ABSTRACT

We search for reflection-dominated Compton-thick active galactic nuclei (CT AGN) candidates in the Lockman Hole region using the data of *SRG/eROSITA* Lockman Hole survey. We selected sources with anomalously hard photon indices in the 0.3—8.0 keV band, untypical for type I AGN. In particular, we required that the upper end of the 90% error interval did not exceed a fiducial boundary of $\Gamma = 1.3$. We found 291 sources which constitute a rare subpopulation among extragalactic X-ray sources detected by *eROSITA* in the Lockman Hole field, \approx 5%. These sources constitute the *eROSITA* sample of CT AGN candidates in the Lockman Hole field. We further divide the sources into three categories depending on the availability of reliable redshift and statistically significant detection of intrinsic absorption. We present two catalogues: the bright sample (37 sources) and the faint one (254). We estimate the fraction and sky density of reflection-dominated CT AGN candidates. We show examples of individual spectra and use stacking analysis to search for possible redshift evolution of their properties with redshift. We analyse combined *eROSITA* spectra of bright sources of different categories with a physically motivated spectral model UXCLUMPY and find them fully consistent with the fits to the ∼ 1 Msec *XMM-Newton* data for one of our reflection-dominated CT candidate, Type 2 galaxy SRGe J105348.6+573032. The catalogues of CT AGN candidates could be a good starting point for planning future studies and follow-ups at all wavelengths.

Key words: galaxies: active – galaxies: nuclei – X-rays: galaxies – surveys – catalogues

1 INTRODUCTION

An active galactic nucleus (AGN) refers to the innermost region of a galaxy that emits an exceptionally large amount of energy across the electromagnetic spectrum. AGNs are powered by the accretion of matter onto supermassive black holes located at the centres of galaxies. AGN studies give insights into the evolution of galaxies and the growth of supermassive black holes [\(Page et al.](#page-11-0) [2004;](#page-11-0) [Marconi](#page-11-1) [et al.](#page-11-1) [2004;](#page-11-1) [Kormendy & Ho](#page-11-2) [2013;](#page-11-2) [Fontanot et al.](#page-11-3) [2020\)](#page-11-3). X-ray surveys are an efficient tool for studying AGNs of various types and their populations in the Universe [\(Brandt & Alexander](#page-11-4) [2015\)](#page-11-4).

In so-called obscured AGNs, the central regions are hidden from direct view by dust and gas. Such AGNs make up a significant fraction or, possibly even the majority of the AGN population [\(Ueda](#page-11-5) [et al.](#page-11-5) [2014;](#page-11-5) [Buchner](#page-11-6) [2015;](#page-11-6) [Ananna et al.](#page-11-7) [2019\)](#page-11-7). Dust is the dominant source of obscuration at UV–IR wavelengths, whereas gas dominates the absorption at X-ray energies [\(Hickox & Alexander](#page-11-8) [2018\)](#page-11-8). Heavily obscured sources may be missed even in the most sensitive X-ray surveys due to the suppression of flux in the soft X-ray range. Obscuring material is believed to be present in the form of a torus surrounding the AGN, which blocks and reprocesses radiation that

originates from the accreting black hole [\(Antonucci](#page-11-9) [1993;](#page-11-9) [Gilli et al.](#page-11-10) [2007;](#page-11-10) [Netzer](#page-11-11) [2015\)](#page-11-11).

The degree of obscuration is characterised by the hydrogen column density of gas $N_{\rm H}$, with AGNs having moderate or high column densities ($N_{\rm H} \ge 10^{22}$ cm⁻²) being referred to as obscured. Sources that have intrinsic absorption column densities $N_{\rm H} \approx 10^{24}$ cm⁻² are termed "Compton-thick" AGN (CT AGN), as in such sources the Thomson optical depth approaches or exceeds unity [\(Comas](#page-11-12)[tri](#page-11-12) [2004\)](#page-11-12), making electron scatterings significant. X-ray surveys are widely used to uncover the population of obscured AGNs (including CT AGNs), with hard band data (> 2 keV) from Chandra [\(Alexan](#page-11-13)[der et al.](#page-11-13) [2001,](#page-11-13) [2003;](#page-11-14) [Fiore et al.](#page-11-15) [2012;](#page-11-15) [Baronchelli et al.](#page-11-16) [2017;](#page-11-16) [Signorini et al.](#page-11-17) [2023\)](#page-11-17), *XMM-Newton* [\(Brusa et al.](#page-11-18) [2010;](#page-11-18) [Comastri](#page-11-19) [et al.](#page-11-19) [2011\)](#page-11-19), *SRG/eROSITA* [\(Waddell et al.](#page-11-20) [2023,](#page-11-20) [2024\)](#page-11-21), and harder bands (> 10 keV) from *Swift/BAT* [\(Kawamuro et al.](#page-11-22) [2016;](#page-11-22) [Ichikawa](#page-11-23) [et al.](#page-11-23) [2019;](#page-11-23) [Baloković et al.](#page-11-24) [2020\)](#page-11-24), *NuSTAR* [\(Ballantyne et al.](#page-11-25) [2011;](#page-11-25) [Stern et al.](#page-11-26) [2014;](#page-11-26) [Brightman et al.](#page-11-27) [2015;](#page-11-27) [Lansbury et al.](#page-11-28) [2017\)](#page-11-28) and *INTEGRAL* [\(Sazonov et al.](#page-11-29) [2007;](#page-11-29) [Malizia et al.](#page-11-30) [2012\)](#page-11-30), allowing to establish the most complete picture of AGN population [\(Ueda et al.](#page-11-5) [2014;](#page-11-5) [Buchner](#page-11-6) [2015;](#page-11-6) [Ananna et al.](#page-11-7) [2019;](#page-11-7) [Peca et al.](#page-11-31) [2023\)](#page-11-31). For a comprehensive review of obscured AGN selection methods in other bands, see [Hickox & Alexander](#page-11-8) [\(2018\)](#page-11-8).

Compton-thick AGN candidates are usually identified via reprocessed signal features, such as the Iron line and the Compton reflec-

e-mail: gilfanov@mpa-garching.mpg.de

tion continuum [\(Guainazzi et al.](#page-11-32) [2005;](#page-11-32) [Tozzi et al.](#page-11-33) [2006;](#page-11-33) [Georgan](#page-11-34)[topoulos et al.](#page-11-34) [2009;](#page-11-34) [Done](#page-11-35) [2010;](#page-11-35) [Gandhi et al.](#page-11-36) [2013;](#page-11-36) [Padovani et al.](#page-11-37) [2017;](#page-11-37) [Buchner et al.](#page-11-38) [2021\)](#page-11-38) or via observations in the high-energy (> 10 keV) band [\(Ricci et al.](#page-11-39) [2015;](#page-11-39) [Akylas et al.](#page-11-40) [2016\)](#page-11-40). The latter is less subject to obscuration and may uncover specific spectral features such as the Compton hump [\(Elvis](#page-11-41) [2000\)](#page-11-41). Broadband spectral modelling (including soft and hard X-ray regimes) is advantageous for identifying CT AGNs [\(Arévalo et al.](#page-11-42) [2014;](#page-11-42) [Padovani et al.](#page-11-37) [2017;](#page-11-37) [Buchner et al.](#page-11-43) [2019\)](#page-11-43). Compton-thick sources constitute a significant fraction of AGNs, and their accurate counting is critical in obtaining a complete census of the population of accreting supermassive black holes [\(Ueda et al.](#page-11-5) [2014;](#page-11-5) [Buchner](#page-11-6) [2015\)](#page-11-6).

We focus on X-ray spectroscopy to search for CT AGN candidates using data from the Lockman Hole region survey with the *eROSITA* telescope [\(Predehl et al.](#page-11-44) [2021\)](#page-11-44) onboard the Spectrum-RG orbital X-ray observatory [\(Sunyaev et al.](#page-11-45) [2021\)](#page-11-45). To this end, we explore reflection signatures in X-ray spectra of Lockman Hole sources. A similar approach was used in [Tozzi et al.](#page-11-33) [\(2006\)](#page-11-33); [Georgantopoulos](#page-11-34) [et al.](#page-11-34) [\(2009\)](#page-11-34). The paper aims to systematically construct a catalogue of CT AGN candidates that can be used as targets in future follow-ups to confirm their Compton-thick nature.

The paper is organised as follows: first, we describe the X-ray data (Sect. [2.2\)](#page-1-0), then we discuss the spectral signatures of obscured AGNs relevant for this work (Sect. [3.1\)](#page-1-1). We characterise our selection method in Sect. [3.2](#page-2-0) and provide examples of spectra in Sect. [4.](#page-4-0) We explore some of our candidates by comparing them with *XMM-Newton* data in Sect. [4.2.](#page-6-0) The paper ends with a discussion of our results and a description of the obtained catalogue of CT AGN candidates in the Lockman Hole region.

Uncertainties are quoted on a 90 per cent confidence interval, unless stated otherwise.

2 X-RAY DATA

The Lockman Hole is an area located in Ursa Major that has the lowest neutral hydrogen column density on the line of sight in the entire sky [\(Lockman et al.](#page-11-46) [1986;](#page-11-46) [Dickey & Lockman](#page-11-47) [1990\)](#page-11-47). This condition makes the Lockman Hole a perfect region to explore extragalactic sources in general and AGNs of various types in particular. The search for obscured AGNs especially benefits from the low neutral hydrogen column density, as it minimizes the interstellar absorption of soft X-rays.

2.1 *SRG/eROSITA* **Lockman Hole survey**

The Lockman Hole observations took place during the performance verification phase of *SRG/eROSITA* in October 2019. The observations were conducted in a raster scanning regime, which allows for obtaining wide-field X-ray images with almost uniform sensitivity and a PSF within the image.

The footprint of the LH survey is $\approx 29 \text{ deg}^2$ with the centre coordinates $\alpha = 10^{\text{h}}35^{\text{m}}$ and $\delta = +57^{\circ}38'$. The total survey duration is 180 ks, mean exposure time is about 8 ks per point. These parameters allow for achieving sensitivity $\approx 3 \times 10^{-15}$ erg s⁻¹ cm⁻² in 0.5 − 2 keV energy range. About 20% of the survey footprint was previously observed with other X-ray telescopes such as *Chandra* and *XMM-Newton*.

2.2 *SRG/eROSITA* **Lockman Hole source catalogue**

The selection of candidates for highly obscured AGN is made among the sources detected by *SRG/eROSITA* [\(Predehl et al.](#page-11-44) [2021;](#page-11-44) [Sunyaev](#page-11-45) [et al.](#page-11-45) [2021\)](#page-11-45) during its deep survey of the Lockman Hole (LH) region. The details of the survey, X-ray source catalogue and procedures used for source detection and catalogue construction are presented in Gilfanov et al. (2024), in prep. The *eROSITA* Lockman Hole source catalogue includes 6885 sources with the detection likelihood $DL > 10$, which approximately corresponds to the 4σ significance threshold for Gaussian distribution.

Optical identification and classification of X-ray sources are presented in [Bykov et al.](#page-11-48) [\(2022\)](#page-11-48); [Belvedersky et al.](#page-11-49) [\(2022\)](#page-11-49). About ∼ 1/3 of X-ray sources have spectroscopic redshifts. For the remaining sources, we used photometric redshifts determined by the SRGz system [\(Meshcheryakov et al.](#page-11-50) [2023\)](#page-11-50). The redshifts of X-ray sources – both spectroscopic and photometric (SRGz), are listed in the source catalogue in Gilfanov et al. (2024) (in prep.). We apply a quality cut to the photometric redshifts as described in the following section, slightly reducing the number of available redshifts. 357 sources were excluded as they are likely Galactic based on their multiwavelength properties (see [Belvedersky et al.](#page-11-49) [2022\)](#page-11-49) and thus are not of interest in the context of this work. This way, the initial sample of sources used in this work consists of 6528 sources (all extragalactic sources in the Lockman Hole).

Source spectra were extracted for all 7 *eROSITA* cameras using a circular aperture of 40'' (corresponding to ≈ 80 per cent encircled energy) centred on the best-fit X-ray source position. To estimate the background spectrum, we used an annulus around the source with inner and outer radii of 120′′ and 250′′–600′′, respectively. The outer radius was chosen so that there were at least 400 counts in the background region. The sources detected in the background region were masked using a circular aperture with a radius of 30′′-60′′, depending on their fluxes. The spectra were extracted using srctool task from eSASS (*eROSITA* Science Analysis Software System, [Brunner](#page-11-51) [et al.](#page-11-51) [2022\)](#page-11-51). Spectral analysis was performed with xspec, version 12.12 [\(Arnaud](#page-11-52) [1996\)](#page-11-52). The quality of spectral fits was accessed using W-statistic^{[1](#page-1-2)} appropriate for spectra with Poisson statistics. To avoid the well-known bias in a profile likelihood, we binned the source spectrum so that every bin in the corresponding background spectrum contains at least 5 counts. The binning was done using the ftgrouppha tool of the HEASoFT package (v. 6.29).

3 SEARCH FOR COMPTON-THICK AGN CANDIDATES

3.1 Qualitative picture

In the unification model of AGN [\(Antonucci](#page-11-9) [1993\)](#page-11-9), at shallow viewing angles, the observer registers direct emission from the accreting black hole which has passed through the torus, and reprocessed emission scattered by the torus material. In the X-ray band, signatures of obscured AGN can be (*i*) an absorption turnover at the lower energy end of the spectrum, and/or (*ii*) reflection signatures, such as a hard spectrum in the standard X-ray band, the Iron fluorescent line at 6.4−6.7 keV with the corresponding K-edge, and the Compton hump at ∼ 20 − 30 keV. Relative contributions of absorbed direct emission (*i*) and reprocessed component (*ii*) are determined by the viewing angle and the column density of the torus material. This behaviour is

¹ <https://heasarc.gsfc.nasa.gov/xanadu/xspec/manual>

illustrated in Fig. [1](#page-2-1) where we show two theoretical spectra calculated using the mytorus model [\(Yaqoob](#page-12-0) [2012\)](#page-12-0).

In the rest frame of the source, the position of the absorption turnover in the transmitted spectrum depends on the equivalent hydrogen column density of the absorbing material. For example, for $N_{\rm H} \sim 10^{23}$ cm⁻², the turnover is located at about ~ 4 keV. Therefore, instruments sensitive in the hard band can detect more heavily obscured AGN compared to the telescopes operating in the soft Xray band. However, this behaviour is modified by the redshift of the source. In the observer frame, the turnover energy is shifted to lower energies by a factor of $1 + z$, where z is the redshift. For this reason, identification of obscured sources (case *i* above) via their low energy turnover generally requires knowledge of the source redshifts. We also note that, given the shape of the *eROSITA* energy response (falling quickly after 2.3 keV), highly obscured sources can be plausibly detected via absorption turnover only if located at the moderate redshift of $\sim 1 - 2$ and/or if they are sufficiently bright.

If an AGN is heavily obscured, the low energy X-ray emission of the central engine might be non-detectable. In this instance, we see only emission reflected from the torus material (case *ii* above) and such sources are called reflection-dominated AGNs [\(Georgan](#page-11-34)[topoulos et al.](#page-11-34) [2009;](#page-11-34) [Masini et al.](#page-11-53) [2019\)](#page-11-53). The spectrum features a shallow slope in the standard X-ray band, a fluorescent Iron line, a Compton reflection hump, and other peculiarities [\(Pounds et al.](#page-11-54) [1990;](#page-11-54) [George & Fabian](#page-11-55) [1991;](#page-11-55) [Magdziarz & Zdziarski](#page-11-56) [1995;](#page-11-56) [Ross &](#page-11-57) [Fabian](#page-11-57) [2007;](#page-11-57) [Kallová et al.](#page-11-58) [2024\)](#page-11-58). Such a shallow slope cannot be produced by unsaturated comptonization in the corona [\(Sunyaev &](#page-11-59) [Titarchuk](#page-11-59) [1980\)](#page-11-59) responsible for the observed X-ray spectral shape of unabsorbed AGNs. The mechanism of the X-ray reflection from the optically thick surface was described in [Basko et al.](#page-11-60) [1974](#page-11-60) for a binary star system but has much in common with the spectral formation in CT AGN.

Measurement of intrinsic absorption for a reflection-dominated AGN is complicated. It requires multi-component self-consistent spectral models (e.g. mytorus, [Yaqoob](#page-12-0) [2012,](#page-12-0) borus, [Baloković et al.](#page-11-61) [2018,](#page-11-61) uxclumpy, [Buchner et al.](#page-11-43) [2019\)](#page-11-43) and a broadband spectrum of sufficient quality to accurately separate reflected and transmitted spectral components and to confirm the CT nature of the source. However, simple yet robust spectral models can be used to identify CT AGN candidates using X-ray data, for example, by measuring the anomalously shallow photon index in the standard X-ray band [\(Tozzi](#page-11-33) [et al.](#page-11-33) [2006;](#page-11-33) [Georgantopoulos et al.](#page-11-34) [2009,](#page-11-34) [2013;](#page-11-62) [Gandhi et al.](#page-11-36) [2013\)](#page-11-36).

In this paper, we focus on the search for reflection-dominated Compton-thick AGN. As it follows from the discussion above, the main signature of such objects in the soft X-ray band should be peculiar shallow spectra, uncharacteristic of classical type I AGN. With some caveats, candidates for such objects can also be identified without prior knowledge of source redshifts. A comprehensive search for moderately absorbed AGN among Lockman Hole sources will be performed in a follow-up publication.

3.2 Search for reflection-dominated Compton-thick candidates

To identify CT AGN candidates, we employ a two-step procedure. First, we fit X-ray spectra of all sources from the initial sample with a power law model (phabs*powerlaw in xspec). The interstellar absorption is fixed at the median value for the Lockman Hole region $N_{\rm H}$ = 7 × 10¹⁹ cm⁻² [\(HI4PI Collaboration et al.](#page-11-63) [2016\)](#page-11-63). We use a conservative fiducial value of $\Gamma_0 = 1.3$ to separate Compton-thick AGN candidates from normal type I AGN. We use 90 per cent errors to select sources whose photon indices are lower than Γ_0 : Γ + Γ_{err} < Γ₀ (see Fig. [2\)](#page-2-2). The choice of Γ₀ is motivated by the distribution

Figure 1. Theoretical spectra of obscured AGN computed using mytorus model (zeroth-order and scattered components, no emission lines are shown) in xspec: (A) a mildly obscured AGN with $N_{\rm H} = 10^{23}$ cm⁻² (blue lines, case (*i*) in Sect. [3.1\)](#page-1-1) and (B) Compton-thick reflection-dominated AGN with $N_{\rm H}$ = 3 × 10²⁴ cm⁻² (pink lines, case (*ii*) in Sect. [3.1\)](#page-1-1). For both cases, solid lines show the total observed spectrum, dotted lines – direct emission from AGN obscured with the corresponding column density, and dashed lines – the scattered continuum (photons reflected once or more from the torus material). The inclination angle between the observer's line of sight and the symmetry axis of the torus was assumed to be 75 degrees for both spectra. The redshift is $z = 1$.

Figure 2. Best-fitting value of the photon index vs. photon index upper error (90 per cent confidence). The red curve is defined as $\Gamma + \Gamma_{\text{err}} = 1.3$. Sources located below this curve and shown by red circles have a 90 per cent upper bound on their photon index lower than 1.3. A small group of 129 sources whose photon index upper bound is unconstrained were excluded from this plot.

Figure 3. Classification scheme. Γ upper limit in the second step refers to the photon index upper limit estimated using phabs*powerlaw model. Reliable redshift refers to either spectroscopic or confident photometric redshift estimation (see text for details). Bright source sample is described in Sect. [3.3.](#page-3-0)

of X-ray spectral indices with the mean $\Gamma \approx 2$ and scatter $\sigma \approx 0.2$ [\(Nandra & Pounds](#page-11-64) [1994;](#page-11-64) [Liu et al.](#page-11-65) [2022\)](#page-11-65). No information about the redshifts is needed at this step and, therefore, this procedure is applied to all extragalactic sources from the *eROSITA* LH catalogue. For a small number (129) of faint sources, the 90 per cent upper bound on the photon index was unconstrained. They obviously cannot belong to the sought group of hard sources and were excluded from further analysis and from the plot in Fig. [2.](#page-2-2) This figure shows the distribution of best-fitting photon index values and their errors. Out of 6528 sources, 291 were found to have anomalously hard spectra with photon indices lower than Γ_0 at 90 per cent confidence (red symbols). The so-constructed group of 291 sources constitutes the full sample of CT AGN candidates.

However, such a simple approach based on the power law fit may, in some cases, misclassify mildly obscured sources as CT AGN candidates. This is because the low-energy absorption turnover can mimic the shallow slope of the reflected spectrum in the standard X-ray band.

To identify such cases, we fit the spectra from the initial sample of 291 CT AGN candidates with the model which includes intrinsic absorption. We use the following xspec model: phabs*zphabs*zpowerlw, where phabs describes the Galactic interstellar absorption (as in the previous step), zphabs describes the intrinsic absorption of the source with account for its redshift, and zpowerlw is a power law emission spectrum. This model requires knowledge of the source redshift, for which we used values from the *eROSITA* LH catalogue (Gilfanov et al., 2024. in prep.). For 50 sources out of 291 spectroscopic redshifts were available. For the photometric redshifts delivered by SRGz [\(Meshcheryakov et al.](#page-11-50) [2023\)](#page-11-50), we required that the relative redshift uncertainty taken at the 68 per cent confidence level did not exceed 30 per cent, namely $\Delta z_{\rm phot}/(1 + z_{\rm phot})$ < 0.3, and that the zConf redshift quality parameter was larger than 0.3 (see [Meshcheryakov et al.](#page-11-50) [2023](#page-11-50) for details). Thus, 130 sources out of 291 have sufficiently accurate redshifts (ei-

Table 1. Description of different source categories.

ther spectroscopic or photometric) to apply the model with intrinsic absorption.

For 81 sources, no statistically significant intrinsic absorption was detected, suggesting that the data do not require absorption turnover. In combination with a Γ < 1.3 spectrum, this may signal a highly obscured nature of the source and a reflection-dominated spectrum. Such sources are labelled as "Category 1" in our work. However, a word of caution is necessary – the upper limits on intrinsic $N_{\rm H}$ for many sources from Category 1 were fairly unconstraining, often in the ~ $10^{22} - 10^{23}$ cm⁻² range. Furthermore, for faint sources, the inclusion of intrinsic absorption added degeneracy to the model parameters, significantly increasing the error on the photon index. To address this issue, we introduce a bright source subsample in Sect. [3.3.](#page-3-0)

For the remaining 49 sources, labelled "Category 2" sources, the inclusion of the intrinsic absorption in the model led to a statistically significant improvement of the fit quality at a confidence level of 90 per cent $-\Delta C$ -stat > 2.71 compared to the Galactic-only absorption fit. We also applied Akaike Information Criterion [\(Akaike](#page-11-66) [1974\)](#page-11-66) widely used in the literature (e.g. [Buchner et al.](#page-11-67) [2014\)](#page-11-67). As well known, AIC accounts for the difference in the number of parameters between the compared models. Expressed in terms of AIC the Category 2 sources all have Δ AIC > 4.71, with the median values of Δ AIC > 5.52. For these 49 sources, the best-fit intrinsic column density is inconsistent with zero at the 90% confidence level.

19 sources have a 90 per cent lower limit on intrinsic N_H larger than 10^{22} cm⁻². No sources with intrinsic absorption above 10^{24} cm⁻² were found. The best-fitting values of the photon index in the model with intrinsic absorption for these sources were found to be consistent with the canonical value of ~ 1.9, albeit with large uncertainties. This is quite natural as in Category 2 sources we are likely observing emission generated in the vicinity of the supermassive black hole obscured by the neutral or molecular gas with moderate $N_{\rm H}$ (case i in Sect. [3.1\)](#page-1-1). We interpret these sources as mildly obscured (i.e. $N_{\rm H} \leq 10^{24} \rm \ cm^{-2}$) AGNs.

The remaining 161 sources do not have sufficiently reliable redshift estimates to measure intrinsic absorption in their spectra. They are marked as "Category 3" sources. Our classification procedure is recapped in Fig. [3](#page-3-1) and category description is provided in Table [1.](#page-3-2)

3.3 Bright source sample

By construction, Category 1 sources should be interpreted as the best candidates for reflection-dominated CT AGN. However, as noted above, the upper limits on the absorption column density are often unconstraining. The same can be said about the value of the photon

Figure 4. Γ and intrinsic N_H estimations (phabs*zphabs*zpowerlw model) for the Category 1 (pink squares) and 2 (blue circles) sources from the bright source sample. Upper limits are at the 90 per cent confidence, while error bars show 1 σ errors. One source from the Category 1 has $\Gamma = 4.6^{+2.2}_{-1.4}$, $N_{\rm H} = 1.3^{+1.3}_{-0.8}$ and is not shown for the sake of visual clarity.

index estimation after including the intrinsic absorption. These two effects make the classification of faint sources less robust.

To make further analysis more meaningful, we selected a bright source sub-sample from the full catalogue of 291 CT AGN candidates. We chose the cut of 100 source counts (i.e. background subtracted) calculated with the eSASS source detection algorithm ERMLDET. This approximately corresponds to the 0.3–2.3 keV flux of ~ 1.5 × 10⁻¹⁴ erg s⁻¹ cm⁻² across most of the *eROSITA*'s Lockman Hole survey footprint. 37 sources pass the photon count selection and make it into the bright subsample: 9 for Category 1, 14 for Category 2 and 14 for Category 3 (see Fig. [3\)](#page-3-1). They are listed in Table [A1.](#page-13-0) We publish two separate catalogues – for the bright subsample and the rest (faint sample). Together, they make up the full sample described in Sect. [3.2.](#page-2-0)

In Fig. [4](#page-4-1) we show Γ - N_H plot for the Category 1 and 2 sources from the bright subsample. The upper limits on the intrinsic absorption are fairly constraining for almost all Category 1 sources, and their photon indices are still quite shallow. On the other hand, Category 2 sources occupy a zone of a "typical" X-ray selected mildly obscured AGN with $\Gamma \sim 2$ and $N_H \sim 10^{22}$ cm⁻². From now on we will be referring to the sources from the bright subsample unless stated otherwise.

4 SPECTRAL ANALYSIS

To illustrate the difference between reflection-dominated CT AGN candidates (Category 1) and mildly obscured AGN (Category 2), we plot the spectra of the four brightest sources from each category in Fig. [5.](#page-5-0) The difference in their spectral shapes is quite obvious.

For sources with spectroscopic redshifts, we searched for the possible evolution of their spectral parameters with redshift (Fig. [6\)](#page-5-1). To this end, we grouped the sources into redshift bins. Since we performed spectral averaging in this exercise, we used all sources, not only the ones from the bright subsample. For sources of a given category and in a given redshift bin, we performed a simultaneous spectral

fitting with all spectral parameters except normalisation tied between sources. The fit was performed separately for reflection-dominated CT AGN candidates (Category 1) and mildly obscured AGNs (Category 2). The same model, phabs*zphabs*zpowerlw, was used for both types of sources. We found, as expected, that photon indices of reflection-dominated CT AGN candidates lie significantly lower than those for the sources with intrinsic absorption (Fig. [6,](#page-5-1) upper panel). Secondly, for CT-AGN candidates, no statistically significant intrinsic absorption was detected in all bins except the third one (the same figure, lower panel). Notably, in the first two redshift bins, where the statistical quality of combined data is sufficiently high, the upper limits on the intrinsic absorption are fairly constraining, at the level of ~ 5×10^{20} and ~ 10^{21} cm⁻², and the photon indices are very shallow ($\Gamma \sim 0.5$). This is consistent with the expectation for reflection-dominated CT AGN, although the particular value of the photon index may be affected by the presence of the soft excess in AGN spectra (see Sect. [5.1](#page-8-0) for a discussion). In the higher redshift bins, uncertainties of the spectral parameters notably increase, due to fewer counts in analysed spectra, and the spectral fit results become less conclusive. Finally, we note that in this analysis we used a simplifying assumption that all sources of the given category in the given redshift bin have identical spectral shapes (spectral parameters except for normalisation were tied to each other).

For the three brightest Category 1 sources with available spectroscopic redshifts (srcid 297, 316 and 671 from Table [A1\)](#page-13-0), we placed upper limits on the equivalent width of the Iron line. We added a redshifted Gaussian emission line (zgauss in xspec, with a fixed energy of 6.4 keV) to the phabs*powerlaw model and calculated 90 per cent upper limits on the equivalent width. For sources 297, 316 and 324 the upper limits are 1.9, 1.5, and 0.6 keV respectively. These numbers should be compared with the equivalent width of ∼ 1 keV expected in the spectrum of reflected emission [\(George & Fabian](#page-11-55) [1991\)](#page-11-55). In this calculation, we assumed a line width of 0.1 keV. The upper limits reduce by ∼ 13% if we assumed intrinsically narrow lines with the width of 0.01 keV. This exercise shows that the Iron lines (if present) are not detectable given our data. Deeper follow-up observations are needed to characterise fluorescent iron lines in these sources.

4.1 Spectral fits with UXCLUMPY model.

We further explored the spectra of candidates from different categories using a physically motivated UXCLUMPY model. UXCLUMPY [\(Buchner et al.](#page-11-43) [2019\)](#page-11-43) is a unification model for a clumpy obscurer in AGN. It combines a clumpy torus component with an optional "inner ring", a Compton-thick reflector near the corona. The thickness of a clumpy torus is characterised by the TORsigma parameter (varying from 0 to 84 deg) − dispersion of the distribution of the cloud population. Parameter CTKcover determines the covering fraction of the inner reflector and varies from 0 to 0.6.

Our attempt to fit individual *eROSITA* spectra with UXCLUMPY yielded unconstraining results with large uncertainties, even for the brightest sources from our sample. We therefore applied UXCLUMPY to combined *eROSITA* spectra from different categories. We used sources from the bright sample having spectroscopic redshift (see Table [A1\)](#page-13-0), namely, four sources from Category 1 (excluding srcid 1430, see below) and seven sources from Category 2. The spectra were fitted simultaneously within each category (C-stat minimization in xspec). Galactic absorption $N_{\text{H,gal}}$ was frozen at 7×10^{19} , cm⁻². Following [Buchner et al.](#page-11-43) [\(2019\)](#page-11-43), we fixed Ecut at 400 keV, and Theta_inc at 90 deg. All parameters of the model except for line of sight $N_{\rm H}$ and normalization were linked between individual sources

Figure 5. Blue line: a spectrum of mildly obscured ($N_H \sim 10^{22}$ cm⁻²) source with a turnover (phabs*zphabs*zpowerlw model, Category 2), red dashed line: a spectrum of CT AGN candidate with reflection-dominated spectrum (phabs*powerlaw model, Category 1). The spectra illustrate the cases *i* and *ii* from the Sect. [3.1.](#page-1-1) Both spectra were unfolded using the model phabs*powerlaw with interstellar absorption fixed at 7 × 10¹⁹ cm^{−2} and Γ fixed at 2. Parameters of these sources are present in Table [A1.](#page-13-0)

Figure 6. *Upper panel:* photon index estimates obtained from phabs*zphabs*zpowerlw model for simultaneously fitted spectra in different redshift bins for categories 1 and 2 (red and blue points respectively). The dashed line marks the $\Gamma = 1.3$ threshold chosen in this work to separate CT AGN candidates from other *eROSITA* sources. *Lower panel:* N_H estimations obtained from the same model, errors are for the 90% confidence level.

within each category. The best fit parameters are presented in Table [2.](#page-6-1) For the line of sight N_H we quote mean value for each category.

As one can see from this table, candidates from different categories are clearly separated in the parameter space, as it is further illustrated in Fig. [7.](#page-6-2) Sources from Category 1 require higher CTKcover values then those from Category 2. At the same time, Category 1 sources need little or no component of clumpy torus as the value of TORsigma is substantially lower for them than for Category 2 sources.

As a sanity check, we randomly chose five "standard" (Type I) *eROSITA* AGN with $\Gamma \approx 2$ (gray dots to the right of the red line in Fig. [2\)](#page-2-2) and source counts more than 300 and fitted their spectra simultaneously with UXCLUMPY model. We found that selected sources have CTKcover and TORsigma consistent with zero, albeit with large uncertainties. As expected, neither Compton-thick inner ring nor absorber are needed to describe X-ray spectra of Type 1 AGN.

Thus, the UXCLUMPY model successfully reproduced *eROSITA* spectra of both categories of sources with compatible slope of the primary power law spectrum and with interpretable values of other key parameters of the model. In particular, we found a clear difference between Category 1 and Category 2 sources. It should be noted that the spectral fits with UXCLUMPY model did not yield canonical values of hydrogen column density $N_H \sim 10^{24}$ cm⁻². This result will be discussed in section [5.](#page-8-1)

Source type	$N_{\rm H}$ [\times 10 ²²]. cm^{-2}	PhoIndex	TORsigma	CTKcover	z (frozen)	const
1430 (XMM)	1.43 ± 0.06	1.52 ± 0.04	$0.31_{-0.13}^{+1.48}$	> 0.49	0.78	0.09 ± 0.08
Category 1	2.0 ± 0.2	1.89 ± 0.23	< 1.51	> 0.49	individual	0.04 ± 0.02
Category 2	0.86 ± 0.40	1.97 ± 0.15	$31.65^{+21.71}_{-14.47}$	$0.45^{+0.05}_{-0.09}$	individual	0.10 ± 0.09

Table 2. Results of spectral fitting of *eROSITA* and *XMM-Newton* data with UXCLUMPY model. See Sections [4.1](#page-4-2) and [4.3](#page-6-3) for details. For *eROSITA* spectra (Category 1 and 2), quoted are are mean values of line of sight $N_{\rm H}$.

Figure 7. The covering fraction of the inner Compton thick ring CTKover and opening angle of the clumpy torus TORsigma in the UXCLUMPY model for *eROSITA* spectra of Category 1 (red) and Category 2 (blue) sources and XMM-Newton spectrum of srcid 1430 (dashed). Contours show 90% error regions, markers show the best-fit values for each region. See Section [4.3](#page-6-3) for details.

4.2 Comparison with the *XMM-Newton* **data**

For a fraction of our bright sample sources, we found counterparts of *eROSITA* sources in the 4XMM DR13 catalogue [\(Webb et al.](#page-11-68) [2020\)](#page-11-68). The cross-match was performed similarly to [Bykov et al.](#page-11-48) [2022](#page-11-48) (their Sect. 3.2). Spectroscopic redshifts were available for 2 sources from Category 1 and 3 sources from Category 2. For each XMM source, in the case of multiple *XMM-Newton* observations, we selected the one with the largest exposure. We fitted XMM spectra with the phabs*zphabs*zpowerlw model and used only pn detector data (for the srcid 1430 MOS data was also used, see below).

We used the XMM Pipeline Processing System (PPS, [Perea-](#page-11-69)[Calderón et al.](#page-11-69) [2019\)](#page-11-69) data products where possible. For one object from Category 2 (srcid 1413) no PPS data products were available, and we used XMM observation data files (ODF) which we processed according to the standard *XMM-Newton* data analysis recipies^{[2](#page-6-4)}.

In Fig. [8](#page-7-0) we compare 90 per cent confidence regions for the hydrogen column density and photon index determined from the *eROSITA* and *XMM-Newton* data. For most sources, there is good agreement between the two. *eROSITA* data appears to be more constraining in

² <https://www.cosmos.esa.int/web/xmm-newton/sas-threads>

the case of srcid 324. The regions do not intersect in the case of srcid 1430, but *XMM-Newton* still shows a notably hard spectrum. The regions lie very close in case 1413. Given that we compare error regions at the 90% some non-zero fraction of such situations is natural. We conclude that overall, there is adequate agreement between *eROSITA* and *XMM-Newton* results. Examples of *eROSITA* and *XMM-Newton* spectra of the two brightest Category 1 sources, 324 and 1430, are shown in Fig. [9.](#page-7-1)

4.3 Detailed spectral analysis of *XMM-Newton* **long exposure data for SRGe J105348.6+573032**

For srcid 1430 (SRGe J105348.6+573032, 4XMM J105348.7+573033), *XMM-Newton* accumulated significant exposure time, about ∼ 10⁶ sec. For this source, we performed a detailed spectral analysis of the full set of available *XMM-Newton* data using the UXCLUMPY model. Four sets of *XMM-Newton* observations of the source were performed between 2000 and 2002, with 4−3 observations in each set. The third set, performed between Oct. 19−27 2002, was significantly affected by the solar activity and we excluded it from our analysis. For the nine remaining observations, both the pn and MOS data were used with a total exposure of 1.04 Msec. The combined data of all observations were fitted to the UXCLUMPY model, the best-fit parameters are listed in Table [2.](#page-6-1) The 90% error region for TORsigma and CTKcover is shown in Fig. [7,](#page-6-2) along with error regions for the Category 1 and 2 combined *eROSITA* spectra. We also fit individual sets of *XMM-Newton* observations and found consistent values of the best fit parameters, albeit with large errors. From Fig. [7](#page-6-2) and Table [2](#page-6-1) one can see that *XMM-Newton* data for srcid 1430 yield results which are fully consistent with those obtained from *eROSITA* spectra of Category 1 sources. Note, that srcid 1430 was excluded from spectral fitting of *eROSITA* data, shown in Fig. [7](#page-6-2) and Table [2.](#page-6-1) We finally note that the best fit value of the photon index in UXCLUMPY *XMM-Newton* fit is rather hard. We carefully investigated the parameter space of the model and confirmed that the minimum found is global. This behaviour might be similar, for example, to the one found for NGC 424 in [Buchner et al.](#page-11-38) [\(2021\)](#page-11-38).

Fluorescent line of neutral iron is modelled self-consistently in UXCLUMPY model. In order to measure its equivalent width directly from the observed spectrum, we fit the *XMM-Newton* spectrum with the power law model with a superimposed Gaussian line, which energy was fixed at the redshifted position of the fluorescent line of neutral iron. Assuming intrinsically narrow line, we obtained best fit value of the equivalent width of 0.19 keV with 90% error interval of $0.09 - 0.27$ keV. This value corresponds to about ~ 1/5 of what is expected in purely reflected spectrum.

Similar to the best fit to *eROSITA* spectra of Category 1 sources (Table [2,](#page-6-1) Fig. [7\)](#page-6-2) we obtained rather low value of hydrogen column density in the UXCLUMPY model, $\sim 10^{22}$ cm⁻². This will be discussed in the following section.

Figure 8. Comparison between the *eROSITA* and *XMM-Newton* spectral parameters. 90 per cent confidence contours of photon index Γ vs intrinsic ^H for the eROSITA are plotted in solid black lines and for the XMM in dashed red lines (phabs*zphabs*zpowerlw model). The first row shows examples of the Category 1 sources (N_H lower limit is consistent with zero based on the *eROSITA* data), and the second row shows a set of Category 2 sources. The stripe limited by the solid grey lines shows the photon index range 1.8 < Γ < 2.2 that is typical for normal AGN [\(Nandra & Pounds](#page-11-64) [1994;](#page-11-64) [Liu et al.](#page-11-65) [2022\)](#page-11-65).

Figure 9. A comparison between (unfolded) *XMM-Newton* and *eROSITA* spectra for two brightest sources from Category 1. Both spectra were unfolded using the model phabs*powerlaw with interstellar absorption fixed at 7×10^{19} cm⁻² and Γ fixed at 2.

5 DISCUSSION

5.1 Limitations of the analysis

The utter simplicity of the method employed in this paper to search for CT AGN candidates allows us to apply it to faint sources with just over ∼ 20 *eROSITA* counts. However, this also brings about its main limitation – a one-component spectral model, an absorbed power law, is used to characterise complex data. Real X-ray spectra of (CT-) AGNs are much more complicated and include several different components: transmitted emission, reflected emission with fluorescent lines and absorption edges (see Sect. [1\)](#page-0-0), and soft excess. For this reason, the photon indices and hydrogen column density values obtained in power fits should be interpreted with a certain caution.

The picture is further complicated by the fact that the physical state of obscuring material may not be neutral, as was implicitly assumed throughout this work, but (partially) ionised. Some AGNs show signatures of absorption of X-rays by mildly ionised optically thin gas, called warm absorber (Reynolds $& Fabian$ [1995\)](#page-11-70). The material responsible for warm absorbers is linked to outflows or winds launched from broad line regions or tori [\(Laha et al.](#page-11-71) [2014\)](#page-11-71). X-ray signatures of warm absorber systems include (blueshifted) absorption lines which require high-resolution spectroscopy to be detected [\(Blustin et al.](#page-11-72) [2005;](#page-11-72) [Kallman & Dorodnitsyn](#page-11-73) [2019\)](#page-11-73).

The relative amplitude of reflected and direct emission may change from source to source and depends on many factors. The geometry of the material giving rise to the reflected emission might also not be as simple as a torus with a smooth surface and may be constrained with high-quality spectra [\(Buchner et al.](#page-11-43) [2019\)](#page-11-43). The exact shape of the Compton hump, fluorescent lines, and the transmitted spectrum depend on the geometry of the source and reprocessing media [\(Nenkova](#page-11-74) [et al.](#page-11-74) [2008;](#page-11-74) [Buchner et al.](#page-11-38) [2021\)](#page-11-38). There is an array of spectral models with various geometries, from the solid torus to the agglomeration of blobs to simulate patchy absorbers. To name a few, mytorus [\(Mur](#page-11-75)[phy & Yaqoob](#page-11-75) [2009;](#page-11-75) [Yaqoob](#page-12-0) [2012\)](#page-12-0), borus [\(Baloković et al.](#page-11-61) [2018\)](#page-11-61), bntorus [\(Brightman & Nandra](#page-11-76) [2011\)](#page-11-76), RXTorus [\(Paltani & Ricci](#page-11-77) [2017\)](#page-11-77), UXCLUMPY [\(Buchner et al.](#page-11-43) [2019\)](#page-11-43) have been applied to the data from some CT AGNs (e.g. [Arévalo et al.](#page-11-42) [2014;](#page-11-42) [Kallová et al.](#page-11-58) [2024\)](#page-11-58).

An additional component, possibly of thermal origin, is often observed in AGN at energies ≤ 1 keV, called "soft excess". It may be related to a warm corona or Comptonised emission from the accretion disc [\(Gierliński & Done](#page-11-78) [2004;](#page-11-78) [Guainazzi & Bianchi](#page-11-79) [2007;](#page-11-79) [Done et al.](#page-11-80) [2012\)](#page-11-80). Such a component is also observed in some CT AGNs (e.g. [Silver et al.](#page-11-81) [2022;](#page-11-81) [Peca et al.](#page-11-31) [2023;](#page-11-31) [Sengupta et al.](#page-11-82) [2023\)](#page-11-82). Indeed, analysing *eROSITA* data from the eFEDS field, [Waddell et al.](#page-11-20) [\(2023\)](#page-11-20) found that a significant portion of hard-band selected AGNs show evidence of complex absorption (with a warm absorber or an absorber with partial covering best describing the data). In addition, they found that a fraction of hard X-ray-selected AGNs possess a soft excess.

We did not find clear statistically significant evidence of a soft excess among our CT AGN candidates. However, the presence of a soft excess in the spectrum will effectively increase the observed photon index in the *eROSITA* band, making sources appear softer. This may result in the loss of some of the true CT-AGNs in our selection procedure based on the photon index cut of Γ < 1.3.

Complexities discussed in this subsection can potentially lead to misclassification or loss of some CT AGNs in our selection procedure (Sect. [3.2\)](#page-2-0). However, a combination of the modest numbers of counts for the majority of sources and the sensitivity range of *SRG/eROSITA*, limited to the standard X-ray band, makes use of more physically motivated models such as mytorus unfeasible for most of the sources. As mentioned, out of 291 candidates, only 37 objects have more than 100 source counts (the typical lower limit for a meaningful X-ray spectral analysis).

All that being said, our selection procedure has picked up a small sub-population of very peculiar sources with the X-ray spectral index much harder, with sufficient statistical confidence, than canonical spectra of AGN. These sources constitute less than \approx 5% of all extragalactic sources in the Lockman Hole field detected by *SRG/eROSITA*. Their spectra are much shallower than what can be produced by unsaturated Comptonisation of soft photons [\(Sunyaev](#page-11-59) [& Titarchuk](#page-11-59) [1980\)](#page-11-59) believed to be the primary mechanism of the generation of X-ray emission in AGN. The sample of CT AGN candidates constructed in this paper can be a good starting point for future follow-ups and broadband spectral studies.

5.2 Comments on UXCLUMPY **spectral fit results**

In order to place our findings in the context of current understanding of CT AGN, we analysed X-ray spectra using a physically motivated spectral model. To do this, we chose the UXCLUMPY model [\(Buchner](#page-11-43) [et al.](#page-11-43) [2019\)](#page-11-43). We fitted with this model combined *eROSITA* spectra of Category 1 and 2 sources from the bright sample (Section [4.1\)](#page-4-2). For comparison, we also considered a similar number of spectra of a randomly chosen standard (Type I) AGN. We found that the UXCLUMPY model can adequately describe both categories of *eROSITA* sources with consistent values of the underlying power law, $\Gamma \approx 1.9$ (Table [2\)](#page-6-1) and an easily interpretable pattern of CTKcover and TORsigma parameters, describing the covering fraction of the Compton-thick inner ring and the (angular) thickness of the clumpy absorber. We found that while, as expected, no Compton-thick inner ring or absorber is required for the spectra of the "standard" AGN, both Category 1 and 2 sources require a Compton-thick inner ring (Fig. [7\)](#page-6-2). For Category 1 sources, larger covering fraction of the inner ring is needed but with very compact, if any, clumpy absorber outside, while for Category 2 sources the clumpy absorber seems to play a role, with significant angular dispersion of $\approx 30^\circ$. This pattern was confirmed by our analysis of deep *XMM-Newton* exposure of one of our Category 1 sources, Type 2 galaxy SRGe J105348.6+573032/4XMM J105348.7+573033 (srcid 1430), for which we obtained best fit parameters fully consistent with those for *eROSITA* spectra of Category 1 sources.

We obtained surprisingly modest values of the line of sight column density $N_{\rm H}$, never reaching canonical $N_{\rm H} \sim 10^{24}$ cm⁻², expected for CT AGN. The values of line-of-sight N_H are similar for *eROSITA* spectra of Category 1 sources as well as for srcid 1430. The reason for such behaviour is not entirely clear. A possible explanation may be that spectral fits reported here are handicapped by the lack of X-ray data above ∼ 5 − 10 keV (recall that the *eROSITA* response falls sharply above \sim 2.3 keV). Indeed, it is is well known, that broadband spectral modelling, including the hard X-ray band, is critical for analysing spectra of highly absorbed and Compton-thick AGNs [\(Arévalo et al.](#page-11-42) [2014;](#page-11-42) [Padovani et al.](#page-11-37) [2017;](#page-11-37) [Buchner et al.](#page-11-43) [2019,](#page-11-43) [2021\)](#page-11-38).

Alternatively, our selection algorithm might have picked up a peculiar subclass of CT AGN. UXCLUMPY spectral fit results, taken at the face value, may suggest that in these sources the supermassive black hole is surrounded by a inner ring of Compton-thick clouds with sufficiently large covering fraction, $\geq 0.5 - 0.6$. The clumpy absorber outside the inner ring is, however, quite transparent, $N_{\rm H} \lesssim 10^{23}$ cm⁻². In this, admittedly speculative, picture we are observing a superposition of two components: (i) the direct emission from the vicinity of the supermassive black hole which passed through the inner ring of clouds unaffected and (ii) its emission reflected from the Comptonthick inner ring. Contribution of the reflected component (ii) explains shallow spectra of these sources, which can not be produced via unsaturated Comptonization, while contribution of the component (i) dilutes reflected emission and explains relative weakness of the fluorescent line of iron, observed in srcid 1430. In order to make further progress in uncovering the true origin of these sources, high quality broad band data is needed.

5.3 Comments on the possible follow-up strategies

The catalogue of potential CT AGN candidates consists of 291 X-ray sources. Although we divided sources into three categories, in principle, any source in the catalogue may be a true CT AGN.

However, we classified Category 2 sources as possibly mildly obscured AGN due to the detection of statistically significant intrinsic absorption and "normal" AGN-like slopes (albeit with large uncertainties) of their spectra. Therefore, potential X-ray follow-up should prioritise Category 1 sources, which *eROSITA* spectra match best the expectations for CT AGN. Since a relatively detailed spectrum is needed to establish CT nature (e.g. to resolve Iron lines, absorption edges and the Compton hump), it would make sense to observe the brightest targets first. Out of 81 sources from Category 1, 9 have more than 100 source counts (see Table [A1\)](#page-13-0).

Of these 9 sources, 5 have publicly available optical spectroscopic classification (SDSS and 2MASS). Interestingly, according to available data, only one of these sources is classified as Type 2 AGN – srcid 1430 which *XMM-Newton* spectrum was analysed in Section [4.3](#page-6-3) and also discussed above. The remaining 4 sources (srcids 297, 316, 671, 711) were classified as Type 1 objects, despite the fact that they have X-ray spectral characteristics similar to srcid 1430 and different from Type 1 AGN from Category 2. Such a discrepancy between optical classification and X-ray spectral properties of AGN has been known before. For example, [Guainazzi et al.](#page-11-83) [2004](#page-11-83) described the case of Mkn 668 which features a reflection-dominated CT X-ray spectrum and yet is classified as Type 1 AGN based on the presence of broad Balmer lines in its optical spectrum. They proposed several explanations for such a behaviour, including uncorrelated variability between the two bands, the possibility that young post-merger AGNs may have more compact molecular torii which do not effectively cover the direct view of the broad line region, and a few other possibilities.

This may open another venue for the follow up in the optical band – to explore spectroscopic classification of these sources further, verifying existing automated classification and making new observations when needed. We note however, that the ultimate marker for the CT nature of these objects would be follow-up X-ray observations covering hard X-ray band, above ∼ 10 keV. Finally, we note for comparison that among 14 bright Category 2 sources, 7 have spectroscopic classification and all of them are Type 1 AGN except srcid 1413, which is classified as "composite" (containing both AGN activity and star formation) in [Toba et al.](#page-11-84) [2014.](#page-11-84)

Category 3 sources do not have reliable redshift measurements. For these sources, it would make sense to select several brightest sources, e.g. with the 0.5–2 keV flux exceeding 10^{-14} erg s⁻¹ cm⁻². For these sources, one might start with optical spectroscopy to measure their redshifts. This may be followed up with detailed X-ray spectral analysis of *eROSITA* data and/or with deeper X-ray observations. It should also be noted that, although accurate hydrogen column density measurement is not possible without knowledge of the source redshift, a qualitative assessment of the presence (or absence) of the absorption turnover may often be possible, as illustrated in Fig. [5.](#page-5-0)

Finally, we emphasise the critical importance of broadband X-ray

data for any X-ray follow-up of CT AGN candidates (e.g. [Traina et al.](#page-11-85) [2021\)](#page-11-85). An important role will be played by *NuSTAR* [\(Harrison et al.](#page-11-86) [2013\)](#page-11-86) and *SRG/ART-XC* [\(Pavlinsky et al.](#page-11-87) [2021\)](#page-11-87) telescopes. Their data will need to be combined with preferably quasi-contemporaneous observations in the standard X-ray band with *XMM-Newton* [\(Jansen](#page-11-88) [et al.](#page-11-88) [2001\)](#page-11-88) and/or *Chandra* [\(Weisskopf et al.](#page-11-89) [2000\)](#page-11-89) telescopes.

5.4 Density of reflection dominated CT AGN

Based on our results, we can estimate the sky density of reflectiondominated CT AGN candidates. Given the area of the Lockman Hole region analysed in this paper, our estimates are not very constraining. However, they may be useful in the context of further studies.

Let us assume that sources with spectra softer than the threshold used to select CT AGN candidates ($\Gamma - \Gamma_{\text{err}} > \Gamma_0$, where $\Gamma_0 = 1.3$ is a threshold value from Section [3.2](#page-2-0) and Γ_{err} is the 90% statistical uncertainty on the photon index Γ) are unlikely to be reflectiondominated CT AGN (non-CT hereafter). This way, the upper limit on the fraction f of reflection-dominated CT AGN in LH will be defined as $(N_{\text{all}} - N_{\text{non-CT}})/N_{\text{all}}$, where N_{all} – all extragalactic point-like sources in Lockman Hole.

The lower limit on the fraction f of reflection-dominated CT AGN in LH is defined as the number of candidates from Category 1, reflection-dominated CT AGN candidates (N_{CT}) , divided by N_{all} .

To estimate the sky density of reflection-dominated CT AGN, we divided the corresponding source numbers by the sky area. The sensitivity map was considered when applying flux thresholds in counting sources. Although the sensitivity is mostly uniform throughout the entire $\approx 29 \text{ deg}^2$ Lockman Hole field, it becomes lower at the field edges. The sensitivity map was produced using the eSASS ersensmap task with the detection likelihood threshold parameter likemin set at 10 (the same value was used to produce the Lockman Hole catalogue).

Table [3](#page-10-0) shows the lower and upper limit of reflection-dominated CT AGN number N_{CT} , sky density ρ (deg⁻²) and their fraction f (in per cent) for the limiting flux 1.5×10^{-14} erg s⁻¹ cm⁻². This flux limit approximately corresponds to the typical sensitivity achieved by *eROSITA* after 4 all-sky surveys. For the Lockman Hole survey, it approximately corresponds to 100 source counts. With this flux limit, the area of the survey is 28.65 deg, $N_{\text{all}} = 1173$ and $N_{\text{non-CT}} = 862$. The lower limit on the sky density is 0.35 deg^{-2} which is consistent with predictions made for a similar limiting flux 10^{-14} erg s⁻¹ cm⁻² in [Akylas et al.](#page-11-90) [2012](#page-11-90) (0.2 – 0.9 deg⁻²). We should note that the latter includes all kinds of CT AGN, not only reflection-dominated sources.

[Ananna et al.](#page-11-7) [2019](#page-11-7) obtained luminosity function of absorbed AGN for intrinsic column densities as high as 10^{26} cm⁻². We use their results to make an independent estimate of the expected numbers of CT AGN with $N_{\rm H} > 10^{25}$ cm⁻². To this end we use the Compton-thick ($N_{\rm H} > 10^{24}$ cm⁻²) number counts from their Fig. 15 to estimate sky density of CT sources for the limiting flux of 1.5×10^{-14} erg s⁻¹ cm⁻² in the energy range of 0.3 – 2.3 keV. In order to convert 2−7 keV flux from their plot to our range of interest, 0.3−2.3 keV, we used the best fit UXCLUMPY model to the Category 1 spectra (Table [2\)](#page-6-1). We also used the assumption from [Ananna et al.](#page-11-7) [\(2019\)](#page-11-7) that the sky density of CT AGN in $log N_H$ between 24 – 25 and $25 - 26$ is equal.

We computed the sky density of CT AGNs with $N_{\rm H} > 10^{25}$ cm⁻² and obtained the values of $0.37 - 0.48 \text{ deg}^{-2}$ for the limiting flux of 1.5×10^{-14} erg s⁻¹ cm⁻² in the 0.3 – 2.3 keV energy range. This estimation a) is in good agreement with the lower limit from our mea-surement, Table [3](#page-10-0) and b) it is much higher than some of the estimates obtained in previous works on the topic (e.g. [Aird et al.](#page-11-91) [2015;](#page-11-91) [Ueda](#page-11-5)

limit	$N_{\rm CT}$	ρ	$f(\%)$
lower	10	0.35	0.85 ± 0.27
upper	311		10.86 26.51 ± 1.29

Table 3. Lower and upper limit estimations of CT AGN number, sky density (ρ, deg^{-2}) and fraction (f) in per cent with the standard error. The limiting flux is 1.5×10^{-14} erg s⁻¹ cm⁻². The errors have been calculated for a binomial distribution.

[et al.](#page-11-5) [2014\)](#page-11-5). We note that the advantage of X-ray luminoisty function from [Ananna et al.](#page-11-7) [2019,](#page-11-7) which adds confidence in this number, is that it correctly predicts *Chandra* COSMOS-Legacy Compton-thick number counts, see their Fig. 15 on which our estimate is also based. On the other hand, the inaccuracy of this estimate may come from the assumption of equal sky densities of CT AGN between $\log N_H$ 24−25 and 25−26. However, this (or similar) assumption is difficult to avoid at present as there are no or little reliable data for objects with $N_{\rm H} > 10^{25}$ cm⁻².

6 CONCLUSION

In this paper, we performed a search for reflection-dominated Compton-thick Active Galactic Nuclei candidates in the Lockman Hole region using the X-ray data from *SRG/eROSITA* telescope. Our search is based on the X-ray spectral indices of extragalactic sources detected by *eROSITA* in this field. More specifically, we required that the upper end of the error interval for the photon index at the 90% confidence did not exceed the fiducial value of $\Gamma_0 = 1.3$. Such shallow spectra are untypical for normal type I AGN and may indicate the dominance of the emission reflected from the molecular torus.

We find 291 sources with such a hard photon index. They represent a very small sub-population of extragalactic X-ray sources detected by *eROSITA* in this region, about \approx 5%. Of those 291 sources, 81 have no evidence of intrinsic absorption, 49 have intrinsic absorption and are likely moderately obscured AGNs, and 161 sources have no reliable redshift to perform the intrinsic absorption analysis. These sources form three categories which may contain bona fide CT AGNs with reflection-dominated spectra.

We present two catalogues, the bright subsample (with source counts higher than 100, 37 sources), and the faint one (254 sources). We list their X-ray properties and estimate their fraction (among all sources) and sky density. We show examples of individual spectra and use stacking analysis to search for possible evolution of their properties with redshift.

In order to interpret our findings in the framework of physically motivated models, we fit grouped *eROSITA* spectra of sources in the bright sample with UXCLUMPY model [\(Buchner et al.](#page-11-43) [2019\)](#page-11-43) and found that Category 1 and 2 sources occupy distinct regions in the parameter space of this model. Using terminology of the UXCLUMPY model, Category 1 sources require larger solid angle subtended by the Comptonthick inner screen and much more compact clumpy absorber than Category 2 sources. This trend is also confirmed by our analysis of the ultra deep (∼ 1 Msec) data on one of our Category 1 sources, Type 2 galaxy SRGe J105348.6+573032/4XMM J105348.7+573033 (srcid 1430). Its best fit and error region for TORsigma and CTKcover parameters of the model are fully consistent with those for the Category 1 *eROSITA* sources. However, our spectral fits yielded surprisingly moderate values the line-of-sight $N_{\rm H}$ values,

never reaching $N_H \sim 10^{24}$ cm⁻² typically expected for CT AGN. We tentatively proposed a plausible interpretation of this result.

We discuss the limitations of the analysis due to the low number of counts and the implications of our inability to apply sophisticated models for spectral fitting. The catalogues of reflection-dominated CT AGN candidates can be used for planning future studies and follow-ups, and possible strategies are discussed.

Further observations of the selected sources from our catalogue of reflection-dominated CT AGN candidates with higher sensitivity in the hard X-ray band, first of all using *NuSTAR* and *SRG/ART-XC* telescopes, will permit the search for fluorescent iron line and Compton reflection continuum, establishing or refuting the highly obscured nature of the sources from our catalogue.

The Lockman Hole region presents a good opportunity for studies of obscured AGNs. It has extensive multiwavelength coverage advantageous for more effective identification of obscured sources, very low interstellar absorption for studying their soft X-ray properties, and a large enough area to discover rare objects. The extension of the method to the *eROSITA* all-sky survey is expected to produce many more CT AGNs candidates. The refinement of the method with the all-sky data and subsequent follow-up will allow for an increase in the purity and completeness of candidate selection.

ACKNOWLEDGEMENTS

This work is based on observations with *eROSITA* telescope onboard SRG observatory. The SRG observatory was built by Roskosmos in the interests of the Russian Academy of Sciences represented by its Space Research Institute (IKI) in the framework of the Russian Federal Space Program, with the participation of the Deutsches Zentrum für Luft- und Raumfahrt (DLR). The *SRG/eROSITA* X-ray telescope was built by a consortium of German Institutes led by MPE, and supported by DLR. The SRG spacecraft was designed, built, launched and is operated by the Lavochkin Association and its subcontractors. The science data are downlinked via the Deep Space Network Antennae in Bear Lakes, Ussurijsk, and Baykonur, funded by Roskosmos. The *eROSITA* data used in this work were processed using the eSASS software system developed by the German *eROSITA* consortium and proprietary data reduction and analysis software developed by the Russian *eROSITA* Consortium. This work was supported by the Ministry of Science and Higher Education grant 075-15-2024-647.

This work used the data obtained with *XMM-Newton*, an ESA science mission with instruments and contributions directly funded by ESA Member States and NASA.

The following software was used: xspec, [\(Arnaud](#page-11-52) [1996\)](#page-11-52), NumPy [\(Harris et al.](#page-11-92) [2020\)](#page-11-92), Matplotlib [\(Hunter](#page-11-93) [2007\)](#page-11-93), SciPy [\(Virtanen et al.](#page-11-94) [2020\)](#page-11-94), pandas [\(Wes McKinney](#page-12-1) [2010\)](#page-12-1), AstroPy [\(Astropy Collabora](#page-11-95)[tion et al.](#page-11-95) [2018\)](#page-11-95).

The authors would like to thank the anonymous referee for insightful and constructive comments which helped to improve the paper.

DATA AVAILABILITY

The catalogues presented in this article are available as online supplementary material. *SRG/eROSITA* data on the sources published in this paper can be made available upon a reasonable request. The catalogue of reflection-dominated Compton-thick AGN candidates

presented here will be made publicly available via the Vizie R^3 R^3 system after the publication of this work.

APPENDIX A: THE BRIGHT SOURCE CATALOGUE

Table [A1](#page-13-0) shows the bright subsample (see Sect. [3.3\)](#page-3-0), sorted in decreasing X-ray flux order (within each category). Only a subset of columns is shown. The full catalogue is available in the supplementary materials and via [VizieR,](https://vizier.cds.unistra.fr/viz-bin/VizieR) as well as a separate catalogue for the faint sample. The excerpt of the latter is shown in Table [A1.](#page-15-0)

A1 Catalogue discription

Both the bright and the faint source catalogues of *SRG/eROSITA* reflection-dominated Compton-thick AGN candidates in the Lockman Hole will be available via the VizieR web service and in supplementary materials. The bright source catalogue contains 37 rows, the faint one – 254. Both contain 23 columns. The columns include the source index, name and coordinates of both the *SRG/eROSITA* sources and their optical candidates taken from [Bykov et al.](#page-11-48) [\(2022\)](#page-11-48). Each candidate has a category assigned in Sect. [3.2,](#page-2-0) description of these categories is given in Table [1.](#page-3-2) Parameters and errors are provided for two models, phabs*powerlaw and phabs*zphabs*zpowerlw. Errors are quoted at the 90 per cent confidence level. X-ray characteristics include 0.5-2.0 keV flux with 1-sigma error and source counts. Spectroscopic redshifts for some optical counterparts were obtained in [Belvedersky et al.](#page-11-49) [\(2022\)](#page-11-49). Photometric redshifts were derived using the SRGz system [\(Meshch](#page-11-50)[eryakov et al.](#page-11-50) [2023\)](#page-11-50).

Table A1: SRG/eROSITA CT AGN candidates in Lockman Hole, bright sample. (1) – source ID from the eROSITA Lockman Hole catalogue, (2) – eROSITA source name, (3) – candidate's category, (4) – photon index derived from the p X-ray and optical coordinates of the source in degrees, $(11) - X$ -ray flux in erg s⁻¹ cm⁻² for 0.5-2.0 keV range, (12) – redshift (spec-z or photo-z). A full table with additional columns is available in the supplementary materials.

Table A2: *SRG/eROSITA* CT AGN candidates in Lockman Hole, faint source catalog. Columns are the same as in Table [A1.](#page-13-1) The full table is available in supplementary materials.

This paper has been typeset from a TEX/LATEX file prepared by the author.
