(Dated: January 16, 2025)

In a transition between nonequilibrium steady states, the entropic cost associated with the maintenance of steady-state currents can be distinguished from that arising from the transition itself through the concepts of excess/housekeeping entropy flux and adiabatic/nonadiabatic entropy production. The thermodynamics of this transition is embodied by the Hatano-Sasa relation. In this letter, we show that for a slow transition between quantum nonequilibrium steady states the nonadiabatic entropy production is, to leading order, given by the path action with respect to a Riemannian metric in the parameter space which can be connected to the Kubo-Mori-Bogoliubov quantum Fisher information. We then demonstrate how to obtain minimally dissipative paths by solving the associated geodesic equation and illustrate the procedure with a simple example of a three-level maser. Furthermore, by identifying the quantum Fisher information with respect to time as a metric in state space, we derive an upper bound on the excess entropy flux that holds for arbitrarily fast processes.

Introduction - Nonequilibrium steady states (NESS) are fundamental to the study of systems maintained far from equilibrium, where persistent currents of energy, particles, or entropy flow continuously due to external driving forces or gradients [1]. Unlike equilibrium states, NESS embody dynamic stability, balancing inflows and outflows while breaking detailed balance, making them central to understanding dissipation, irreversibility, and entropy production [2]. These states are of paramount importance in a range of physical settings, from molecular motors [3] and nanoscale heat engines to quantum thermoelectric devices [4] and biological systems [5], where steady-state currents drive functionality.

For quantum systems NESS are also key to understand dissipation and coherence-driven processes in quantum technologies [6, 7]. In condensed matter, they are central to define the phenomenology of quantum transport [8, 9] and the emergence of diffusion [10] and nonequilibrium quantum critical phenomena [11, 12]. Despite this significance, the study of transitions between NESS, a critical process for driving systems under time-dependent protocols, remains under-explored in quantum thermodynamics. While in classical stochastic thermodynamics, transitions between NESS have been extensively studied as encapsulated by the Hatano-Sasa relation [13–19], providing deep insights into irreversibility and dissipation, only a few works have addressed the issue of NESS-to-NESS transitions in the quantum domain [20–23]. By connecting both the excess entropy flux as well as the nonadiabatic entropy production to the geometry of the control parameter space, we provide new tools to quantify and optimize dissipation in quantum transitions.

The geometric perspective on thermodynamics is by now well established, as [24–26] have provided profound

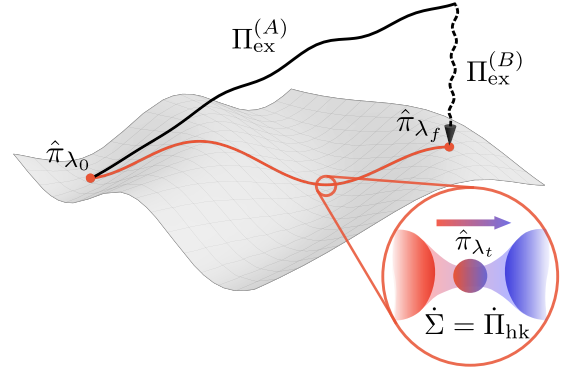

FIG. 1. Schematic of a protocol driving the system between two nonequilibrium steady states. The system is initialized at a NESS $\hat{\pi}_{\lambda_i}$ specified by λ_i . In a quasistatic protocol connecting parameters λ_i and λ_f (orange line), the system remains in the manifold of NESS (grey surface), with $\hat{\pi}_{\lambda_i}$, at all times. A NESS is characterized by the entropy production rate $\dot{\Sigma}$ being balanced by the housekeeping flux rate \dot{I}_{hk} . For the finite-time transition (black line), we divide the “excess” entropy flux into a path dependent Π_{ex}^A and pure relaxation part Π_{ex}^B .

insights into the costs of finite-time processes, with thermodynamic length and metrics offering tools to analyze dissipation and design efficient protocols [27, 28]. This approach has been recently adopted to quantum thermodynamics [29], where it was used for process optimization [30, 31] and to derive thermodynamic bounds [32, 33]. These developments underscore the power of geometric frameworks to unify and generalize thermodynamic principles. Despite this progress, the geometry of transitions between NESS remains largely confined to the classical domain [19]. In this Letter, we extend the geometric framework to analyze NESS-to-NESS transitions in the quantum regime. This approach both builds on and ex-

‡ gooldj@tcd.ie

tends classical results [19], providing a unified quantum framework for understanding and optimizing dissipation in NESS transitions. We show that the leading term of the excess entropy flux is given by the integral of a Riemannian metric along a path plus a boundary term. This boundary term is, as we discuss, precisely the excess flux of a pure relaxation process to the final NESS and the change in von Neumann entropy between initial and final NESS. In addition we provide a completely general upper bound on the excess entropy flux in NESS transitions which is based on recent works that explore the Fisher information with respect to time as applied to classical and quantum dynamics [34–40].

Thermodynamics - We adopt a standard Lindblad master equation formalism where a time-dependent Liouvillian \mathcal{L}_λ is specified by control parameters λ_t and the system evolves according to

$$\dot{\hat{\rho}}_t = \mathcal{L}_\lambda[\hat{\rho}_t]. \quad (1)$$

We assume that, for a fixed λ , the system relaxes to a unique NESS $\hat{\pi}_\lambda$, satisfying $\mathcal{L}_\lambda[\hat{\pi}_\lambda] = 0$. As is often done in phenomenological nonequilibrium thermodynamics [41] we split the entropy production rate $\dot{\Sigma}$ as

$$\frac{dS}{dt} = \dot{\Sigma} - \dot{\Pi}, \quad (2)$$

where S is the von Neumann entropy of the system and $\dot{\Pi}$ is the entropy flux from the environment. For example, when the environment consists of multiple thermal baths at inverse temperature β_α , $\dot{\Pi} = \sum_\alpha \beta_\alpha \langle \hat{J}_\alpha^Q \rangle$, where $\langle \hat{J}_\alpha^Q \rangle$ is the average heat current from bath α .

We adopt the approach of splitting $\dot{\Sigma}$ into adiabatic ($\dot{\Sigma}_{\text{ad}}$) and nonadiabatic ($\dot{\Sigma}_{\text{na}}$) contributions:

$$\dot{\Sigma} = \dot{\Sigma}_{\text{ad}} + \dot{\Sigma}_{\text{na}}, \quad \dot{\Sigma}_{\text{na}} = -\text{Tr} \left[\dot{\hat{\rho}}_t (\log \hat{\rho}_t - \log \hat{\pi}_{\lambda_t}) \right]. \quad (3)$$

Here $\dot{\Sigma}_{\text{na}}$ is nonnegative [20, 42] and is zero only if the system is in the steady state. Importantly, in a pure relaxation process, where $\hat{\pi}_\lambda$ is fixed, it coincides with Spohn's expression for entropy production [42]: $\dot{\Sigma}_{\text{na}} = -\partial_t D(\hat{\rho}_t || \hat{\pi}_\lambda)$, where $D(\cdot || \cdot)$ is the relative entropy, which links it to an interpretation as a free entropy consumption rate [17]. When the system is in a NESS, the only nonzero component is $\dot{\Sigma}_{\text{ad}}$ and is interpreted as the baseline dissipation in the NESS associated with the steady-state current that maintains the state.

For classical Markovian systems, both components can be defined at the level of trajectories, are nonnegative and individually satisfy fluctuation theorems [18]. In quantum systems governed by a Lindblad equation, this is only true if further conditions are imposed on the jump operators, which imply that the steady state commutes with the system Hamiltonian [22, 43]. Nevertheless, even when these conditions are not met, Eq. (3) can still be used at the average level [22], and provides a robust quantifier for the additional dissipation in the process. While historically the first splitting to be proposed was that of

the heat current [13, 14, 16, 17], here we consider the splitting of the entropy flux into *excess* and *housekeeping flux* [3].

The housekeeping entropy flux is equivalent, by construction, to the adiabatic component of the entropy production $\dot{\Pi}_{\text{hk}} = \dot{\Sigma}_{\text{ad}}$ as it is the only nonzero component in the steady state. This term quantifies the entropy supplied by the environment to maintain the NESS. The excess entropy flux is defined to be the difference $\dot{\Pi}_{\text{ex}} = \dot{\Pi} - \dot{\Pi}_{\text{hk}}$, which can be rewritten as (see Appendix A)

$$\dot{\Pi}_{\text{ex}} = \text{Tr} \left[\dot{\hat{\rho}}_t \log \hat{\pi}_{\lambda_t} \right]. \quad (4)$$

Notice that this quantity is zero in the steady state. With these definitions in hand, one can write a generalized Clausius inequality as (see Appendix A)

$$\frac{dS}{dt} + \dot{\Pi}_{\text{ex}} = \dot{\Sigma}_{\text{na}} \geq 0, \quad (5)$$

which is a version of the celebrated Hatano-Sasa theorem [14]. Within this framework, a transition between NESS parallels a transition between equilibrium states, but with $\dot{\Sigma}_{\text{na}}$ playing the role of entropy production and $\dot{\Pi}_{\text{ex}}$ of the entropy flux.

Slow-driving - Now let us consider a protocol in which the system is initially prepared in a NESS $\hat{\pi}_{\lambda_i}$ and the control parameters are slowly varied from λ_i to λ_f over a total time T , followed by a pure relaxation process to a new NESS $\hat{\pi}_{\lambda_f}$. The excess flux of the entire protocol Π_{ex} is the sum of the excess flux accumulated over the parameter path and the pure relaxation process, which we denote by $\Pi_{\text{ex}}^{(A)}$ and $\Pi_{\text{ex}}^{(B)}$, respectively (see Fig. 1). Eq. (4) motivates the introduction of the nonequilibrium potential [14], which is an Hermitian operator defined by

$$\hat{\Phi}_\lambda = -\log \hat{\pi}_\lambda, \quad (6)$$

such that $\dot{\Pi}_{\text{ex}} = \text{Tr} \left[\dot{\hat{\rho}}_t \hat{\Phi}_\lambda \right]$. Notice that $\dot{\Pi}_{\text{ex}}$ is not a complete differential, since $\hat{\pi}_\lambda$ also changes over time. By taking the derivative of $\langle \hat{\Phi}_\lambda \rangle = -\text{Tr}[\hat{\rho}_t \log \hat{\pi}_\lambda]$, we can write

$$\dot{\Pi}_{\text{ex}} = -\frac{d\langle \hat{\Phi}_\lambda \rangle}{dt} - \text{Tr} \left[\dot{\hat{\rho}}_t \frac{d \log \hat{\pi}_\lambda}{dt} \right]. \quad (7)$$

For a pure relaxation protocol, where $\hat{\pi}_\lambda$ is fixed, the second term vanishes. Therefore,

$$\Pi_{\text{ex}}^{(B)} = \text{Tr} \left[(\hat{\pi}_{\lambda_f} - \hat{\rho}_T) \hat{\Phi}_{\lambda_f} \right], \quad (8)$$

which is the difference in expectation value of the nonequilibrium potential computed at $\hat{\rho}_T$ and $\hat{\rho}_{\lambda_f}$.

Let us now focus on $\Pi_{\text{ex}}^{(A)}$. Following [19, 45], we introduce a small parameter ϵ proportional to the driving speed, such that $\epsilon \propto 1/T$. For sufficiently slow driving,

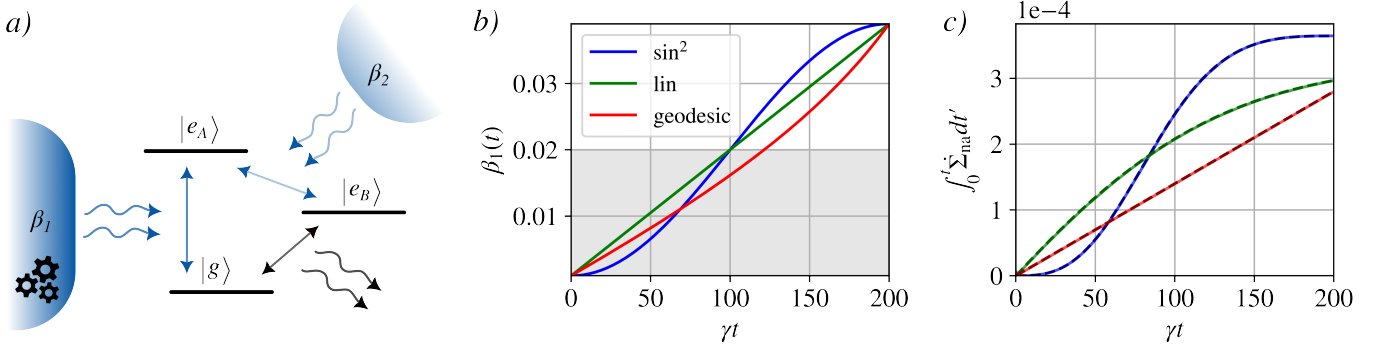

FIG. 2. a) Schematic of the three-level maser operating as a quantum heat engine. The two reservoirs are modeled as thermal light sources with inverse temperatures β_1 and β_2 , respectively. The absorption and emission of photons with frequencies $\omega_1 = \epsilon_A - \epsilon_g$ and $\omega_2 = \epsilon_A - \epsilon_B$ induces transitions between the respective levels. The population inversion, which enables stimulated emission at frequency $\omega_3 = \epsilon_B - \epsilon_g$, which in this set-up is the work output, occurs between the levels $|g\rangle$ and $|e_B\rangle$. When $\omega_2/\omega_1 > \beta_1/\beta_2$ the machine operates as a heat engine (grey shaded in b)), whereas, in the complementary region, it operates as a refrigerator [44]. b) Geodesic protocol for β_1 as well as two ‘naive’ protocols, defined in Appendix F. c) In the slow-driving regime, $\langle \hat{\Phi}_\lambda \rangle \Big|_0^T + \int_0^T \dot{\Pi}_{\text{ex}} dt' \approx \int_0^T \dot{\Sigma}_{\text{na}} dt' = \int_0^T \lambda^T \zeta \dot{\lambda} dt'$. Therefore, the total nonadiabatic entropy production is minimized for the optimal protocol with duration T described by a geodesic connecting β_1^0 and β_1^T in parameter space. The dashed lines represent the slow-driving approximation, while the solid lines are obtained from the exact expression. Parameters: $\gamma_1 = \gamma_2 = \gamma_3 = \gamma$, $\omega_1 = 50\gamma$, $\omega_2 = 10\gamma$, and $\gamma\beta_2 = 0.1$, $\gamma\beta_1^0 = 0.001$ to $\gamma\beta_1^T = 0.039$ and $\gamma T = 200$.

the system will remain close $\hat{\pi}_{\lambda_t}$, up to a small correction. Consider the expansion

$$\hat{\rho}_t = \hat{\pi}_\lambda + \delta\hat{\rho}_t, \quad (9)$$

where $\text{Tr}[\delta\hat{\rho}_t] = 0$, by the preservation of trace. Inserting this expansion into Eq. (1) and using that $\mathcal{L}_\lambda[\hat{\pi}_\lambda] = 0$, we obtain a differential equation for $\delta\hat{\rho}_t$ [19, 29, 45]:

$$\left(\mathcal{L}_\lambda - \frac{d}{dt}\right)[\delta\hat{\rho}_t] = \frac{d\hat{\pi}_\lambda}{dt}. \quad (10)$$

Eq. (10) can be formally solved by the introduction of the Drazin inverse operator [46], which is defined as the unique operator satisfying the properties (i) $\mathcal{L}_\lambda \mathcal{L}_\lambda^+[\hat{A}] = \mathcal{L}_\lambda^+ \mathcal{L}_\lambda[\hat{A}] = \hat{A} - \hat{\pi}_\lambda \text{Tr}[\hat{A}]$, (ii) $\mathcal{L}_\lambda^+[\hat{\pi}_\lambda] = 0$ and (iii) $\text{Tr}[\mathcal{L}_\lambda^+[\hat{A}]] = 0$. It can be shown that the Drazin inverse has an integral representation given by [46]

$$\mathcal{L}_\lambda^+[\hat{A}] := \int_0^\infty d\tau e^{\mathcal{L}_\lambda \tau} \left(\hat{\pi}_\lambda \text{Tr}[\hat{A}] - \hat{A} \right). \quad (11)$$

By applying \mathcal{L}_λ^+ on both sides, we obtain the expansion (see Appendix B for details)

$$\hat{\rho}_t = \hat{\pi}_\lambda + \sum_{n=1}^{\infty} \left(\mathcal{L}_\lambda^+ \frac{d}{dt} \right)^n \hat{\pi}_\lambda. \quad (12)$$

Notice that the n^{th} term in this series contains an n^{th} -order derivative of $\hat{\pi}_\lambda$, and is thus proportional to ϵ^n , which means that Eq. (12) can be seen as an expansion in powers of ϵ .

As an important consistency check, Eq. (12) can be used to obtain an expression for $\dot{\Pi}_{\text{ex}}$ in the quasistatic

limit. In this case, the final state is already a NESS, thus $\Pi_{\text{ex}}^{(B)} = 0$ and $\dot{\Pi}_{\text{ex}} = \dot{\Pi}_{\text{ex}}^{(A)}$. By taking the derivative of Eq. (12) and keeping only terms up to first order in ϵ , we see that $\dot{\hat{\rho}}_t = \dot{\hat{\pi}}_\lambda + \mathcal{O}(\epsilon^2)$. Inserting this result into Eq. (4) we obtain

$$\dot{\Pi}_{\text{ex}} = -\frac{dS}{dt} + \mathcal{O}(\epsilon^2). \quad (13)$$

Here, since $\hat{\rho}_t$ coincides with $\hat{\pi}_{\lambda_t}$, $S(\hat{\pi}_\lambda) = S(\hat{\rho}_t)$. By integrating over the path, we get the generalized Clausius equality $\Delta S + \int_0^T dt \dot{\Pi}_{\text{ex}} \stackrel{\text{qs}}{=} 0$.

To go beyond the quasistatic limit, we insert the expansion (12) into Eq. (7), which results in

$$\dot{\Pi}_{\text{ex}} = -\frac{d\langle \hat{\Phi}_\lambda \rangle}{dt} - \sum_{n=1}^{\infty} \text{Tr} \left[\frac{d \log \hat{\pi}_\lambda}{dt} \left(\mathcal{L}_\lambda^+ \frac{d}{dt} \right)^n \hat{\pi}_\lambda \right], \quad (14)$$

where we used the fact that $\text{Tr} \left[\hat{\pi}_\lambda \frac{d \log \hat{\pi}_\lambda}{dt} \right] = 0$ [20] to start the sum for $n = 1$. By integrating over the protocol and keeping only the leading order term, we obtain

$$\Pi_{\text{ex}}^{(A)} = -\langle \hat{\Phi}_\lambda \rangle \Big|_0^T - \int_0^T dt \text{Tr} \left[\frac{d \log \hat{\pi}_\lambda}{dt} \mathcal{L}_\lambda^+ \frac{d \hat{\pi}_\lambda}{dt} \right] + \mathcal{O}(\epsilon^2), \quad (15)$$

where $\langle \hat{\Phi}_\lambda \rangle \Big|_0^T = \text{Tr}[\hat{\rho}_T \hat{\Phi}_{\lambda_f}] - \text{Tr}[\hat{\pi}_{\lambda_i} \hat{\Phi}_{\lambda_i}]$. In Appendix C, we show that the boundary term can be expressed as

$$\langle \hat{\Phi}_\lambda \rangle \Big|_0^T = -\Delta S(\hat{\pi}_\lambda) + \Pi_{\text{ex}}^{(B)}, \quad (16)$$

where $\Delta S(\hat{\pi}_\lambda) = S(\hat{\rho}_{\lambda_f}) - S(\hat{\rho}_{\lambda_i})$. Notice that this quantity depends only on the endpoints of the protocol.

Therefore, by incorporating the full relaxation process, we can proceed without assuming that the velocity of the protocol is zero at the endpoints, extending the results of [19]. Using the chain rule, we can write

$$\Pi_{\text{ex}} = -\Delta S(\hat{\pi}_\lambda) + \sum_{\mu\nu} \int_0^T dt \dot{\lambda}_\mu \zeta_{\mu\nu} \dot{\lambda}_\nu, \quad (17)$$

where $\zeta_{\mu\nu} = \frac{1}{2}(\xi_{\mu\nu} + \xi_{\nu\mu})$ is the symmetric part of

$$\xi_{\mu\nu} = -\text{Tr} \left[\frac{\partial \log \hat{\pi}_\lambda}{\partial \lambda_\nu} \mathcal{L}_\lambda^\dagger \frac{\partial \hat{\pi}_\lambda}{\partial \lambda_\mu} \right], \quad (18)$$

Furthermore, in Appendix D, we derive the Green-Kubo relation for ξ , showing that

$$\xi_{\mu\nu} = \int_0^\infty d\tau \langle \hat{F}^\mu(0), \hat{F}^\nu(\tau) \rangle_{\hat{\pi}_\lambda}, \quad (19)$$

where $\langle \cdot, \cdot \rangle_{\hat{\pi}_\lambda}$ stands for the Kubo-Mori-Bogoliubov (KMB) inner product [47], defined as $\langle \hat{A}, \hat{B} \rangle_{\hat{\pi}_\lambda} = \int_0^1 ds \text{Tr} [\hat{\pi}_\lambda^s \hat{A}^\dagger \hat{\pi}_\lambda^{1-s} \hat{B}]$ and $\hat{F}^\mu(\tau)$ is the result of a time-evolution in the Heisenberg picture the logarithmic derivative operator, which is defined as $\hat{F}^\mu = \frac{\partial \log \hat{\pi}_\lambda}{\partial \lambda_\mu}$.

Following [19, 28], the friction tensor ζ can be related to the KMB quantum Fisher information matrix (QFI), which is defined as

$$\mathcal{I}_{\mu\nu} = \langle \hat{F}^\mu, \hat{F}^\nu \rangle_{\hat{\pi}_\lambda}, \quad (20)$$

by the introduction of the generalized integral relaxation time

$$\tau_{\mu\nu} = \int_0^\infty d\tau \frac{\langle \hat{F}^\mu, \hat{F}^\nu(\tau) \rangle_{\hat{\pi}_\lambda}}{\langle \hat{F}^\mu, \hat{F}^\nu \rangle_{\hat{\pi}_\lambda}}, \quad (21)$$

which is the characteristic time for \hat{F}^μ and \hat{F}^ν to become uncorrelated [48]. By inspection, we see that $\xi_{\mu\nu} = \tau_{\mu\nu} \mathcal{I}_{\mu\nu}$, therefore

$$\zeta_{\mu\nu} = \frac{1}{2}(\tau_{\mu\nu} \mathcal{I}_{\mu\nu} + \tau_{\nu\mu} \mathcal{I}_{\nu\mu}). \quad (22)$$

In Appendix E, we show that $\zeta(\lambda)$ is a positive semi-definite matrix. Since it is also symmetric by construction, it establishes a Riemannian metric on the space of NESS parameterized by λ .

We emphasize that, while our quantum generalization is analogous to the classical result, its derivation significantly differs from [19] due to the noncommuting nature of the operators. Moreover, we have shown that the friction tensor is related to one particular quantum Fisher information (KMB), which also emerges in the context of transitions between thermal states [29].

In Appendix E, we also show that the action of this metric is connected to nonadiabatic entropy production by

$$\int_0^T dt \sum_{\mu\nu} \dot{\lambda}_\mu \zeta_{\mu\nu} \dot{\lambda}_\nu = \int_0^T dt \dot{\Sigma}_{\text{na}} + \mathcal{O}(\epsilon^2), \quad (23)$$

By the Cauchy-Schwarz inequality, this implies that the geometric action is bounded from below by the square of the path length, $l = \int_0^T dt \sqrt{\sum_{\mu\nu} \dot{\lambda}_\mu \zeta_{\mu\nu} \dot{\lambda}_\nu}$, divided by the protocol duration T , so that, $\Sigma_{\text{na}} \geq l^2/T$. Importantly, equality holds only for a geodesic. This motivates seeking such minimal-length paths, which in the slow-driving regime, correspond to minimally dissipative protocols. **Geodesics and optimal protocols** - The geodesic path is the solution to the geodesic equation

$$\frac{d^2 \lambda^\alpha}{dt^2} + \Gamma_{\beta\gamma}^\alpha \frac{d\lambda^\beta}{dt} \frac{d\lambda^\gamma}{dt} = 0 \quad (24)$$

where the Christoffel symbols

$$\Gamma_{\beta\gamma}^\alpha = \frac{1}{2} \zeta^{\alpha\delta} \left(\frac{d\zeta_{\gamma\delta}}{d\lambda_\beta} + \frac{d\zeta_{\beta\delta}}{d\lambda_\gamma} - \frac{d\zeta_{\beta\gamma}}{d\lambda_\delta} \right), \quad (25)$$

depend on the friction tensor ζ , which we previously identified as a metric. An analytic expression for the optimal protocol is typically unavailable, requiring reliance on numerical methods to determine the geodesic.

To illustrate our results, we analyze dissipation during the execution of a slow-driving protocol using a three-level maser (TLM) as the working medium of a quantum thermal machine, as shown in Fig. 2a). The protocols we consider connect two distinct operational regimes: the TLM initially operates as a heat engine and then transitions to a regime where it functions as a refrigerator [44]. To this end, we control the inverse temperature $\beta_1(t)$ (see Fig. 2a) and b)). Leveraging the fact that the nonadiabatic entropy production can be expressed as the path action for the metric ζ , we obtain a minimally dissipative protocol by finding a geodesic path in parameter space (see Eqs. (24) and (25)). This procedure, and its simplification for a single-parameter protocol, is discussed in detail in Appendix G. The resulting geodesic protocol for $\beta_1(t)$ is shown in Fig. 2b) alongside two naive protocols (see Appendix F). We observe excellent agreement between the slow-driving approximation and the exact integrated excess flux, as illustrated by the solid and dashed lines in Fig. 2c). As expected, the nonadiabatic entropy production is minimized by the optimal protocol represented by the geodesic.

Arbitrary-speed transitions - To move beyond the limitations of slow driving, we now explore dissipation dynamics independent of driving speed. While one approach involves incorporating higher-order terms in the expansion of the instantaneous state, it is unlikely to yield broadly applicable results. Instead, by transitioning from the geometric space of control parameters to a time-parameterized geometric space [34–40] (see Appendix H), we link the excess entropy flux to the statistical length, providing new insights into fast-driving dynamics. To this end, we may make use of the fact that any member of the family of QFI with respect to the time parameter,

$$I_Q^f(t) = \sum_{x,y} \frac{|\partial_t \hat{\rho}_{xy}(t)|^2}{p_x(t) f(p_y(t)/p_x(t))}. \quad (26)$$

with the corresponding standard monotone functions f (see Appendix H), spectrally decomposed density matrix $\hat{\rho} = \sum_x p_x |x\rangle \langle x|$ and $d\hat{\rho}_{xy} := \langle x| d\hat{\rho}|y\rangle$, plays the role of metric in state space [49, 50]. This means that for small changes in t we can assign an infinitesimal length element

$$ds_f^2 = \frac{1}{4} I_Q^f dt^2, \quad (27)$$

which lets us identify $ds_f/dt = 1/2\sqrt{I_Q^f} =: 1/2v_f$ as speeds in state space. Building on this geometric connection, in [39, 51] a generalized speed limit on an arbitrary observable \hat{A} in terms of v_f , resembling the celebrated Mandelstam-Tamm time-energy uncertainty relation [52],

$$|\dot{a}| \leq \sigma_{\hat{\rho}}^f[\hat{A}]v_f, \quad (28)$$

where $\sigma_{\hat{\rho}}^2[\hat{A}] = \text{Tr}[\hat{A}_0 L_{\hat{\rho}} f(L_{\hat{\rho}}^{-1} R_{\hat{\rho}})(\hat{A}_0)]$, with $\hat{A}_0 = \hat{A} - \text{Tr}[\hat{\rho}\hat{A}]$, is a generalized variance that reduces to the standard one for the commonly used QFI based on the symmetric logarithmic derivative (SLD), and super-operators $L_{\hat{\rho}}(\cdot) = \hat{\rho}(\cdot)$ and $R_{\hat{\rho}}(\cdot) = (\cdot)\hat{\rho}$. The observable of interest in the context of excess entropy flux is the nonequilibrium potential, $\hat{\Phi} = -\log \hat{\pi}_\lambda$, since $\dot{\Pi}_{\text{ex}} = -\text{Tr}[\dot{\hat{\rho}}\hat{\Phi}]$. This connection allows us to derive a geometric bound on the excess entropy flux

$$|\dot{\Pi}_{\text{ex}}| \leq \sigma_{\hat{\rho}}^f[\hat{\Phi}]v_f. \quad (29)$$

We emphasize that this bound holds for arbitrary-speed transitions. Upon integration, one finds

$$\int_0^T dt |\dot{\Pi}_{\text{ex}}| \leq \int_0^T dt \sigma_{\hat{\rho}}^f[\hat{\Phi}] \sqrt{I_Q^f} \quad (30)$$

and thus a bound on the excess entropy flux. Alternatively, the geometric interpretation of v_f as a speed in state space allows its integration to yield the statistical

length

$$\int_0^T dt \frac{|\dot{\Pi}_{\text{ex}}|}{\sigma_{\hat{\rho}}^f[\hat{\Phi}]} \leq \int_0^T dt v_f = 2\ell_f, \quad (31)$$

where $\ell_f = \int_\gamma ds_f$. These bounds reveal how the system's path γ in state space during transitions between different NESS, or, in fact, for arbitrary Lindblad dynamics with a unique fixed point, imposes geometric constraints on dissipation dynamics. Notably, the upper bound in the integrated speed limit (31) is most stringent for a geodesic in state space, whose length can be determined analytically from a closed-form expression when the QFI metric is given by either the SLD-based quantum Fisher information or the Wigner-Yanase skew information.

Conclusion - In this Letter, we have extended the geometric framework of thermodynamics to slow transitions between quantum nonequilibrium steady states (NESS), revealing the critical role of the Kubo-Mori-Bogoliubov quantum Fisher information in quantifying and optimizing dissipation. By deriving geodesics in the parameter space, we identified paths of minimal nonadiabatic entropy production, providing a versatile tool for designing efficient quantum processes. In addition, we were also able to derive a geometric upper bound on the excess flux by switching from the space of control parameters to time — a result that holds for arbitrary speed NESS transitions, and more generally, for arbitrary Lindblad dynamics with a unique fixed point. Ongoing work focuses on applying these insights to quantum dissipative phase transitions, aiming to uncover new universality classes in nonequilibrium quantum systems

Appendix A: Excess/housekeeping entropy flux

In this appendix we derive Hatano-Sasa’s relation [Eq. (5)] and Eq. (4) from the splittings of the entropy production and entropy flux. We start by inserting the splittings $\dot{\Sigma} = \dot{\Sigma}_{\text{ad}} + \dot{\Sigma}_{\text{na}}$ and $\dot{\Pi} = \dot{\Pi}_{\text{ex}} + \dot{\Pi}_{\text{hk}}$ in the expression for the second law (2), which results in

$$\frac{dS}{dt} = \left(\dot{\Sigma}_{\text{ad}} + \dot{\Sigma}_{\text{na}} \right) - \left(\dot{\Pi}_{\text{ex}} + \dot{\Pi}_{\text{hk}} \right). \quad (\text{A1})$$

By definition, $\dot{\Pi}_{\text{hk}} = \dot{\Sigma}_{\text{ad}}$, so these two terms cancel. Therefore, we arrive at

$$\frac{dS}{dt} + \dot{\Pi}_{\text{ex}} = \dot{\Sigma}_{\text{na}} = -\text{Tr} \left[\dot{\rho}_t (\log \hat{\rho}_t - \log \hat{\pi}_{\lambda_t}) \right] \geq 0. \quad (\text{A2})$$

which is Eq. (5) of the main text. Inserting the definition of $\dot{\Sigma}_{\text{na}}$ in this equation, we obtain

$$\begin{aligned}\dot{\Pi}_{\text{ex}} &= \frac{dS}{dt} - \text{Tr} \left[\dot{\hat{\rho}}_t (\log \hat{\rho}_t - \log \hat{\pi}_{\lambda_t}) \right] \\ &= \text{Tr} \left[\dot{\hat{\rho}}_t \log \hat{\rho}_t \right] - \text{Tr} \left[\dot{\hat{\rho}}_t (\log \hat{\rho}_t - \log \hat{\pi}_{\lambda_t}) \right] \\ &= -\text{Tr} \left[\dot{\hat{\rho}}_t \log \hat{\pi}_{\lambda_t} \right],\end{aligned}\tag{A3}$$

which is Eq. (4) of the main text.

Appendix B: Slow-driving expansion

In this section, we derive the slow-driving expansion for $\hat{\rho}_t$. Applying \mathcal{L}_λ^+ on both sides of Eq. (10) results in

$$\mathcal{L}_\lambda^+ \mathcal{L}_\lambda [\delta \hat{\rho}_t] - \mathcal{L}_\lambda^+ \frac{d(\delta \hat{\rho}_t)}{dt} = \mathcal{L}_\lambda^+ \frac{d\hat{\pi}_\lambda}{dt}.\tag{B1}$$

By property (i) of the Drazin inverse, $\mathcal{L}_\lambda^+ \mathcal{L}_\lambda [\delta \hat{\rho}_t] = \delta \hat{\rho}_t - \hat{\pi}_\lambda \text{Tr}[\delta \hat{\rho}_t]$, therefore

$$\mathbb{1} - \hat{\pi}_\lambda \text{Tr}[\delta \hat{\rho}_t] - \mathcal{L}_\lambda^+ \frac{d(\delta \hat{\rho}_t)}{dt} = \mathcal{L}_\lambda^+ \frac{d\hat{\pi}_\lambda}{dt}.\tag{B2}$$

Using the fact that $\text{Tr}[\delta \hat{\rho}_t] = 0$, we get

$$\left(\mathbb{1} - \mathcal{L}_\lambda^+ \frac{d}{dt} \right) [\delta \hat{\rho}_t] = \mathcal{L}_\lambda^+ \frac{d\hat{\pi}_\lambda}{dt}.\tag{B3}$$

This equation can be formally solved by inverting the operator $(\mathbb{1} - \mathcal{L}_\lambda^+ \frac{d}{dt})$:

$$\delta \hat{\rho}_t = \left(\mathbb{1} - \mathcal{L}_\lambda^+ \frac{d}{dt} \right)^{-1} \mathcal{L}_\lambda^+ \frac{d\hat{\pi}_\lambda}{dt}.\tag{B4}$$

The inversion is done via the expansion

$$\left(\mathbb{1} - \mathcal{L}_\lambda^+ \frac{d}{dt} \right)^{-1} = \sum_{n=0}^{\infty} \left(\mathcal{L}_\lambda^+ \frac{d}{dt} \right)^n,\tag{B5}$$

which follows by formally treating the expansion $(1-x)^{-1} = 1 + x + x^2 + \dots$ as power series generating function. Therefore,

$$\hat{\rho}_t = \sum_{n=0}^{\infty} \left(\mathcal{L}_\lambda^+ \frac{d}{dt} \right)^n \hat{\pi}_\lambda.\tag{B6}$$

Appendix C: Boundary term

In the following we derive Eq. (16) of the main text. Using that $\hat{\rho}_T = \hat{\pi}_{\lambda_T} + \delta \hat{\rho}_T$, Eq. (8) can be rewritten as

$$\Pi_{\text{ex}}^{(B)} = -\text{Tr} \left[\delta \hat{\rho}_T \hat{\Phi}_{\lambda_f} \right],\tag{C1}$$

Since $\hat{\rho}_0 = \hat{\pi}_{\lambda_i}$, we then have that

$$\begin{aligned}\langle \hat{\Phi}_\lambda \rangle \Big|_0^T &= \text{Tr} [\hat{\rho}_T \log \hat{\pi}_{\lambda_f}] - \text{Tr} [\hat{\pi}_{\lambda_i} \log \hat{\pi}_{\lambda_i}] \\ &= \text{Tr} [\hat{\pi}_{\lambda_f} \log \hat{\pi}_{\lambda_f}] - \text{Tr} [\hat{\pi}_{\lambda_i} \log \hat{\pi}_{\lambda_i}] - \text{Tr} [\delta \hat{\rho}_T \log \hat{\pi}_{\lambda_f}] \\ &= -\Delta S(\hat{\rho}_\lambda) - \Pi_{\text{ex}}^{(B)},\end{aligned}\tag{C2}$$

which completes the proof.

Appendix D: Green-Kubo relations

In this section we derive a Green-Kubo relation for the friction tensor ζ . Using the integral form of the Drazin inverse, see Eq. (11), in Eq. (18), we get

$$\xi_{\mu\nu} = - \int_0^\infty d\tau \text{Tr} \left[\frac{\partial \log \hat{\pi}_\lambda}{\partial \lambda_\nu} e^{\mathcal{L}\lambda\tau} \left(\hat{\pi}_\lambda \text{Tr} \left[\frac{\partial \hat{\pi}_\lambda}{\partial \lambda_\mu} \right] - \frac{\partial \hat{\pi}_\lambda}{\partial \lambda_\mu} \right) \right] \quad (\text{D1})$$

$$= - \int_0^\infty d\tau \text{Tr} \left[\frac{\partial \log \hat{\pi}_\lambda}{\partial \lambda_\nu} e^{\mathcal{L}\lambda\tau} \left(\frac{\partial \hat{\pi}_\lambda}{\partial \lambda_\mu} \right) \right] \quad (\text{D2})$$

$$= - \int_0^\infty d\tau \text{Tr} \left[\hat{F}^\nu e^{\mathcal{L}\lambda\tau} \left(\frac{\partial \hat{\pi}_\lambda}{\partial \lambda_\mu} \right) \right] \quad (\text{D3})$$

where in the second equality we used that $\text{Tr} \left[\frac{\partial \hat{\pi}_\lambda}{\partial \lambda_\mu} \right] = 0$, by conservation of the trace. Recall that in the Heisenberg picture, operators evolve according to $\hat{F}^\nu(\tau) = e^{\mathcal{L}^\dagger \tau} [\hat{F}^\nu]$, where \mathcal{L}^\dagger is formally defined as the adjoint of \mathcal{L} under the Hilbert-Schmidt inner product, which means that $\text{Tr} [\hat{A} \mathcal{L}(\hat{B})] = \text{Tr} [\mathcal{L}^\dagger(\hat{A}) \hat{B}]$, for \hat{A}, \hat{B} Hermitian matrices. Therefore, $\text{Tr} \left[\hat{F}^\nu e^{\mathcal{L}\lambda\tau} \left(\frac{\partial \hat{\pi}_\lambda}{\partial \lambda_\mu} \right) \right] = \text{Tr} \left[e^{\mathcal{L}^\dagger \tau} (\hat{F}^\nu) \frac{\partial \hat{\pi}_\lambda}{\partial \lambda_\mu} \right]$, then

$$\xi_{\mu\nu} = - \int_0^\infty d\tau \text{Tr} \left[\hat{F}^\nu(\tau) \frac{\partial \hat{\pi}_\lambda}{\partial \lambda_\mu} \right]. \quad (\text{D4})$$

To proceed, we notice that the logarithmic derivative operator \hat{F}^ν satisfies the property [53]

$$\frac{\partial \hat{\pi}_\lambda}{\partial \lambda_\mu} = \int_0^1 ds \hat{\pi}_\lambda^s \hat{F}^\mu \hat{\pi}_\lambda^{1-s}, \quad (\text{D5})$$

which can also be used as an implicit definition of \hat{F}^μ . Using this expression in Eq. (D5), we get

$$\begin{aligned} \xi_{\mu\nu} &= - \int_0^\infty d\tau \int_0^1 ds \text{Tr} \left[\hat{F}^\mu(\tau) \hat{\pi}_\lambda^s \hat{F}^\nu \hat{\pi}_\lambda^{1-s} \right] \\ &= - \int_0^\infty d\tau \int_0^1 ds \text{Tr} \left[\hat{\pi}_\lambda^s \hat{F}^\nu \hat{\pi}_\lambda^{1-s} \hat{F}^\mu(\tau) \right] \\ &= \int_0^\infty d\tau \langle \hat{F}^\mu(0), \hat{F}^\nu(\tau) \rangle_{\hat{\pi}_\lambda}, \end{aligned} \quad (\text{D6})$$

where in the second equality we used the cycling property of the trace. This completes the proof of Eq. (18).

Appendix E: Positivity of the friction tensor

In this appendix, we show that the matrix $\zeta(\lambda)$ is positive semidefinite for any λ . To do so, we will show that, up to second order in ϵ , $\sum_{\mu\nu} \dot{\lambda}_\mu \zeta_{\mu\nu} \dot{\lambda}_\nu = \dot{\Sigma}_{\text{na}} \geq 0$. Keeping only the leading term in Eq. (14), we obtain

$$\begin{aligned} \dot{\Pi}_{\text{ex}} &= - \frac{d\langle \hat{\Phi}_\lambda \rangle}{dt} - \text{Tr} \left[\frac{d \log \hat{\pi}_\lambda}{dt} \mathcal{L}_\lambda^+ \frac{d\hat{\pi}_\lambda}{dt} \right] + \mathcal{O}(\epsilon^3) \\ &= - \frac{d\langle \hat{\Phi}_\lambda \rangle}{dt} + \sum_{\mu\nu} \dot{\lambda}_\mu \zeta_{\mu\nu} \dot{\lambda}_\nu + \mathcal{O}(\epsilon^3) \end{aligned} \quad (\text{E1})$$

From Hatano-Sasa's relation [Eq. (5)], $\dot{\Pi}_{\text{ex}}^{(A)} = -\dot{S} + \dot{\Sigma}_{\text{na}}$. By inserting this in Eq. (E1) and rearranging the result, we can see that

$$\sum_{\mu\nu} \dot{\lambda}_\mu \zeta_{\mu\nu} \dot{\lambda}_\nu = \frac{d}{dt} \left(\langle \hat{\Phi}_\lambda \rangle - S(\hat{\rho}_t) \right) + \dot{\Sigma}_{\text{na}} + \mathcal{O}(\epsilon^3). \quad (\text{E2})$$

Now, we notice that the difference $\langle \hat{\Phi}_\lambda \rangle - S(\hat{\rho}_t)$ is, in fact, the relative entropy, which can be seen from its definition:

$$D(\hat{\rho}_t || \hat{\pi}_\lambda) = \text{Tr}[\hat{\rho}_t(\log \hat{\rho} - \log \hat{\pi}_\lambda)] = -S(\rho_t) + \langle \hat{\Phi}_\lambda \rangle. \quad (\text{E3})$$

Therefore,

$$\sum_{\mu\nu} \dot{\lambda}_\mu \zeta_{\mu\nu} \dot{\lambda}_\nu = \frac{d}{dt} D(\hat{\rho} || \hat{\pi}_\lambda) + \dot{\Sigma}_{\text{na}} + \mathcal{O}(\epsilon^3). \quad (\text{E4})$$

We will now show that the derivative of the relative entropy is of order $\mathcal{O}(\epsilon^3)$, and therefore is negligible for slow processes. The relative entropy can be expanded as [54]

$$D(\hat{\pi}_\lambda + \delta\hat{\rho}_t || \hat{\pi}_\lambda) = \text{Tr}[\delta\hat{\rho}_t \mathbb{J}_{\hat{\pi}}^{-1}(\delta\hat{\rho}_t)] + \mathcal{O}(\epsilon^3). \quad (\text{E5})$$

where $\mathbb{J}_{\hat{\pi}}^{-1}$ is the super-operator

$$\mathbb{J}_{\hat{\pi}}^{-1}(\cdot) = \int_0^\infty ds (\hat{\pi} + s\mathbb{1})^{-1}(\cdot)(\hat{\pi} + s\mathbb{1})^{-1}, \quad (\text{E6})$$

which is in fact the inverse of the Kubo-Mori operator, $\mathbb{J}_{\hat{\pi}}(\cdot) = \int_0^1 ds \hat{\pi}_\lambda^s(\cdot)\hat{\pi}_\lambda^{1-s}$. From the expansion in Eq. (12), we see that $\delta\hat{\rho} = \mathcal{O}(\epsilon)$, therefore $\text{Tr}[\delta\hat{\rho}_t \mathbb{J}_{\hat{\pi}}^{-1}(\delta\hat{\rho}_t)] = \mathcal{O}(\epsilon^2)$. Taking the derivative, we have that

$$\frac{d}{dt} D(\hat{\rho} || \hat{\pi}_\lambda) = \mathcal{O}(\epsilon^3). \quad (\text{E7})$$

Therefore,

$$\sum_{\mu\nu} \dot{\lambda}_\mu \zeta_{\mu\nu} \dot{\lambda}_\nu = \dot{\Sigma}_{\text{na}} + \mathcal{O}(\epsilon^3). \quad (\text{E8})$$

Integrating over the path leads to

$$\int_0^T dt \sum_{\mu\nu} \dot{\lambda}_\mu \zeta_{\mu\nu} \dot{\lambda}_\nu = \int_0^T dt \dot{\Sigma}_{\text{na}} + \mathcal{O}(\epsilon^2), \quad (\text{E9})$$

which is Eq. (23) of the main text. Now, to prove that $\zeta(\lambda)$ is positive semidefinite, we need to show that $\sum_{\mu\nu} x_\mu \zeta_{\mu\nu} x_\nu \geq 0$ for every vector x . For a given λ_0 , consider the linear protocol $\lambda_t = \lambda_0 + \epsilon x t$. By Eq. (E8),

$$\epsilon^2 \sum_{\mu\nu} x_\mu \zeta_{\mu\nu}(\lambda_0) x_\nu = \dot{\Sigma}_{\text{na}} + \mathcal{O}(\epsilon^3). \quad (\text{E10})$$

Therefore, by taking ϵ small enough, we have that $\sum_{\mu\nu} x_\mu \zeta_{\mu\nu}(\lambda_0) x_\nu = \dot{\Sigma}_{\text{na}} \geq 0$, which completes the proof.

Appendix F: Three-Level Maser

In the following, the set-up of the three-level maser (see e.g. Ref. [44] for a recent review), shown in Fig. 2a) in the main text, is discussed. The two baths with inverse temperatures β_1 and β_2 , respectively, couple the levels $|g\rangle \leftrightarrow |e_A\rangle$ and $|e_B\rangle \leftrightarrow |e_A\rangle$. The work bath is assumed to have an infinite temperature and mediates the transition $|g\rangle \leftrightarrow |e_B\rangle$. Because of the infinite temperature assumption, there is no entropy flux due to the energy flow from the central system to the respective bath. The GKLS master equation for the three-level system is given by

$$\frac{d\hat{\rho}}{dt} = -i[H, \hat{\rho}] + \mathcal{D}_1(\hat{\rho}) + \mathcal{D}_2(\hat{\rho}) + \mathcal{D}_3(\hat{\rho}) \quad (\text{F1})$$

with the Hamiltonian $H = \epsilon_g |g\rangle\langle g| + \epsilon_A |e_A\rangle\langle e_A| + \epsilon_B |e_B\rangle\langle e_B|$ and dissipators

$$\begin{aligned} \mathcal{D}_x(\hat{\rho}) = & \gamma_x \left(\hat{A}_x \hat{\rho} \hat{A}_x^\dagger - \frac{1}{2} \left\{ \hat{A}_x^\dagger \hat{A}_x, \hat{\rho} \right\} \right) \\ & + \gamma_x \exp(-\beta_x \omega_x) \left(\hat{A}_x^\dagger \hat{\rho} \hat{A}_x - \frac{1}{2} \left\{ \hat{A}_x \hat{A}_x^\dagger, \hat{\rho} \right\} \right) \end{aligned} \quad (\text{F2})$$

with $\hat{A}_1 = |g\rangle\langle e_A|$, $\hat{A}_2 = |e_B\rangle\langle e_A|$, $\hat{A}_3 = |g\rangle\langle e_B|$, and $\omega_1 = \epsilon_A - \epsilon_g$, $\omega_2 = \epsilon_A - \epsilon_B$ and $\omega_3 = \epsilon_B - \epsilon_g$. The two naive protocols we consider in the main text are, given a protocol duration T , and the initial and target inverse temperatures β_1^0 and β_1^T ,

$$\beta_h^{\text{lin}}(t) = \beta_1^0 + (\beta_1^T - \beta_1^0) \frac{t}{T} \quad (\text{F3})$$

$$\beta_h^{\text{sin}^2}(t) = \beta_1^0 + (\beta_1^T - \beta_1^0) \sin\left(\frac{\hat{\pi}}{2} \frac{t}{T}\right)^2. \quad (\text{F4})$$

Appendix G: Geodesics for single-parameter protocols

Since we consider a single-parameter protocol, the geodesic drive $\beta_1(t)$, given a finite protocol duration T , can be obtained as follows: We know that the speed along the geodesic v_{geo} is constant. This means that the total statistical distance traveled along the geodesic path is $\ell_T^{\text{geo}} = v_{\text{geo}}T$, so that

$$\ell_T^{\text{geo}} = \int_0^T dt \frac{d\beta_1}{dt} \sqrt{m_{\beta_1}} = \int_{\beta_1^0}^{\beta_1^T} d\beta_1 \sqrt{m_{\beta_1}} = v_{\text{geo}}T. \quad (\text{G1})$$

Therefore, we can obtain $v_{\text{geo}} = \ell_T^{\text{geo}}/T$. This yields the inverse function of what we would like to obtain: $t(\beta_1)$, for any $0 \leq t \leq T$

$$t(\beta_1) = \frac{1}{v_{\text{geo}}} \int_{\beta_1^0}^{\beta_1} d\tilde{\beta}_1 \sqrt{m_{\tilde{\beta}_1}}. \quad (\text{G2})$$

By inverting this function, we obtain the geodesic drive $\beta_1(t)$, without having to solve the geodesic equation. For the example of the three-level maser, we find the analytical form of the metric as a function of the control parameter β_1

$$m_{\beta_1} = \frac{\omega_1^2 e^{2\beta_1(\epsilon_g + \epsilon_A)} (e^{\beta_2 \epsilon_B} + e^{\beta_2 \epsilon_A})}{\gamma (e^{\beta_1 \epsilon_g} + 2e^{\beta_1 \epsilon_A})^3 (e^{\beta_1 \epsilon_g + \beta_2 \epsilon_B} + e^{\beta_1 \epsilon_g + \beta_2 \epsilon_A} + e^{\beta_2 \epsilon_B + \beta_1 \epsilon_A})}, \quad (\text{G3})$$

$$I_{\beta_1}^{\text{KMB}}(\hat{\pi}_{\beta_1}) = \frac{\omega_1^2 e^{(2\epsilon_g + \epsilon_A)} (e^{\beta_2 \epsilon_B} + e^{\beta_2 \epsilon_A})}{(e^{\beta_1 \epsilon_g} + 2e^{\beta_1 \epsilon_A})^2 (e^{\beta_1 \epsilon_g + \beta_2 \epsilon_B} + e^{\beta_1 \epsilon_g + \beta_2 \epsilon_A} + e^{\beta_2 \epsilon_B + \beta_1 \epsilon_A})}, \quad (\text{G4})$$

$$\tau_{\beta_1} = \frac{1}{\gamma(2 + e^{-\beta_1 \omega_1})}, \quad (\text{G5})$$

which factorizes into the generalized relaxation time τ_{β_1} and the KMB quantum Fisher metric of the the instantaneous steadystate $I_{\beta_1}^{\text{KMB}}$, as discussed in the main text. Interestingly, the integral relaxation time depends solely on γ , which sets the time scale of the dynamics, and the Boltzmann factor $e^{-\beta_1 \omega_1}$ associated with transitions in the central system induced by interactions with the bath. In the infinite temperature limit, $\beta_1 \rightarrow 0$, $\tau_0 = \frac{1}{3\gamma}$, whereas in the zero temperature limit, $\beta_1 \rightarrow \infty$, $\tau_\infty = \frac{1}{2\gamma}$.

Appendix H: Quantum Fisher information with respect to time

When discussing (quantum) Fisher information, one typically considers a finite set of parameters $\theta = (\theta_1, \dots, \theta_M)$ that are encoded into the state of a system. The manifold of states with parameters as coordinates is equipped with a metric tensor m_{ij} , defining the distance measure between states

$$ds^2 = \frac{1}{4} \sum_{ij} m_{ij} d\theta_i d\theta_j. \quad (\text{H1})$$

The metric m_{ij} is known as the (quantum) Fisher information matrix. One may alternatively treat time itself as a parameter, and then the (quantum) Fisher information becomes

$$F(t) = \sum_{ij} \frac{d\theta_i}{dt} m_{ij} \frac{d\theta_j}{dt} \quad (\text{H2})$$

again providing a metric $ds^2 = \frac{1}{4}F(t)dt^2$ that can be employed to define a statistical distance.

Let us first consider a classical scenario of a discrete state system with a finite number M of configurations. The system state can then be described by the discrete set of occupation probabilities $\{p_x(t)\}$ with $x = 1, \dots, M$ ($p_x(t) \geq 0$ and $\sum_x p_x(t) = 1$), and in that case the metric is uniquely defined by $m = \sum_x p_x(t) \left(\frac{\partial \log p_x(t)}{\partial t} \right)^2$ [55]. The significance of the classical Fisher information with respect to time for stochastic thermodynamics is discussed in Refs. [35, 36]. In quantum dynamics, the quantum Fisher information (QFI) with respect to time has also gained significant interest, particularly in developing quantum speed limits [38, 56, 57] and due to its connection to stochastic thermodynamics [40]. The QFI in quantum systems, defined on a manifold of density matrices, generalizes the classical Fisher information. It is characterized by a family of metrics, governed by the Morozova, Čencov, and Petz theorems [49, 58]. Any metric contractive under stochastic maps, serving as faithful measures of distinguishability in quantum state space [59], must yield a squared line element of the form

$$ds^2 = \frac{1}{4} \sum_{x,y} \frac{|d\hat{\rho}_{xy}|^2}{p_x f(p_y/p_x)}, \quad (\text{H3})$$

where $\hat{\rho} = \sum_x p_x |x\rangle\langle x|$ is the density matrix, $d\hat{\rho}_{xy} := \langle x| d\hat{\rho} |y\rangle$, and f is an operator monotone, self-inversive function satisfying $f(1) = 1$. The infinitesimal line element is given by

$$ds^2 = \frac{1}{4} \sum_{x,y} \frac{|\partial_t \hat{\rho}_{xy}(t)|^2}{p_x(t) f(p_y(t)/p_x(t))} dt^2, \quad (\text{H4})$$

and the quantum Fisher information $F_Q(t)$ is

$$F_Q(t) = \sum_{x,y} \frac{|\partial_t \hat{\rho}_{xy}(t)|^2}{p_x(t) f(p_y(t)/p_x(t))}. \quad (\text{H5})$$

Prominent examples of QFIs include the symmetric logarithmic derivative (SLD) QFI, the Wigner-Yanase (WY) QFI, Kubo-Mori-Bogoliubov (KMB) QFI and the harmonic mean (HM) QFI, with different functions f , see Ref. [59] for a recent review.
