}{\sum_{\ell=1,\ell \neq k}^K |\hat{\mathbf{h}}_k \mathbf{f}_\ell|^2 + \sum_{\ell=1}^K \mathbf{f}_\ell^H \mathbf{\Phi}_k \mathbf{f}_\ell + \frac{\sigma^2}{p} } \right)
$$
\n
$$
= \bar{R}_{p,k}.
$$
\n(19)

Note that the derivation is similar to [\(17\)](#page-5-0).

Remark 1. Note that we use the Shannon capacity as our main performance metric. This is reasonable because we mainly consider relatively heavy payload IoT communication scenarios, for example immersive virtual reality or video message for automotive applications and Internet-of-Drones (IoD). In [\[14\]](#page-11-12), the payload sizes of these IoT services are typically  $2.5 \sim 20KB$ . Conservatively, the rate back-off factor in this case is less than 0.1 at the SNR of 10dB and the error probability of  $10^{-8}$  as mentioned in the earlier section. Accordingly, the rate back-off and the error probability are negligible in this regime, which validates our choice of performance metric. Further, we also note that the classical Shannon capacity has been widely used for IoT scenarios where latency matters [\[46\]](#page-12-4)–[\[49\]](#page-12-5).

When considering the finite blocklength regime, SIC in RSMA may not be perfect, which incurs additional interference when decoding the private message [\[12\]](#page-11-39), [\[13\]](#page-11-11). Incorporating this effect into our framework is interesting future work.

### IV. ERROR COVARIANCE MATRIX APPROXIMATION

To evaluate  $\bar{R}_{c,k}$  [\(17\)](#page-5-0) and  $\bar{R}_{p,k}$  [\(19\)](#page-5-1), the error covariance matrix  $\Phi_k$  is necessary. However, it is not straightforward to obtain  $\Phi_k$  because i) the 2D-NOMP algorithm is highly nonlinear and ii) no prior distribution on the channel parameters is assumed in our setup.

To address this, we exploit a concept of the FIM. Let us define the channel parameter vector as

$$
\psi_k = [\psi_{k,1}^\mathsf{T}, \psi_{k,2}^\mathsf{T}, \cdots, \psi_{k,L_k}^\mathsf{T}]^\mathsf{T} \in \mathbb{R}^{4L_k \times 1}
$$
 (20)

<span id="page-5-0"></span>and

$$
\psi_{k,\ell} = [\tau_{k,\ell}^{\text{ul}}, \theta_{k,\ell}^{\text{ul}}, \text{Re}\{\alpha_{k,\ell}^{\text{ul}}\}, \text{Im}\{\alpha_{k,\ell}^{\text{ul}}\}]^{\mathsf{T}} \in \mathbb{R}^{4 \times 1}, \qquad (21)
$$

where the vectors contain the true downlink channel parameters. We let the vectors  $\hat{\psi}_k$  and  $\hat{\psi}_{k,\ell}$  represent their estimated parameters. For now, we assume  $\eta_{k,\ell} = 1$ ,  $\forall k, \ell$  in [\(5\)](#page-3-0) (We will relax this later). Then, the CRLB is derived as

$$
\mathbf{\Phi}_k \ge \mathbf{C}(f) \triangleq (\mathbf{J}_k(f))^{\mathsf{H}} \mathbf{I}^{-1}(\boldsymbol{\psi}_k) \mathbf{J}_k(f), \tag{22}
$$

where  $J_k(f) \in \mathbb{C}^{4L_k \times N}$  and  $I(\psi_k) \in \mathbb{C}^{4L_k \times 4L_k}$  denote the Jacobian and FIM, respectively. Specifically, the Jacobian matrix is

$$
\mathbf{J}_k(f) = \frac{\partial \mathbf{h}_k^{\mathsf{T}}}{\partial \psi_k},\tag{23}
$$

where  $\mathbf{h}_k^T$  is from [\(4\)](#page-2-2). The FIM is

$$
\mathbf{I}(\boldsymbol{\psi}_k) = \mathbb{E}\left[ -\frac{\partial^2 \log f(\mathbf{y}|\boldsymbol{\psi}_k)}{\partial \boldsymbol{\psi}_k \partial \boldsymbol{\psi}_k^{\mathsf{T}}}\right],\tag{24}
$$

where  $f(\mathbf{y}|\psi_k)$  represents the likelihood of **y** given the true parameter vector  $\psi_k$ . The MSE between  $h_k$  and  $\hat{h}_k$  is lower bounded by the diagonal element of  $C(f)$ .

<span id="page-5-1"></span>In [\[41\]](#page-11-38), it was demonstrated that the 2D-NOMP algorithm achieves near-CRLB performance in terms of the MSE. This observation provides a strong evidence that the error covariance matrix can be tightly approximated by using a notion of CRLB with  $C(f)$ , i.e,

$$
\hat{\Phi}_k \simeq \mathcal{C}(f) \circ \mathbf{I}_N. \tag{25}
$$

Still, however, it is infeasible to compute  $I(\psi_k)$  because it relies on the true uplink channel parameters  $\psi_k$ , which cannot be obtained in practice.

To resolve this challenge, we propose to use a notion of O-FIM. Denoting the observed uplink reference signal as **y**, under an assumption that the channel parameters  $\psi_k$  follow the Gaussian distribution, the O-FIM is obtained by

$$
[\hat{\mathbf{I}}(\hat{\psi}_k)]_{i,j} = \frac{2}{\sigma^2} \text{Re} \left\{ \sum_{n=1}^N \sum_{m=1}^M \left( \frac{\partial \hat{\mathbf{y}}_{n,m}^*}{\partial \psi_i} \frac{\partial \hat{\mathbf{y}}_{n,m}}{\partial \psi_j} \right) - \sum_{n=1}^N \sum_{m=1}^M (\mathbf{y}_{n,m} - \hat{\mathbf{y}}_{n,m})^* \frac{\partial^2 \hat{\mathbf{y}}_{n,m}}{\partial \psi_i \partial \psi_j} \right\} \Big|_{\psi_k = \hat{\psi}_k}, \quad (26)
$$

where  $\hat{y}$  is the observed uplink reference signal conditioned on  $\hat{\psi}_k$ , namely

$$
\hat{\mathbf{y}} \triangleq \sum_{\ell=1}^{\hat{L}_k} \hat{\alpha}_{k,\ell}^{\text{ul}} \mathbf{u}(\hat{\tau}_{k,\ell}^{\text{ul}}, \hat{\theta}_{k,\ell}^{\text{ul}}) \in \mathbb{C}^{MN \times 1}.
$$
 (27)

Using the O-FIM, we approximate the error covariance matrix as

$$
\hat{\Phi}_k \triangleq \hat{C}(f) = (\hat{\mathbf{J}}_k(f))^{\mathsf{H}} \hat{\mathbf{I}}^{-1}(\hat{\psi}_k) \hat{\mathbf{J}}_k(f), \quad (28)
$$

where  $\hat{\mathbf{J}}_k(f) = \frac{\partial \hat{\mathbf{h}}_k^{\mathsf{T}}(f)}{\partial \hat{\mathbf{h}}_k^{\mathsf{T}}}$  $\frac{\mathbf{h}_k^{\mathsf{T}}(f)}{\partial \hat{\psi}_k} \in \mathbb{C}^{4\hat{L}_k \times L}.$ 

Note that  $\hat{\Phi}_k$  in [\(28\)](#page-6-0) assumes  $\eta_{k,\ell} = 1$ . When  $\eta_{k,\ell} \neq 1$ , the approximated error covariance matrix is further addressed in the following corollary.

**Corollary 1.** For general  $\eta_{k,\ell}$ , the approximated error *covariance matrix is modified to*

$$
\hat{\Phi}_k = \frac{1}{L_k} \left( \sum_{\ell=1}^{L_k} \eta_{k,\ell}^2 \right) \hat{C}(f) + \frac{1}{L_k} \left( \sum_{\ell=1}^{L_k} (1 - \eta_{k,\ell}^2) \right) \mathbf{I}_N. \quad (29)
$$

*Proof.* Assuming perfect reciprocity between the uplink and downlink channels, where  $\eta_{k,\ell} = 1, \forall k, \ell$ , the error covariance of the reconstructed downlink channel is represented as follows:

$$
\Phi_{k} = \mathbb{E}\left[\left(\sum_{\ell=1}^{L_{k}} \alpha_{k,\ell}^{\mathrm{dl}} \mathbf{u}(\tau_{k,\ell}^{\mathrm{dl}}, \theta_{k,\ell}^{\mathrm{dl}}) - \sum_{\ell=1}^{L_{k}} \hat{\alpha}_{k,\ell}^{\mathrm{dl}} \mathbf{u}(\hat{\tau}_{k,\ell}^{\mathrm{dl}}, \hat{\theta}_{k,\ell}^{\mathrm{dl}})\right) \times \left(\sum_{\ell=1}^{L_{k}} \alpha_{k,\ell}^{\mathrm{dl}} \mathbf{u}(\tau_{k,\ell}^{\mathrm{dl}}, \theta_{k,\ell}^{\mathrm{dl}}) - \sum_{\ell=1}^{L_{k}} \hat{\alpha}_{k,\ell}^{\mathrm{dl}} \mathbf{u}(\hat{\tau}_{k,\ell}^{\mathrm{dl}}, \hat{\theta}_{k,\ell}^{\mathrm{dl}})\right)^{H}\right].
$$
\n(30)

Extending to the general case incorporating [\(5\)](#page-3-0), the error covariance can be reformulated as

$$
\Phi_{k} = \mathbb{E}\left[\left(\sum_{\ell=1}^{L_{k}}(\eta_{k,\ell}\alpha_{k,\ell}^{\text{ul}} + \sqrt{1-\eta_{k,\ell}^{2}}g)\mathbf{u}(\tau_{k,\ell}^{\text{ul}},\theta_{k,\ell}^{\text{ul}}) - \sum_{\ell=1}^{L_{k}}\eta_{k,\ell}\hat{\alpha}_{k,\ell}^{\text{ul}}\mathbf{u}(\hat{\tau}_{k,\ell}^{\text{ul}},\hat{\theta}_{k,\ell}^{\text{ul}})\right] \times \left(\sum_{\ell=1}^{L_{k}}(\eta_{k,\ell}\alpha_{k,\ell}^{\text{ul}} + \sqrt{1-\eta_{k,\ell}^{2}}g)\mathbf{u}(\tau_{k,\ell}^{\text{ul}},\theta_{k,\ell}^{\text{ul}}) - \sum_{\ell=1}^{L_{k}}\eta_{k,\ell}\hat{\alpha}_{k,\ell}^{\text{ul}}\mathbf{u}(\hat{\tau}_{k,\ell}^{\text{ul}},\hat{\theta}_{k,\ell}^{\text{ul}})\right)^{H}\right], \quad (31)
$$

where  $\hat{\alpha}_{k,\ell}^{\text{dl}} = \eta_{k,\ell} \hat{\alpha}_{k,\ell}^{\text{ul}}$  based on the correlation knowledge. Furthermore, there is no error correlation between different devices or paths, which means

$$
\mathbb{E}\left[\left(\alpha_{k,\ell}^{\text{ul}}\mathbf{u}(\tau_{k,\ell}^{\text{ul}},\theta_{k,\ell}^{\text{ul}})-\hat{\alpha}_{k,\ell}^{\text{ul}}\mathbf{u}(\hat{\tau}_{k,\ell}^{\text{ul}},\hat{\theta}_{k,\ell}^{\text{ul}})\right)\times \left(\alpha_{k',\ell'}^{\text{ul}}\mathbf{u}(\tau_{k',\ell'}^{\text{ul}},\theta_{k',\ell'}^{\text{ul}})-\hat{\alpha}_{k',\ell'}^{\text{ul}}\mathbf{u}(\hat{\tau}_{k',\ell'}^{\text{ul}},\hat{\theta}_{k',\ell'}^{\text{ul}})\right)^{\text{H}}\right] \approx 0,\forall k \neq k' \text{ or } \ell \neq \ell'. \tag{32}
$$

Using the relationship between g and  $(\alpha_{k,\ell}^{\text{ul}}, \hat{\alpha}_{k,\ell}^{\text{ul}})$ , [\(31\)](#page-6-1) is rewritten as follows:

$$
\mathbb{E}\left[\sum_{\ell=1}^{L_k} \eta_{k,\ell}^2 (\alpha_{k,\ell}^{\text{ul}} \mathbf{u}(\tau_{k,\ell}^{\text{ul}}, \theta_{k,\ell}^{\text{ul}}) - \hat{\alpha}_{k,\ell}^{\text{ul}} \mathbf{u}(\hat{\tau}_{k,\ell}^{\text{ul}}, \hat{\theta}_{k,\ell}^{\text{ul}})) \times \n(\alpha_{k,\ell}^{\text{ul}} \mathbf{u}(\tau_{k,\ell}^{\text{ul}}, \theta_{k,\ell}^{\text{ul}}) - \hat{\alpha}_{k,\ell}^{\text{ul}} \mathbf{u}(\hat{\tau}_{k,\ell}^{\text{ul}}, \hat{\theta}_{k,\ell}^{\text{ul}}))^{\mathsf{H}} + \n\sum_{\ell=1}^{L_k} (1 - \eta_{k,\ell}^2) g g^{\mathsf{H}} \mathbf{u}(\tau_{k,\ell}^{\text{ul}}, \theta_{k,\ell}^{\text{ul}}) \mathbf{u}(\tau_{k,\ell}^{\text{ul}}, \theta_{k,\ell}^{\text{ul}})^{\mathsf{H}} \right] \n= \frac{1}{L_k} \left( \sum_{\ell=1}^{L_k} \eta_{k,\ell}^2 \right) \Phi_k + \frac{1}{L_k} \left( \sum_{\ell=1}^{L_k} (1 - \eta_{k,\ell}^2) \right) \mathbf{I}_N, \tag{33}
$$

<span id="page-6-0"></span>where  $\mathbb{E}[gg^{\text{H}}] = \sigma_{\text{path},k}^2 = 1/(NL_k)$  by channel normal-ization. We get [\(29\)](#page-6-2) by replacing  $\Phi_k$  with  $\hat{C}(f)$ , which completes the proof.

<span id="page-6-2"></span>We use  $\hat{\Phi}_k$  as the approximated error covariance matrix in place of  $\Phi_k$ . Now we are ready to optimize the precoders.

## V. MAX-MIN FAIRNESS PRECODING OPTIMIZATION

At this point, we obtain the estimated downlink CSI  $\hat{\mathbf{h}}_k$  and the approximated error covariance matrix  $\hat{\mathbf{\Phi}}_k$ . Accordingly, we are able to evaluate  $\bar{R}_{c,k}$  [\(17\)](#page-5-0) and  $\bar{R}_{p,k}$ [\(19\)](#page-5-1). Building on this, we formulate the MMF problem and develop an efficient optimization method to solve the problem.

#### *A. Problem Formulation*

In RSMA, the common rate is determined as the minimum value among  $\bar{R}_{c,k}$  for  $\forall k \in \mathcal{K}$ , i.e,  $R_c \triangleq \min_{k \in \mathcal{K}} (\bar{R}_{c,k}).$ With this, device  $k$ 's portion included in the common rate is denoted as  $C_k \ge 0$ , where  $\sum_{\ell=1}^{K} C_{\ell} = R_c$ . Thus, the total rate achieved by device k is defined as  $C_k + \overline{R}_{p,k}$ . Taking this into account, the MMF problem is formulated as follows:

$$
\begin{array}{ll}\text{maximize} & \min\limits_{\mathbf{f}_c, \{\mathbf{f}_k\}_{k \in \mathcal{K}}, \mathbf{c}} \quad (C_k + \bar{R}_{p,k})\\ \end{array} \tag{34}
$$

subject to  $\min_{k \in \mathcal{K}} (\bar{R}_{c,k}) \geq \sum_{k=1}^{n}$  $\overline{K}$  $\overline{\ell=1}$  $C_{\ell}, \forall \ell \in \mathcal{K}$  (35)

<span id="page-6-5"></span><span id="page-6-3"></span>
$$
C_k \ge 0, \forall k \in \mathcal{K},
$$
  
tr $(\mathbf{FF}^H) \le 1,$  (36)

<span id="page-6-1"></span>where  $\mathbf{c} = [C_1, \cdots, C_K]^\top \in \mathbb{C}^{K \times 1}$ . Unfortunately, finding the global optimal solution of [\(34\)](#page-6-3) is challenging due to its non-convexity and non-smoothness. Addressing this, we reformulate [\(34\)](#page-6-3) into a tractable form in the next subsection.

## *B. Reformulation into a Tractable Form*

We first apply the LogSumExp (LSE) technique to approximate the non-smooth minimum function in [\(34\)](#page-6-3). With the LSE, the minimum function is approximated as

<span id="page-6-4"></span>
$$
\text{LSE}\left\{\min_{k \in \mathcal{K}} \left(C_k + \bar{R}_{p,k}\right)\right\} \approx -\alpha \log \left(\sum_{i=1}^K \exp\left(\frac{C_i + \bar{R}_{p,i}}{-\alpha}\right)\right),\tag{37}
$$

<span id="page-7-8"></span><span id="page-7-5"></span>,

<span id="page-7-6"></span>.

where [\(37\)](#page-6-4) becomes tight as  $\alpha \rightarrow 0+$ . Now, we arrange the beamforming vectors  $f_c, f_1, \cdots, f_K$  by stacking them into a single vector denoted as  $\mathbf{\overline{f}} = [\mathbf{f}_c^{\mathsf{T}}, \mathbf{f}_1^{\mathsf{T}}, \cdots \mathbf{f}_K^{\mathsf{T}}]^{\mathsf{T}} \in \mathbb{C}^{N \times (K+1)}$ , where  $\|\mathbf{\bar{f}}\|^2 = 1$ . With this, we rewrite  $\bar{R}_{p,k}$  and  $\bar{R}_{c,k}$  in a Rayleigh quotients form, i.e.,

$$
\bar{R}_{p,k} = \log_2\left(\frac{\bar{\mathbf{f}}^{\mathsf{H}}\mathbf{A}_k\bar{\mathbf{f}}}{\bar{\mathbf{f}}^{\mathsf{H}}\mathbf{B}_k\bar{\mathbf{f}}}\right), \bar{R}_{c,k} = \log_2\left(\frac{\bar{\mathbf{f}}^{\mathsf{H}}\mathbf{C}_k\bar{\mathbf{f}}}{\bar{\mathbf{f}}^{\mathsf{H}}\mathbf{D}_k\bar{\mathbf{f}}}\right),\tag{38}
$$

where

$$
\mathbf{A}_{k} = \text{Blkdiag}\left[\mathbf{0}, \left(\hat{\mathbf{h}}_{k}\hat{\mathbf{h}}_{k}^{\mathsf{H}} + \hat{\mathbf{\Phi}}_{k}\right), \cdots, \left(\hat{\mathbf{h}}_{k}\hat{\mathbf{h}}_{k}^{\mathsf{H}} + \hat{\mathbf{\Phi}}_{k}\right)\right] + \frac{\sigma^{2}}{P}\mathbf{I}_{N(K+1)}
$$
\n(39)

$$
\mathbf{B}_{k} = \mathbf{A}_{k} - \text{Blkdiag}\left[\mathbf{0}, \mathbf{0}, \cdots, \underbrace{\hat{\mathbf{h}}_{k} \hat{\mathbf{h}}_{k}^{\mathsf{H}}}, \cdots, \mathbf{0}\right] \quad (40)
$$

$$
\mathbf{C}_{k} = \text{Blkdiag}\left[\left(\hat{\mathbf{h}}_{k}\hat{\mathbf{h}}_{k}^{\mathsf{H}} + \hat{\boldsymbol{\Phi}}_{k}\right), \cdots, \left(\hat{\mathbf{h}}_{k}\hat{\mathbf{h}}_{k}^{\mathsf{H}} + \hat{\boldsymbol{\Phi}}_{k}\right)\right] + \frac{\sigma^{2}}{P}\mathbf{I}_{N(K+1)}
$$
(41)

$$
\mathbf{D}_k = \mathbf{C}_k - \text{Blkdiag}\left[\hat{\mathbf{h}}_k \hat{\mathbf{h}}_k^{\mathsf{H}}, \mathbf{0}, \cdots, \mathbf{0}\right]
$$
(42)

Since we can normalize both nominator and denominator of [\(38\)](#page-7-0) with  $\|\mathbf{\bar{f}}\|$ , we omit the power constraint in [\(36\)](#page-6-5). With the LSE approximation technique and the Rayleigh quotient reformulation, the problem [\(34\)](#page-6-3) is transformed to

maximize 
$$
\left\{ (-\alpha) \log \left[ \sum_{i=1}^{K} \exp \left\{ -\frac{1}{\alpha} \left( C_i + \log_2 \left( \frac{\bar{\mathbf{f}}^{\mathsf{H}} \mathbf{A}_i \bar{\mathbf{f}}}{\bar{\mathbf{f}}^{\mathsf{H}} \mathbf{B}_i \bar{\mathbf{f}} } \right) \right) \right\} \right\}
$$
 (43)

subject to  $\min_{k \in \mathcal{K}} (\bar{R}_{c,k}) \geq \sum_{k=1}^{n}$  $\overline{K}$  $\overline{\ell=1}$  $C_{\ell}, \forall \ell \in \mathcal{K}$  $C_k \geq 0, \forall k \in \mathcal{K}.$  (44)

Now we tackle [\(43\)](#page-7-1).

## *C. Proposed MMF Optimization Method*

For [\(43\)](#page-7-1) with [\(44\)](#page-7-2), we find local optimal **F** and **c**. To this end, we exploit the two stage algorithm [\[31\]](#page-11-27), wherein the two stages are alternated to solve the problem iteratively. Specifically, in the first stage, we use the GPI-based beamforming method to find **F** given **c**, and the second stage, we use a waterfilling-like method to find **c** for fixed **F**.

The Lagrangian function of the problem [\(43\)](#page-7-1) is identified by

$$
\lambda(\bar{\mathbf{f}}) = (-\alpha) \log \left[ \sum_{k=1}^{K} \exp \left\{ -\frac{1}{\alpha} \left( C_k + \log_2 \left( \frac{\bar{\mathbf{f}}^{\mathsf{H}} \mathbf{A}_k \bar{\mathbf{f}}}{\bar{\mathbf{f}}^{\mathsf{H}} \mathbf{B}_k \bar{\mathbf{f}}} \right) \right) \right\} \right] - \gamma \left[ \sum_{\ell=1}^{K} C_\ell + \alpha \log \left\{ \sum_{k=1}^{K} \exp \left( \log_2 \left( \frac{\bar{\mathbf{f}}^{\mathsf{H}} \mathbf{C}_k \bar{\mathbf{f}}}{\bar{\mathbf{f}}^{\mathsf{H}} \mathbf{D}_k \bar{\mathbf{f}}} \right)^{-\frac{1}{\alpha}} \right) \right\} \right],
$$
(45)

where  $\lambda$  is the Lagrange multiplier. With [\(45\)](#page-7-3), we enter the first stage as follows.

*1) Stage 1: Beamforming Design:* The first-order optimality condition of the Lagrangian function [\(45\)](#page-7-3) is obtained in the following lemma.

<span id="page-7-0"></span>Lemma 1. *The first-order optimality condition of* [\(45\)](#page-7-3) *is satisfied if the following holds:*

$$
\mathbf{Y}_{\mathsf{KKT}}^{-1}(\bar{\mathbf{f}})\mathbf{X}_{\mathsf{KKT}}(\bar{\mathbf{f}})\bar{\mathbf{f}} = \lambda(\bar{\mathbf{f}})\bar{\mathbf{f}},\tag{46}
$$

*where*

¯**f**)

$$
\mathbf{X}_{\mathsf{KKT}}(\mathbf{\bar{f}})
$$
\n
$$
= \sum_{k=1}^{K} \left\{ \frac{\exp\left(-\frac{1}{\alpha} \left(C_k + \bar{R}_{p,k}\right)\right) \frac{A_k}{\mathbf{\bar{f}}^{\mathsf{H}} A_k \mathbf{\bar{f}}}}{\sum_{\ell=1}^{K} \exp\left(-\frac{1}{\alpha} \left(C_{\ell} + \bar{R}_{p,\ell}\right)\right)} + \frac{\exp\left(-\frac{1}{\alpha} \bar{R}_{c,k}\right) \frac{\gamma C_k}{\mathbf{\bar{f}}^{\mathsf{H}} C_k \mathbf{\bar{f}}}}{\sum_{\ell=1}^{K} \exp\left(-\frac{1}{\alpha} \bar{R}_{c,\ell}\right)} \right\}
$$
\n(47)

 $\mathbf{Y}_{\mathsf{KKT}}(\bar{\mathbf{f}})$ 

$$
= \sum_{k=1}^{K} \left\{ \frac{\exp\left(-\frac{1}{\alpha} \left(C_k + \bar{R}_{p,k}\right)\right) \frac{\mathbf{B}_k}{\mathbf{\bar{f}}^{\mathsf{H}} \mathbf{B}_k \mathbf{\bar{f}}}}{\sum_{\ell=1}^{K} \exp\left(-\frac{1}{\alpha} \left(C_{\ell} + \bar{R}_{p,\ell}\right)\right)} + \frac{\exp\left(-\frac{1}{\alpha} \bar{R}_{c,k}\right) \frac{\gamma \mathbf{D}_k}{\mathbf{\bar{f}}^{\mathsf{H}} \mathbf{D}_k \mathbf{\bar{f}}}}{\sum_{\ell=1}^{K} \exp\left(-\frac{1}{\alpha} \bar{R}_{c,\ell}\right)} \right\}
$$
(48)

*Proof.* The first-order optimality condition of [\(45\)](#page-7-3) is derived as follows:

$$
\frac{\partial \lambda(\bar{\mathbf{f}})}{\partial \bar{\mathbf{f}}^{\mathsf{H}}} = \sum_{k=1}^{K} \left\{ \frac{\exp\left(-\frac{1}{\alpha} \left(C_{k} + \bar{R}_{p,k}\right)\right) \left(\frac{\mathbf{A}_{k}\bar{\mathbf{f}}}{\bar{\mathbf{f}}^{\mathsf{H}}\mathbf{A}_{k}\bar{\mathbf{f}}}-\frac{\mathbf{B}_{k}\bar{\mathbf{f}}}{\bar{\mathbf{f}}^{\mathsf{H}}\mathbf{B}_{k}\bar{\mathbf{f}}}\right)}{\sum_{\ell=1}^{K} \exp\left(-\frac{1}{\alpha} \left(C_{\ell} + \bar{R}_{p,\ell}\right)\right)} \right\} + \sum_{k=1}^{K} \left\{ \frac{\exp\left(-\frac{1}{\alpha} \bar{R}_{c,k}\right) \left(\frac{\gamma C_{k}\bar{\mathbf{f}}}{\bar{\mathbf{f}}^{\mathsf{H}}C_{k}\bar{\mathbf{f}}}-\frac{\gamma \mathbf{D}_{k}\bar{\mathbf{f}}}{\bar{\mathbf{f}}^{\mathsf{H}}\mathbf{D}_{k}\bar{\mathbf{f}}}\right)}{\sum_{\ell=1}^{K} \exp\left(-\frac{1}{\alpha} \bar{R}_{c,\ell}\right)} \right\}.
$$
\n(49)

<span id="page-7-1"></span>When [\(49\)](#page-7-4) equals to 0, the optimality condition is satisfied:

<span id="page-7-2"></span>
$$
\sum_{k=1}^{K} \left\{ \frac{\exp\left(-\frac{1}{\alpha} \left(C_{k} + \bar{R}_{p,k}\right)\right) \frac{A_{k}\bar{f}}{\bar{f}^{H}A_{k}\bar{f}}}{\sum_{\ell=1}^{K} \exp\left(-\frac{1}{\alpha} \left(C_{\ell} + \bar{R}_{p,\ell}\right)\right)} + \frac{\exp\left(-\frac{1}{\alpha} \bar{R}_{c,k}\right) \frac{\gamma C_{k}\bar{f}}{\bar{f}^{H}C_{k}\bar{f}}}{\sum_{\ell=1}^{K} \exp\left(-\frac{1}{\alpha} \left(C_{k} + \bar{R}_{p,k}\right)\right) \frac{B_{k}\bar{f}}{\bar{f}^{H}B_{k}\bar{f}} + \frac{\exp\left(-\frac{1}{\alpha} \bar{R}_{c,k}\right) \frac{\gamma D_{k}\bar{f}}{\bar{f}^{H}D_{k}\bar{f}}}{\sum_{\ell=1}^{K} \exp\left(-\frac{1}{\alpha} \left(C_{\ell} + \bar{R}_{p,\ell}\right)\right)} + \frac{\exp\left(-\frac{1}{\alpha} \bar{R}_{c,k}\right) \frac{\gamma D_{k}\bar{f}}{\bar{f}^{H}D_{k}\bar{f}}}{\sum_{\ell=1}^{K} \exp\left(-\frac{1}{\alpha} \bar{R}_{c,\ell}\right)} \tag{50}
$$

Substituting  $(45)$ ,  $(47)$ , and  $(48)$  into  $(50)$ , we get the following equation

$$
\mathbf{X}_{\mathsf{KKT}}(\bar{\mathbf{f}})\bar{\mathbf{f}} = \lambda(\bar{\mathbf{f}})\mathbf{Y}_{\mathsf{KKT}}(\bar{\mathbf{f}})\bar{\mathbf{f}},
$$
(51)

which leads to the equation [\(46\)](#page-7-8).  $\Box$ 

<span id="page-7-7"></span><span id="page-7-4"></span>.

<span id="page-7-3"></span>Note that [\(46\)](#page-7-8) is interpreted as a non-linear eigenvectordependent eigenvalue problem, where  $\mathbf{\bar{f}}$  represents a eigenvector and  $\lambda(\mathbf{\bar{f}})$ , the Lagrangian function in [\(45\)](#page-7-3), is the corresponding eigenvalue. Accordingly, if we find a leading eigenvector of the matrix  $\mathbf{Y}_{\text{KKT}}^{-1}(\mathbf{\bar{f}})\mathbf{X}_{\text{KKT}}(\mathbf{\bar{f}})$  in [\(46\)](#page-7-8) given the optimal Lagrange multiplier  $\gamma$ , it maximizes the objective function in [\(43\)](#page-7-1) while satisfying the first-order optimality condition (its gradient is zero). However, it is not trivial to find a leading eigenvector of [\(46\)](#page-7-8) due to its dependency on the eigenvector itself. In particular, the matrix

 $Y_{\text{KKT}}^{-1}(\bar{\mathbf{f}})X_{\text{KKT}}(\bar{\mathbf{f}})$  in [\(46\)](#page-7-8) is a function of  $\bar{\mathbf{f}}$ , making classical methods such as power iteration or eigenvalue decomposition unsuitable for our problem. We note that if the matrix  $Y_{\text{KKT}}^{-1}(\bar{\mathbf{f}})X_{\text{KKT}}(\bar{\mathbf{f}})$  does not depend on  $\bar{\mathbf{f}}$ , our problem reduces to a classical eigenvalue problem.

To deal with this, we devise a GPI-based method that iteratively finds a leading eigenvector of [\(46\)](#page-7-8). Specifically, we update the beamforming vector in *t*-th iteration,  $\mathbf{\bar{f}}^{(t)}$  as

$$
\overline{\mathbf{f}}^{(t)} = \frac{\mathbf{Y}_{\mathsf{KKT}}^{-1}(\overline{\mathbf{f}}^{(t-1)})\mathbf{X}_{\mathsf{KKT}}(\overline{\mathbf{f}}^{(t-1)})\overline{\mathbf{f}}^{(t-1)}}{\|\mathbf{Y}_{\mathsf{KKT}}^{-1}(\overline{\mathbf{f}}^{(t-1)})\mathbf{X}_{\mathsf{KKT}}(\hat{\mathbf{f}}^{(t-1)})\overline{\mathbf{f}}^{(t-1)}\|}.\tag{52}
$$

It repeats until  $\|\bar{\mathbf{f}}^{(t)} - \bar{\mathbf{f}}^{(t-1)}\|$  bounded by the predetermined parameter  $\epsilon$ .

*2) Stage 2: Common Rate Portions Allocation:* The main purpose of the second stage is to determine  $C_k$  so as to maximize the worst spectral efficiency for given  $\mathbf{\bar{f}}$ . To this end, based on the obtained  $\mathbf{\vec{f}}$  in the first stage, we use a waterfilling-like method to allocate  $C_k$ . Here, we represent the common and private rate given  $\bar{\mathbf{f}}$  as  $\hat{R}_{c,k}$  and  $\hat{R}_{p,k}$ , where they are considered constants at this stage.

Following the well-known waterfilling principle, we reallocate  $C_k$  by

$$
C_k = \left(\mu - \hat{R}_{p,k}\right)^+, \tag{53}
$$

where  $\mu$  is determined by

$$
\sum_{k=1}^{K} (\mu - \hat{R}_{p,k})^{+} = \min_{k} (\hat{R}_{c,k}).
$$
 (54)

Applying this, more  $C_k$  is allocated to devices with lower private rates, prioritizing those requiring more common rate portions to maximize the minimum rate. The term  $(\mu - \hat{R}_{p,k})^+$  determines  $C_k$ , with  $\mu$  representing the waterlevel, and  $x^+ \triangleq \max(x, 0)$  ensures non-negative allocations. The total allocation satisfies [\(54\)](#page-8-0), where  $\mu$  is adjusted so that the sum of  $C_k$  matches  $\min_k (\hat{R}_{c,k})$ .

The above two stages are repeated by gradually increasing the Lagrangian multiplier  $\gamma$ . Upon completing the process, we select the best  $\mathbf{\bar{f}}$  and  $\mathbf{c}$  that yield the maximum objective value.

# VI. NUMERICAL RESULTS

In this section, we demonstrate the performances of the proposed framework. For the used simulations environments, we basically follow the setup described in Section [II.](#page-2-3) More specifically, we assume  $N = 12, K = 4, L_k = 5$  for  $k \in$  $\mathcal{K}, 0.5 \leq \gamma \leq 0.9, \sigma^2 = 1$ . For the proposed algorithm parameters, we set  $\alpha = 0.1$  and  $\epsilon = 0.01$ . For the downlink channel reconstruction, we assume that  $\eta_{k,\ell} = 0.9 \; \forall (k,\ell)$ in [\(5\)](#page-3-0) and the angular spread is  $\pi/10$ . The uplink SNR are fixed as 10 dB.

As baseline methods, we consider the followings:

• MRT: The precoding vectors are aligned by the estimated channel vectors, i.e.,  $f_k = \hat{h}_k$ .

<span id="page-8-1"></span>

Fig. 2: The minimum spectral efficiency performance among devices versus SNR comparison of different methods.

<span id="page-8-2"></span>TABLE I: Comparison for the average RSMA Precoder Computation Time (Sec.)

- **ZF**: This method eliminates the interference by  $f_k =$  $(\hat{\mathbf{H}}\hat{\mathbf{H}}^{\mathsf{H}} + \frac{\sigma^2}{P}\mathbf{I})^{-1}\hat{\mathbf{h}}_k$ , where  $\hat{\mathbf{H}} = [\hat{\mathbf{h}}_1, \cdots, \hat{\mathbf{h}}_k].$
- <span id="page-8-0"></span>• WMMSE: This method uses the WMMSE algorithm to solve the MMF problem as shown in [\[38\]](#page-11-35).
- GPI without RS: This method uses GPI as a precoding optimizer without considering RSMA.

We note that all the above cases adopt the reconstructed downlink CSI from the uplink pilots as in the proposed framework.

# *A. Spectral Efficiency*

At first, we evaluate the minimum spectral efficiency performance in Fig. [2.](#page-8-1) For the proposed method, we also illustrate a case that does not use the error covariance matrix approximation. In this case, we let  $\hat{\Phi}_k = 0$ .

As observed in Fig. [2,](#page-8-1) the proposed method outperforms other approaches, achieving performance gains of 12.54% compared to WMMSE, 24.11% compared to the proposed framework without error covariance matrix approximation, and 60.09% compared to GPI without RS at 40 dB. We interpret this result as follows. The significant gains of the proposed method over GPI without RS highlights the advantages of RSMA under imperfect downlink CSI reconstruction. This finding is consistent with the results in [\[31\]](#page-11-27), [\[35\]](#page-11-32), [\[36\]](#page-11-33), demonstrating RSMA's robustness in scenarios with imperfect CSI.

It is evident that applying RSMA without our approximation of the error covariance matrix significantly degrades the performance gains. This is because, the interference caused by imperfect downlink CSI reconstruction is not properly

<span id="page-9-0"></span>

Fig. 3: Transmission process in terms of latency.

accounted into the optimization, leading to degraded performance [\[27\]](#page-11-23).

We also observe the gains of the proposed method compared to WMMSE. As described in [\[32\]](#page-11-28), WMMSE leverages the rate-MSE equivalence to transform the rate maximization problem into a more tractable weighted MSE minimization problem. In this process, the MSE-based formulation does not adequately account for the impact of interference caused by imperfect CSI, resulting in degraded performance compared to the proposed method. Moreover, it is also worthwhile to note that solving weighted MSE minimization problem needs to use a off-the-shelf optimization toolbox such as CVX [\[50\]](#page-12-6), so that WMMSE requires an average computation time approximately 9.14 times longer than that of the proposed method (Table [I\)](#page-8-2). This adversely affects latency performance, rendering WMMSE less suitable for IoT communication scenarios. This underscores the advantages of the proposed method as a more efficient and appropriate solution, which will be further explored in the next section.

# *B. Latency*

We now evaluate the latency performance to provide a more rigorous demonstration of the proposed framework. To analyze the communication latency, we particularly focus on the following three processes, which constitute the major components of latency in practical 5G-NR systems.

1) Downlink CSI acquisition: This process counts the latency in acquiring downlink CSI. To be specific, following the conventional approach in 5G-NR, the

BS first sends CSI-RS to the scheduled device. Subsequently, the device computes the CSI and sends the CSI feedback containing RI, PMI, and CQI to the BS [\[37\]](#page-11-34). Typically, in FDD MIMO, the entire process is known to take approximately  $6 \sim 10$  ms. We denote the latency corresponding to the downlink CSI acquisition as  $T_1 = 6$  ms.

- 2) Precoder optimization: Given the downlink CSI, the BS runs the optimization algorithm to design the precoder. The latency of precoder optimization, denoted as  $T_2$ , is counted in this process. However, accurately measuring the actual latency associated with precoder optimization is very challenging. This is because it heavily depends on the implementation details of the precoder design algorithms, which are beyond the scope of this paper. Further, while [\[37\]](#page-11-34) specifies timing requirements for device processing capabilities, the BS processing time requirements are not explicitly defined, as they are left to vendor implementation. Incorporating practical BS computational constraints, we assume that the maximum allowable latency for FPGAimplemented precoder optimization, denoted as  $T_2^{\text{max}}$ , is 1 ms. This assumption is supported by state-of-the-art FPGA implementations such as [\[51\]](#page-12-7), where precoding optimization for MU-MIMO systems achieved a processing latency of 0.6 ms using optimized hardware architectures. Then, using WMMSE as a baseline, which consumes 1.94 CPU time, we denote this baseline computation time as  $T_2^{\text{max}}$ . Since the proposed method requires only 11.6% of the WMMSE computation time, its relative processing time can be expressed as  $T_2^{\text{max}} \times 0.116$  ms. The relative processing times of other baseline precoding methods, including MRT and ZF, are measured and normalized in the same manner.
- 3) Data transmission: Using the precoder designed in the precoder optimization process, the BS sends the information symbols to the devices. Assuming hybrid automatic repeat request (HARQ) with incremental redundancy (IR), the accumulated mutual information achieved in device  $k$  during the  $T$ -th HARQ round is expressed as [\[52\]](#page-12-8)

$$
I_k^{\text{acc.}}[T] = \sum_{t=1}^T \left\{ C_k[t] + R_{p,k}[t] \right\},\tag{55}
$$

where  $C_k[t]$  and  $R_{p,k}[t]$  represent the achieved common rate portion and the private rate of device  $k$  at the -th HARQ round, respectively. The total HARQ round  $T^*$  is determined as

<span id="page-9-1"></span>
$$
T^* = \min\{T | I_k^{\text{acc.}}[T] \ge \text{Payload}_k\},\tag{56}
$$

which represents the minimum number of HARQ rounds required for the accumulated mutual information to be greater than or equal to the given payload. Consequently, the total latency in this process is computed as  $T_3 = T^* \times T_3^{\text{ind.}}$ , where  $T_3^{\text{ind.}}$  represents the latency of each HARQ round, including transmission air time,

<span id="page-10-0"></span>

Fig. 4: Comparison of the conventional CSI-RS based transmission and the proposed UL-SRS based transmission

decoding, and feedback processing. Based on practical system parameters in [\[37\]](#page-11-34), we assume  $T_3^{\text{ind.}}$  to be 2 ms, which accounts for one slot transmission (0.5 ms with 30 kHz subcarrier spacing), IoT device processing time (1 ms), and HARQ feedback processing (0.5 ms).

The whole process is illustrated in Fig. [3.](#page-9-0) Since the proposed framework does not rely on any direct CSI acquisition process, we assume  $T_1 = 0$  for the proposed framework. In contrast, for schemes using conventional downlink CSI acquisition processes, we assume perfect downlink CSI is obtained with  $T_1 = 6$  ms. The system operates with a fixed SNR of 30 dB and a transmission bandwidth of 20 MHz. Given the precoding method and bandwidth, we calculate the total number of HARQ rounds, and  $T_3$  is subsequently determined as [\(56\)](#page-9-1). The total latency is then calculated as  $T_1 + T_2 + T_3$ . While this evaluation framework provides approximations rather than exact measurements, it enables fair comparison of latency performance across different precoding methods. For the payload size, we consider 25,000 bits (3.125 KB) and 50,000 bits (6.25 KB). We plot the latency cumulative distribution function (CDF) in Fig. [4.](#page-10-0)

As shown in Fig. [4,](#page-10-0) the proposed method achieves substantially lower latency across both payload scenarios. At the 90th percentile of IoT devices, the proposed method reduces latency by approximately 5.96 ms compared to conventional approaches when the payload size is 25,000 bits. This latency reduction comes from directly estimating downlink CSIT from the uplink channel, thereby eliminating the need for CSIT feedback. In contrast, the feedback-based method requires a minimum latency of 6 ms even with perfect CSIT, primarily due to the feedback process delay of  $T_1 = 6$  ms. This latency gap remains significant even when the payload size increases to 50,000 bits, where spectral efficiency becomes the dominant factor.

Among the feedback-free methods, the proposed approach achieves the lowest latency by applying the proposed robust precoder design that combines RSMA and error covariance matrix approximation. This design enhances spectral efficiency, allowing devices to meet their payload requirements in fewer transmission rounds. Furthermore, despite these sophisticated components, our GPI-based precoder optimization requires only 11.6% of WMMSE's computation time, as shown in Table [I.](#page-8-2) These combined advantages result in approximately 2.56 ms lower latency at the 90th percentile of IoT devices, compared to the WMMSE method when the payload size is 25,000 bits.

While feedback-free ZF and MRT offer low computational complexity, their spectral efficiency is inherently limited, as demonstrated in Fig. [2.](#page-8-1) Consequently, these methods require more HARQ rounds, increasing  $T_3$ . As a result, more latency is required, specifically 1.75 ms for ZF and 3.74 ms for MRT at the 90th percentile, compared to the proposed method. This performance gap becomes more pronounced with a payload size of 50,000 bits, where their limited spectral efficiency leads to substantially higher latency due to increased HARQ rounds.

## VII. CONCLUSION

In this paper, we presented a novel framework for enabling low-latency FDD MIMO transmission in IoT networks. By reconstructing downlink CSIT from uplink reference signals and addressing interference with RSMA, we significantly reduce communication overhead by eliminating CSIT feedback. To mitigate the effects of imperfect CSIT from the reconstruction, estimating the error covariance matrix further enhances robustness of the RSMA precoder. Additionally, the GPI-based approach efficiently computes the precoding vector, reducing computational complexity. Simulation results validate the performance of the robust precoder in maximizing the minimum spectral efficiency and the effectiveness of our approach in achieving low-latency, offering a promising solution for URLLC in IoT.
