(Dated: January 15, 2025)

This work analyzes the behavior of the interface between a ferromagnetic material and an altermagnet. We use a well-established line of arguments based on electronic mean-field calculations to show that new surface phenomena that lead to altermagnetic materials induce an exchange bias effect on the nearby ferromagnet. We reveal the physical mechanisms behind this phenomenon that lead to quantitative control over its strength. Interestingly, we predict exotic electric-field-induced phenomena. This is an analogy to the relationship between exchange bias and the injection of spin currents in spin-transfer-dominated scenarios, which has been reported earlier in the traditional antiferromagnetic/ferromagnetic junction.

INTRODUCTION

Recent advances have introduced a novel type of collinear magnetism referred to as altermagnetism[1–6]. Such a magnetic phase features a strong breaking of time-reversal symmetry, a staggering magnetic configuration, and spin-splitting in its band structures while maintaining zero net magnetization. Altermagnetism integrates attributes once thought exclusive to conventional collinear ferromagnetism or antiferromagnetism, enabling new phenomena and capabilities unheard of within these traditional magnetic categories. Initially suggested through theoretical models, the existence of the altermagnetic phase has been confirmed by various experimental studies that have validated its distinctive characteristics and potential for practical applications. In altermagnetic materials, the magnetic moments (spins) align, leading to a pattern of alternating magnetization on an atomic scale. However, unlike antiferromagnets, the electronic band structure remains split by spin. The symmetry properties associated with the spin group of materials[7, 8], coexistence of magnetic and orbital ordering, and electronic band structure with broken Kramers degeneracy, which translates into a spin splitting even without an external magnetic field, which can give rise to unusual transport properties[9], piezomagnetism [10], the generation of spin-splitter torque in MRAM geometries[11], chiral split magnon bands[12, 13], and as a possible route towards Majorana physics[14], among others. Recently, it was shown that nanoscale imaging of altermagnetic states in manganese telluride (MnTe) is possible[15]. Several theoretical works have focused on modulation in the altermagnetic order parameter [12, 16] and realization of the altermagnetic order in generalized systems[17, 18] as well as the generalization of altermagnetism to noncollinear magnets[19]. Furthermore, the anomalous Hall effect was reported in altermagnetic ruthenium dioxide[20]. This concept is new in condensed matter physics and is currently a subject of active research as scientists explore its fundamental properties and potential technological applications [21]. In addition, we highlight a profound connection between

altermagnetism and the physics of superfluid He³ [22] that promises a myriad of analogies.

The role altermagnetism will play in heterostructures is still in the making. Some works point to exciting effects in superconducting-alter magnetic hybrids, where effects such as nonreciprocal superconductivity, also known as the superconducting diode effect, have been predicted[23].

In the field of altermagnetic spintronics, there are proposals for giant magnetoresistance and tunnel magnetoresistance[24, 25]. These are critical physical effects used in commercial spintronics devices to read information. These effects are based on the transmission of a spin current between a reference ferromagnetic electrode and a sensing one within a multilayer structure. Naturally, they can occur in the context of altermagnetic systems. Spin Hall and Edelstein effects in noncollinear altermagnets were predicted in[26]. Recently, spin transfer phenomena have been discussed in the context of altermagnetism [27]. In this work, we focus on the effect of exchange bias.

Exchange bias (EB) is a phenomenon observed in systems consisting of an interface between a ferromagnetic material (FM) and an antiferromagnetic material (AF) [28–33], which results in a shift of the material’s magnetization curve when exposed to an external magnetic field. This phenomenon, first discovered in the 1950s, has been the subject of extensive research due to its relevance in technological applications, such as magnetic storage devices[34]. Today, it is part of the standard lore of magnetism research and is relevant in modern low-dimensional magnetism research[35–39]. The exchange bias effect has been observed in multiferroic field effect devices[40] as well as polycrystalline thin films[41]. The picture behind the physical processes involved in the effect of exchange bias has become more apparent since the different roles played by the nucleation and propagation of domain walls in exchange bias were disentangled in a recent article[42]. The theory of EB has evolved over the years and several models have been proposed to explain the effect[43, 44].

The above leads us to question how the interface be-

tween a ferromagnet and an altermagnet would behave. This could generate interesting emergent interactions because of altermagnetism (AM) similarity to antiferromagnetism (AF). Still, the additional properties of altermagnetism could result in different behaviors, such as spin density oscillations in AM and control of AM dynamics by an electric field[45]. Moreover, it opens up the possibility of working with conducting materials since the relationship between Exchange Bias (EB) and the injection of electric currents has been studied [46–48]. This work analyzes the behavior of an interface between a ferromagnetic material and an altermagnetic material using all-fermion calculations. We use a line of arguments along [49] and show that new surface phenomena occur because of a material with spin-split bands.

BASIC MODEL

The basic altermagnetic/ferromagnet (AM/FM) hybrid model is based on the model described in [21, 50]. We consider a square lattice. A two-orbital electronic system with Hamiltonian written in terms of fermion operators $\psi_{ia\sigma}$, where the label i stands for space position, the label a for orbital and the label σ for spin species. The kinetic energy is written as[51]:

$$\mathcal{H}_t = - \sum_{\langle ij \rangle} \sum_{ab} \sum_{\sigma} t_{ij}^{ab} \psi_{ia\sigma}^{\dagger} \psi_{jb\sigma}.$$

The coefficients t_{ij}^{ab} are obtained from a discretization of the Hamiltonian in [21]. Additionally, the model is supplemented by two interaction energies, a Heisenberg-like exchange in spin space, \mathcal{H}_J , and an Ising-like exchange in orbital space, \mathcal{H}_V . These contributions are given by:

$$\mathcal{H}_J = J \sum_{\langle ij \rangle} \mathbf{S}_i \cdot \mathbf{S}_j, \text{ and } \mathcal{H}_V = V \sum_{\langle ij \rangle} \mathbf{N}_i^z \mathbf{N}_j^z,$$

where $\mathbf{S}_i = \sum_{a,\sigma,\sigma'} \psi_{ia\sigma}^{\dagger} \vec{\tau}_{\sigma\sigma'} \psi_{ia\sigma'}$ and $\mathbf{N}_i = \sum_{a,b,\sigma} \psi_{ia\sigma}^{\dagger} \vec{\tau}_{ab} \psi_{ib\sigma}$. For positive J and V , we therefore expect that H_J induces (π, π) -AFM (antiferromagnetic order) and, crucially, that H_V induces (π, π) -OO (orbital order). Due to the absence of spin-orbit coupling, $[\mathcal{H}, \mathbf{S}_i] = 0$ implies that the spin remains a good quantum number in the original model. However, for realistic systems, including a form of anisotropy becomes necessary. We do so, from a phenomenological point of view, by including a term:

$$\mathcal{H}_{\Delta} = \sum_{ia\sigma} \Delta_i \psi_{ia\sigma}^{\dagger} \psi_{ia\sigma},$$

where Δ_i stands for a local potential, we have $\Delta_i = -e\vec{E} \cdot (i_x, i_y, (-1)^i)\ell$ where $\vec{E} = (E_x, E_y, \Delta)$ where the later term represents an electric field in the out-of-plane direction[45].

FIG. 1. Cartoon of the model described in the main text. The colored dot represents the spin component, blue meaning up and red down. The orbitals are depicted by orthogonal lobes that alternate (in the AM region). At the interface, the last row of the altermagnet is commensurate with the first row of the ferromagnet. Their spin coupling is defined to be J_{int} . The deficit in the coordination of the last altermagnetic row results in a magnetically weak layer.

Our calculations will use this model for the altermagnet/ferromagnet heterostructure. In the altermagnetic region, we will choose parameters such as $J_{\text{AM}} > 0$ and $V_{\text{AM}} > 0$. For the ferromagnetic region, we use $J_{\text{FM}} < 0$ while exploring the consequences of different values of V_{FM} . At the interface, we assign a value J_{int} for the spin exchange between spins in other systems.

Finally, we will drive the magnetic reversal using an external magnetic field \mathbf{H} ,

$$\mathcal{H}_B = -g\mu_0 \sum_i \mathbf{S}_i \cdot \mathbf{H}.$$

The complete Hamiltonian acquires the form: $\mathcal{H} = \mathcal{H}_t + \mathcal{H}_J + \mathcal{H}_V + \mathcal{H}_{\Delta} + \mathcal{H}_B$. This constitutes the essence of the model. Since we consider an AM/FM junction, the values of the coupling constants will change according to the region. The interface between the two systems will be described by a different exchange coupling J_{int} . We make the assumption $J_{\text{FM}} < J_{\text{AM}}$ while varying J_{int} across the parameter space. This parameter will prove essential for the physical behavior of the interface. A cartoon of the model is presented in Fig. (1). The deficit in the number of neighbors of the last altermagnetic row results in a magnetically tunable layer whose magnetization will fluctuate as it is subjected to external fields. We use self-consistent mean-field theory for both the magnetic and orbital order parameters, following the ideas of [21], to determine the local magnetic and orbital orderings for various external magnetic field values. We perform this calculation on a path that simulates a hysteresis cycle.

RESULTS

Our results are organized in three paragraphs. The first is a detailed scrutiny of the stability of the altermagnetic order exposed to a magnetic field. The second

is an analysis of the interfacial exchange induced by the altermagnet on a nearby ferromagnet. Finally, the third addresses the AM/FM junction exchange bias effect.

Altermagnetic state vs magnetic field

In this paragraph, we report on altermagnetic stability under the influence of a magnetic field. This analysis will help us to understand the results in subsequent sections. Our calculations are a relaxation of the mean-field equations for different Fermi levels and external magnetic fields. These relaxations are performed for an isolated altermagnet under periodic boundary conditions. Our results, rendered in Fig.(2), indicate that for a wide range of magnetic fields, the altermagnetic order is stable. Only for large fields is the altermagnetic state challenged. This conclusion is meaningful since it allows us to swipe the field within the hysteresis loop with confidence that the altermagnetic order will be preserved. Regarding the effect of the Fermi level, we must mention that the altermagnetic state is stable in regions where the system is metallic.

Interfacial exchange interaction

Here, we study the interfacial exchange interaction between the altermagnet in a ferromagnetic neighbor. We set $K = 0$ and calculate the net energy of the system prepared with different orientations for the self-consistent spin field. The strategy is similar to the one in [52–54]. We pick an orientation for each ferromagnetic and altermagnetic order parameter and report the energy associated with the configuration. The results are presented in Fig. (3a). Fig.(3b) shows the magnitude of the interfacial exchange interaction as a function of J_{int} . We appreciate that while for large J_{int} , the behavior is close to a $\cos\theta$ function (reflecting the usual exchange $\mathbf{n} \cdot \mathbf{m}$, where \mathbf{n} is the Néel vector of the AM and \mathbf{m} is the magnetization vector of the FM), as J_{int} is reduced, there is an apparent deviation. In the extreme case $J_{\text{int}} = 0$, the magnitude of interfacial exchange is depressed. This effect is dominated by second-order hopping exchange mechanisms of[55].

Exchange Bias

In this paragraph, we study the effect of exchange bias on the AM/FM interface. This effect manifests itself as a shift in the magnetic hysteresis loop along the axis of the applied field. Specifically, the external field required to reverse the magnetization of the ferromagnetic layer becomes asymmetric with respect to the origin, resulting in a displacement of the hysteresis loop. The exploration

FIG. 2. Phase diagram of the altermagnet (a) denoting three major regions, (I) OO + AF with 3/4-filling, (II) OO with half-filling and (III) with OO + AF and 1/4-filling. The altermagnetic phases (I) and (III) are surrounded by a conducting state marked by the dark blue sections, but for the Fermi energies of the light blue section the altermagnet remains an insulator. The band structure at the fermi level is showed in (b), showing the altermagnetic behaviour for the points denoted in (a), i.e., with and without magnetic field applied.

of EB and quantum effects in magnetic interfaces opens up a vast and promising field of research. As our understanding of these phenomena deepens and evolves, new opportunities will likely emerge for developing advanced technologies. Therefore, the primary purpose of this section is to investigate the impact of altermagnetism on the EB phenomenon. When the AM/FM system is cooled below the altermagnetic critical temperature while under the influence of an applied magnetic field, the antiferromagnetic moments align and exert an interfacial coupling force on the ferromagnetic layer. This interaction shifts the hysteresis loop in one direction, generating the exchange bias effect. The term "compensated" is used to refer to an antiferromagnetic (AFM) layer where the magnetic moments at the interface with a ferromagnetic (FM) layer essentially cancel each other out, resulting in a negligible net magnetic moment. At the same time, "uncompensated" means that there are unpaired spins

FIG. 3. Interfacial exchange interaction with a magnetically uncompensated altermagnetic interface. Main plot: Energy as a function of the relative orientation between the magnetization and the altermagnetic Néel order parameter for seven evenly distributed $J_{\text{int}}/J_{\text{AM}}$ between 0 and 0.3. As shown in the inset, the interfacial exchange strength depends on the interfacial exchange constant J_{int} . The inset shows the energy gap between orientations, described by $\Delta_E = E_{\theta=\pi} - E_{\theta=0}$ and its dependency on the interface exchange.

at the interface, leading to a significant net magnetic moment, which is the primary driver of the exchange bias effect in most systems[56]; essentially, a compensated interface produces a much weaker exchange bias compared to an uncompensated one[57]. The same categories can be applied to AM interfaces. In this work, we tried two limit cases: a compensated situation that led to no exchange bias effect (in this case, more realistic systems might still achieve a nonvanishing exchange bias by appealing to the extrinsic features not included in our model, such as Dzyalonsinskii-Moriya interactions[58]) and a fully uncompensated structure like the one illustrated in Fig.(1). All the results below refer to this later case.

We performed fermionic numerical simulations within the mean-field approximation of hysteresis loops for different parameters. The loops are characterized by two reversions at two different coercivities H_c^1 and H_c^2 . The exchange bias is characterized by the midpoint between these two: $H_{\text{eb}} = (H_c^1 + H_c^2)/2$. The reversal process is catalyzed by the nucleation of domain walls at the AM/FM interface. These propagate in response to the external magnetic field crossing the FM, leading to its magnetization reversal. Analysis of the coercivity fields at the reversal stage allows us to estimate the exchange bias. Through Fig. (4), we report a significant strength of the exchange bias effect. In particular, it depends on the interfacial exchange coupling, J_{int} . For $J_{\text{int}} = 0$, the effects vanish, and as we increase its value, so does the shift in the hysteresis loop.

FIG. 4. (a) Representative hysteresis cycle showing exchange bias for different interface exchange J_{int} . The red curve corresponds to $J_{\text{int}} = 0$ and does not display exchange bias as expected. The reversion curves are symmetric for positive and negative fields. The green curve, on the other hand, represents the hysteresis loop for $J_{\text{int}} = 0.2J_{\text{AM}}$. It presents a noticeable exchange bias effect. (b) and (c) Track of the z component of the spin of the AM at the interface along the hysteresis loop. In (b) $J_{\text{int}} = 0$ while in (c) $J_{\text{int}} = 0.2J_{\text{AM}}$ highlights the asymmetric magnetization at the moments of the ferromagnet reversion. In (b) and (c), the inset represents the distribution of spins near the interface in the field indicated by the star. (d) Strength of the exchange bias effect as a function of J_{int} for different values of t_{FM} .

The spin orientation at the interfacial layer is volatile since it is connected to only half of the neighbors within the altermagnet. In Figs.(4b) and (4c), we depict the net spin of the interfacial layer along the hysteresis loop. In

FIG. 5. Exchange bias dependence on applying the electric field in the three possible directions. The fields are depicted in $t/(e\ell)$ units. Simulations show a different behavior if the altermagnet is in a conductor state (blue) or in an insulator state (orange), according to the values in 2.

Fig. (4b), $J_{\text{int}} = 0$, and the system presents a vanishing exchange bias effect, while in (4c), the $J_{\text{int}} = 0.2J_{\text{AM}}$ is chosen to ensure an exchange bias. The asymmetry of Fig. (4c) can be linked directly to the exchange bias effect in the system at hand.

The exchange bias field H_{eb} is generally described by the phenomenological expression[30, 44]: $H_{\text{eb}} = \frac{J_{\text{int}}}{M_s t_{\text{FM}}}$, where M_s is the saturation magnetization of the ferromagnet and t_{FM} is the thickness of the ferromagnetic layer. We compare this phenomenological behavior with the results of our simulations. We see that H_{eb} from our simulations follows this trend for small J_{int} , but then it saturates due to the effects of the FM system on the AM. We report a similar behavior for different values of t_{FM} in contrast to the phenomenological estimate. This discrepancy is probably due to the absence of dipolar interactions that disturb the free motion of the domain wall.

Effects of an electric field

We have performed simulations, including electric fields in different directions. We show our results in Fig.(5). The results show clearly the dependence of the exchange bias field on the strength and direction of the electric field. We have different results depending on the metallic or insulating regime in which the AM is located. For certain configurations, changes over 50% can be achieved.

CONCLUSION

Altermagnetic spintronics[59–62] is in an early stage. Casting new effects and adapting well-known effects to the altermagnetic context might open many scientific and technological possibilities. This work analyzes the behavior of an interface between a ferromagnetic material and an altermagnet. We use a well-established line of arguments and show that emergent surface phenomena occur because of the altermagnetic materials with spin-split bands. In addition, the model is supplemented by two interaction energies, a Heisenberg-like exchange in spin space \mathcal{H}_J and an Ising-like exchange in orbital space. We show that the altermagnetic order is impervious to the effects of an external magnetic field for moderated fields. Furthermore, we anticipate an interfacial exchange interaction induced in the am/fm interface that manifests itself in the form of a dependence of the energy of the joint system on the angle between the altermagnetic Néel vector and the magnetization. Finally, we report on the effect of exchange bias and discuss its phenomenology and origin. Exchange bias is usually regarded as a phenomenon observed in magnetic systems composed of a ferromagnetic (FM) layer and an antiferromagnetic (AFM) layer. We have explored the mechanism behind its altermagnetic version, showing that it exists in principle, and shed some light on the fundamental physics determining its strength. In particular, we have illustrated how, in a striking difference from the common AFM-based exchange bias, the AM-induced exchange bias effect can be further manipulated by electric fields. This effect is widely used in various technological applications, particularly in spintronics and magnetic storage. It is fundamental to developing high-performance magnetic devices and ensuring stability, reliability, and efficiency in multiple technologies.
