Monoclinic nonlinear metasurfaces for resonant engineering of polarization states

Abstract: Polarization is a fundamental property of light that can be engineered and controlled efficiently with optical metasurfaces. Here, we employ *chiral* metasurfaces with monoclinic lattice geometry and achiral meta-atoms for resonant engineering of polarization states of light. We demonstrate, both theoretically and experimentally, that a monoclinic metasurface can convert linearly polarized light into elliptically polarized light not only in the linear regime but also in the nonlinear regime with the resonant generation of the third-harmonic field. We reveal that the ellipticity of the fundamental and higher-harmonic fields depends critically on the angle of the input linear polarization, and the effective chiral response of a monoclinic lattice plays a significant role in the polarization conversion.

Keywords: chiral metasurface; third-harmonic generation, nonlinear resonant metaphotonics.

1 Introduction

Among many remarkable achievements associated with the name Federico Capasso, metasurfaces play an im-

portant role as efficient planar components of future photonic devices [\[1\]](#page-6-0)–[\[3\]](#page-6-1). One of the fundamental functionalities of metasurfaces is the control of polarization of light, which is a versatile degree of freedom that can be manipulated or engineered for numerous applications [\[4\]](#page-6-2), [\[5\]](#page-6-3). Conventional approaches to manipulating polarization often rely on bulk components such as wave plates. Although effective, these components are constrained by their size.

Metasurfaces, composed of subwavelength structures, that is, meta-atoms, are powerful tools for overcoming size and weight limitations, allowing ultra-thin and multifunctional optical devices [\[6\]](#page-6-4)–[\[8\]](#page-6-5). The operational principle for using metasurfaces in the control of polarization relies on transforming an incident wave-

form into an ensemble of individual beams generated by meta-atoms with different polarization states that beat along the optical axis, thereby changing the resulting polarization at will. Many recent papers have been devoted to the study of linear polarization conversion with single metasurfaces (see, e.g, Refs. [\[9\]](#page-6-6)–[\[13\]](#page-6-7)), as well as multiple metasurfaces with stacking and twisted configurations [\[14\]](#page-6-8), [\[15\]](#page-6-9). Polarization transformations with metasurfaces have been extensively explored by the Federico Capasso group [\[16\]](#page-6-10)–[\[18\]](#page-6-11). In particular, the designer-specified polarization response was shown to be employed for computer-generated holograms whose far-fields implement parallel polarization analysis and customized waveplates [\[18\]](#page-6-11).

Chiral metasurfaces are particularly suitable for polarization engineering because of their inherit ability to mix polarization states, e.g. to convert directly linearly polarized light into elliptically or circularly polarized states. The use of resonant effects in metasurfaces has been demonstrated to enhance polarization conversion efficiencies and enable functionalities such as circularly polarized lasing and high-contrast polarization detection [\[19\]](#page-6-12), [\[20\]](#page-6-13).

In this work, we uncover the hidden potential of resonant chiral monoclinic metasurfaces, recently introduced and characterized in Ref. [\[21\]](#page-6-14), for polarization conversion of linearly polarized light, and we also expand this concept to the nonlinear polarization conversion for the generation of third-harmonic chiral fields (Fig. [1\)](#page-0-0). Using both computational and experimental approaches, we demonstrate their ability to convert linearly polarized light into elliptically polarized light in both the linear and nonlinear regimes. Specifically, we explore the third harmonic generation (THG) process and show that the ellipticity of the generated light is strongly dependent on the input polarization angle. By analyzing the role of chiral resonances, we underpin the underlying mechanisms that govern these effects, highlighting the versatility of monoclinic metasurfaces as compact polarization engineering platforms. This builds on previous work exploring multifunctional metasurfaces for polarization conversion and control [\[22\]](#page-6-15), [\[23\]](#page-6-16).

2 Results

The object of our research is a chiral resonant dielectric metasurface, which consists of Si cylinders in a monoclinic arrangement on a Si2O substrate. Such meta-

Fig. 2: Poincarè sphere and illustration of the polarization states.

surface is geometrically chiral, i.e. it does not possess any mirror symmetry: the up-down mirror symmetry is broken by the substrate, and all in-plane mirror symmetries are broken by the monoclinic arrangement itself. Circular dichroism studies of such metasurface can be found in Ref. [\[21\]](#page-6-14).

Realization of a polarization transformation can be conveniently visualized on the unit Poincaré sphere [\[5\]](#page-6-3), [\[24\]](#page-7-0) via the following three parameters:

$$
\tau = |e_x|^2 - |e_y|^2 = \frac{I_V - I_H}{I_V + I_H}
$$

\n
$$
\chi = 2 \operatorname{Re} (e_x^* e_y) = \frac{I_D - I_A}{I_D + I_A}
$$

\n
$$
\sigma = 2 \operatorname{Im} (e_x^* e_y) = \frac{I_L - I_R}{I_L + I_R}.
$$
\n(1)

These parameters show the degrees of the vertical/horizontal (τ) , diagonal/anti-diagonal (χ) , and right-hand/left-hand circular polarizations (σ) , see Fig. [2.](#page-1-0) Here, the complex components of the electric field e_x and e_y are normalized so that $|e_x|^2 + |e_y|^2 = 1$. In the far-field plane the field is transverse, i.e. $e_z = 0$. Experimentally, Stokes parameters are calculated by performing six different intensity measurements: vertical and horizontal $I_{V/H}$, diagonal and anti-diagonal $I_{\text{D/A}}$, polarized on the right and left circular $I_{\text{R/L}}$. The normalized Stokes parameters satisfy $\tau^2 + \chi^2 + \sigma^2 \leq 1$, where " \lt " is achieved for the partially or fully unpolarized signal.

The metasurface exhibits resonant behavior. The design parameters are as follows: the meta-atoms are cylinders with a height of 400 nm and a radius of 430 nm, composed of silicon (Si); the monoclinic arrangement is defined by two lattice vectors with lengths $a = 1100$ nm and $b = 1000$ nm, and a lattice angle of [1](#page-0-0)05° (Fig. 1a); the substrate is made of $SiO₂$. We find several eigenmodes of the systems in the vicinity of

Fig. 3: Linear chiral optical properties. a . b . Theoretical (c) and experimental (d) degree of circular polarization σ dependence on input polarization angle and wavelength. Output theoretical (e) and experimental (f) polarization state (red dots) for various input linear polarization angles (blue dots) plotted on the Poincare sphere.

the wavelength telecommunication range. In particular, there is an eigenmode with a resonant wavelength of 1553 nm and Q-factor of $Q \approx 100$. We show its electric field distribution in Fig. [3](#page-2-0)a. Geometrically chiral metasurface supports chiral eigenmodes, however, their high level of chirality — selective interaction with right and left circularly polarized output channels — is not guaranteed, and it has to be engineered [\[21\]](#page-6-14), [\[25\]](#page-7-1)–[\[27\]](#page-7-2). It was shown in Ref. [\[21\]](#page-6-14) that the eigenmode shown in Fig. [3](#page-2-0)a exhibits strong chiral properties, which manifests in a strong circular dichroism.

Helicity density is a local property of the electromagnetic field distribution which is also relevant in the context of chiral metasurfaces, e.g. in chiral sens-ing [\[28\]](#page-7-3), [\[29\]](#page-7-4). For monochromatic field at frequency ω it is written as [\[30\]](#page-7-5)–[\[32\]](#page-7-6)

$$
\mathfrak{S} = \frac{1}{2\omega c} \operatorname{Im} \left(\mathbf{H}^* \cdot \mathbf{E} \right),\tag{2}
$$

where E and H are the electric and magnetic fields, c is the speed of sound. The quantity [\(2\)](#page-2-1) characterizes the difference between the numbers of right-hand and lefthand circularly polarized photons. We plot the distribution of helicity density of the eigenmode in Fig. [3](#page-2-0)b.

Next, we study the polarization transformation of such metasurface for the linearly polarized input light in the linear and nonlinear regime, i.e. polarization state of the third harmonic generation signal.

2.1 Polarization transformation in linear transmission

Here we examine the manifestation of the chiral mode of choice in the context of polarization transformation for the linearly polarized input. We set the input field to be a monochromatic linearly polarized plane wave at frequency ω and wavevector $\mathbf{k} = -\hat{\mathbf{z}}k$ (we assume a $e^{-i\omega t}$ time dependence):

$$
\mathbf{E}_{\rm in}^{(\omega)} = E_0 \left(\hat{\mathbf{x}} \cos \varphi + \hat{\mathbf{y}} \sin \varphi \right) e^{-ikz}, \tag{3}
$$

where angle φ shows linear polarizaiton orientation with respect to the x-axis, $\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, $\hat{\mathbf{z}}$ are the Cartesian unit vectors. Based on Eq. [\(1\)](#page-1-1), this implies the input Stokes parameters to be

$$
\tau_{\rm in} = \cos(2\varphi), \quad \chi_{\rm in} = \sin(2\varphi), \quad \sigma_{\rm in} = 0. \tag{4}
$$

We incrementally change polarization angle φ in the range $[0, \pi]$ with a constant step $\Delta \varphi$, as the results are π -periodic.

Adjusting the polarization angle φ and the wavelength λ of the incident wave, we examine the polarization of the outgoing signal (Fig. [3](#page-2-0)c). Near the chiral resonance, circular polarization degree σ is strongly dependent on λ and φ . At certain λ and φ , the transmitted field approaches circular polarization, $|\sigma| \approx 1$. Although the input polarization states [\(4\)](#page-2-2) are evenly spaced, the output states are not. This is illustrated on the Poincarè sphere in Fig. [3](#page-2-0)e. In particular, the output states form a circle on the sphere, indicated by red dots.

Fig. 4: Nonlinear theory. a Third harmonic intensity output from a linearly polarised beam along x -axis. c The green and magenta lines are the intensity of the right and left circular polarization intensities of the third harmonic signal, respectively. **b** Poincarè spheres which show simulated polarization states of the third harmonic output taken at different wavelengths for linear polarization input at different angles on the fundamental frequency.

To validate our theoretical prediction regarding the polarization change, we measure all Stokes parameters of light transmitted through the metasurface taking into account Eq. [\(1\)](#page-1-1) (see the Methods section for experimental details). The experimentally determined values of σ , as a function of the wavelength and the input polarization angle, are presented in Fig. [3](#page-2-0)c. The output light exhibits elliptical polarization around the optical resonance. The behavior observed qualitatively agrees with theoretical protection. However, the degree of circular polarization varies from −0.30 to 0.31 at 1572 nm. The out polarization state is illustrated in Fig. [3](#page-2-0)f by red dots, while the input polarization state is also depicted by blue dots. The experimental pattern is similar to the theoretical prediction. The difference between theoretical and experimental results is primarily attributed to the fabrication imperfection and the broad range of incident light wave vectors in the experiment.

2.2 Polarization engineering of the third harmonic generation

At higher intensities, the electron oscillations within a dielectric structure become anharmonic, which can be effectively described using the extended Lorentz model [\[33\]](#page-7-7). Silicon, being a centrosymmetric material in its bulk crystalline form, exhibits a symmetric electron potential, allowing only odd harmonic generation. Consequently, the second harmonic generation is symmetry-forbidden in bulk silicon, with the sole exception of surface effects [\[34\]](#page-7-8). However, at sufficiently high intensities, THG becomes significant. The nonlinear polarization current responsible for THG can be expressed as $\mathbf{P}^{(3\omega)} = \varepsilon_0 \hat{\chi}^{(3)} \mathbf{E}^{(\omega)} \mathbf{E}^{(\omega)} \mathbf{E}^{(\omega)}$, where ε_0 is the dielectric constant, $\mathbf{E}^{(\omega)}$ is the electric field at the fundamental frequency, and $\hat{\chi}^{(3)}$ is the fourth-rank nonlinear susceptibility tensor. Silicon has space group $m3m$, which results in only 21 nonzero elements in $\hat{\chi}^{(3)}$ with only 4 independent [\[33\]](#page-7-7). For simplicity, we assume all non-zero components to be equal. To model THG, we employ the undepleted pump approximation and simulate the process in COMSOL Multiphysics using a two-step approach. In this framework, the nonlinear polarization $\mathbf{P}^{(3\omega)}$ is used as the initial condition for solving the higher harmonic wave equations.

The coupling strength of the incident field to the resonant mode strongly depends on the overlap integral between the two [\[21\]](#page-6-14), [\[25\]](#page-7-1), [\[27\]](#page-7-2), [\[35\]](#page-7-9). This coupling shows a strong polarization dependence, providing different field distribution at the fundamental frequency $\mathbf{E}^{(\omega)}$ for different input polarizations, and hence different $\mathbf{P}^{(3\omega)}$ and third harmonic response.

We evaluate the nonlinear numerical results by calculating the THG for a linearly polarized pump and

Fig. 5: Experimental nonlinear polarization properties. THG intensity (a) and degree of circular polarization (b) from the metasurface as a function of the pump wavelength and polarization angle. c Poincarè spheres illustrating polarization states of the output THG at 1510 nm and 1635 nm wavelengths for linear polarized input, varying linear polarization angle at the fundamental harmonic.

decomposing THG transmission signal into the rightand left-circular polarized components, $I_{\rm R}^{(3\omega)}$ $I_{\rm R}^{(3\omega)}$ and $I_{\rm L}^{(3\omega)}$ L (Fig. [4](#page-3-0)a). The wavelength-dependent THG intensities for right and left circular polarized components are shown in Fig. [4](#page-3-0)c by the green and magenta lines, respectively. The results exhibit a pronounced resonant behavior revealing significant enhancement of the THG at the vicinity of the structure resonances. Remarkably, for the first resonance (1555 nm) the right-circular polarized component dominates, while for the second resonance (1634 nm) the left-circular polarized component becomes dominant. Next, we investigate the effect of varying the polarization angle of the pump at specific wavelengths and extract all polarization parameters for the THG. The simulated polarization states are represented on the Poincarè spheres in Fig. [4](#page-3-0)b. Near the chiral resonances, the polarization trajectories for pump wavelengths of 1555 nm and 1634 nm exhibit high degrees of circular polarization, with $|\sigma|$ values approaching 1. This behavior indicates the generation of highly circularly polarized THG near these resonances. Unlike the linear case, the polarization points do not lie within a single plane and lack a clear pattern. This complexity likely arises from the interplay between polarization states on the fundamental frequency and the THG, rather than just one effect as in the linear case. In contrast, for the wavelength away from the resonances (1590 nm) the output polarization closely resembles the input polarization indicating minimal modification.

For validation of our theoretical simulations, we measure the THG from the metasurface (see the Methods section for more details). The laser wavelength was

tuned from 1500–1730 nm at 5 nm intervals, while the polarization angle was varied from 0° to 180° with 10°. For each combination of these parameters, we record the THG spectra and extract the maximum values. Fig. [5](#page-4-0)a shows the maximum THG value as a function of the pump wavelength and input polarization angle. As expected, the THG enhancements are observed close to the resonances identified from the theory. To investigate the degree of circular polarization σ we extract this parameter from the THG data taking into account Eq. (1) — the dependence on the pump wavelength and input polarization angle is shown in Fig. [5](#page-4-0)b. The results reveal complex dependencies with significant changes in the polarization state as the pump polarization angle. We further extract the polarization parameters for the resonant wavelengths 1510 nm and 1635 nm. These values are plotted on Poincarè spheres, showing σ ranges of -0.73 to 0.71 at the wavelength of 163[5](#page-4-0) nm and -0.74 to 0.70 at 1510 nm (Fig. 5c). Likewise the theoretical results, these points do not lie in a single plane as we would expect from the experimental results, and reach higher values for circular polarization than those in the linear regime. The deviation between the experimental and theoretical results is attributed to the same factors as in the linear case. Additionally, the THG exhibits greater sensitivity to all possible imperfections and pump parameters compared to the linear regime. Considering the impact of the modes at the THG wavelength, it is challenging to fully replicate the simulated result in a real finite sample.

3 Conclusions

We have studied the effect of resonances on the polarization conversion in chiral dielectric metasurfaces, for both linear and nonlinear regimes. We have demonstrated that metasurfaces composed of a monoclinic lattice of achiral meta-atoms possess a chiral response that can be employed for active polarization engineering. We have verified that such an intrinsic chirality of the metasurface can transform input linearly polarized light into elliptically polarized light, and we have demonstrated that this effect can be used to control the polarization of the generated third harmonic field. We believe that our results provide the first step in exploring polarization transformations in the nonlinear regime for resonant chiral metasurfaces, and they lay the foundation for future work to optimize such phenomena for applications in chiral sensing, chirality encoding, and chiral imaging.

4 Methods

4.1 Sample fabrication

The silicon metasurface was fabricated with a combined process of electron-beam (E-beam) evaporation, E-beam lithography and inductive coupled plasma (ICP) etching. Basically, 400 nm silicon film was deposited by E-beam evaporation, and then covered with 26 nm Cr layer and 80 nm E-beam resist (PMMA A2). The nanostructures designed in PMMA are patterned via an E-beam aligner (Raith E-line, 30 kV) and developed in MIBK: IPA for 60 s. Taking the PMMA as a mask, the Cr layer was etched with O_2 and Cl_2 (Gas flow of O_2 is 12.5 sccm, gas flow of Cl_2 is 37.5 sccm, pressure is 12 mTorr) in ICP. The Si metasurface was achieved by further etching the Si layer with a mixture of SF_6 and C_4F_8 (Gas flow of SF_6 is 35 sccm, gas flow of C_4F_8 is 40 sccm, pressure is 15 mTorr) in ICP and removing the Cr layer with chromium etchant.

4.2 Optical experiments

For the transmission measurements, a quartz tungstenhalogen lamp was used as the light source. The emitted light passed through a linear polariser mounted on the motorised rotatable stage enabling precise adjustment of the linear polarization angle. Next, the polarised light is focused onto the sample by a CF_2 lens with a focal length of 50 mm. The transmitted signal after passing through the sample was collected by a 20X Mitutoyo Plan Apo NIR objective lens. Then, the light passed through a quarter-wave plate and a linear polariser, both mounted on rotatable stages, enabling the extraction of all polarization parameters through various combinations of orientations. Subsequently, the light collected was coupled into an optical fibre by an aspherical lens with a focal length of 8 mm and delivered to the NIRQuest Ocean Optics spectrometer.

For nonlinear transmission measurement, a laser system comprising a femtosecond laser (Ekspla Femtolux 3) operating at a wavelength of 1030 nm and an optical parametric amplifier (MIROPA Hotlight Systems) was used as THG pump source. The optical parameter amplifier generated tunable NIR radiation in the range of 1500–1700 nm. The laser pulses had a duration of 250 fs, a repetition rate of 5.14 MHz and an average power of 20 mW. The NIR laser radiation was linearly polarised with vertical linear polariser. Next, the polarization was rotated by a half-wave plate mounted on a rotatable stage. The polarised laser beam was focused onto the sample by a $CF₂$ lens with a focal length of 50 mm. The transmitted THG signal was collected after passing through the sample by a 20X Mitutoyo Plan Apo NIR objective lens. Subsequently, the THG signal was directed through a quarter-wave plate and a linear polariser, both mounted on rotatable stages, allowing for the extraction of all polarization parameters by varying their orientations. Finally, the THG signal was coupled into an optical fiber using an aspherical lens with a focal length of 8 nm and delivered to the QE Pro Ocean Optics spectrometer.
