(Dated: January 20, 2025)

In this study, we explore a static, spherically symmetric black hole solution in the context of a self-interacting Kalb-Ramond field coupled with a global monopole. By incorporating the effects of Lorentz-violating term ℓ and the monopole charge η in the KR field, we derive the modified gravitational field equations and analyze the resulting black hole spacetime. The obtained solution exhibits deviations from the Schwarzschild metric with topological defect, as it is influenced by the monopole charge and self-interaction potential. We investigate the thermodynamic properties of the black hole, including its Hawking temperature, entropy, and specific heat, revealing novel stability conditions. Additionally, we perform solar system tests such as perihelion precession, gravitational redshift, light deflection, and time delay of signals to impose constraints on the Lorentz-violating parameter and monopole charge. Our findings suggest that these parameters have to be significantly small, although there are different constraints imposed by individual tests, ranging from $10^{-9} \le |\ell| \le 10^{-4}$ and $10^{-9} \le \eta \le 10^{-6}$ $\rm m^{-1}.$

I. INTRODUCTION

Lorentz symmetry plays a pivotal role in modern physics, ensuring the consistency of the fundamental laws of nature across all inertial reference frames. This symmetry has been validated through extensive experimental observations. However, various theoretical approaches propose that Lorentz symmetry could be violated at high energy scales. Prominent examples of such theories include string theory $[1]$, loop quantum gravity $[2]$, Hořava-Lifshitz gravity $[3]$, non-commutative field theory [\[4\]](#page-15-2), as well as others such as Einstein-æther theory [\[5\]](#page-15-3), massive gravity [\[6\]](#page-15-4), $f(T)$ gravity [\[7\]](#page-15-5), and very special relativity [\[8\]](#page-15-6). Understanding the breakdown of Lorentz symmetry is crucial for exploring the high-energy characteristics of physical systems and the nature of gravity $[9-14]$ $[9-14]$.

Lorentz symmetry breaking (LSB) can occur in two distinct forms: explicit and spontaneous. Explicit LSB arises when the Lagrangian does not respect Lorentz invariance, meaning that the physical laws take different forms in different reference frames. On the other hand, spontaneous LSB occurs when the Lagrangian itself remains Lorentz invariant, but the vacuum state of the system does not exhibit Lorentz symmetry [\[15](#page-15-9)[–28\]](#page-15-10). The Standard-Model extension (SME) [\[29\]](#page-15-11) offers a comprehensive framework for studying spontaneous LSB, with bumblebee models [\[1,](#page-14-0) [30–](#page-15-12)[33\]](#page-15-13) being some of the simplest examples within this framework. These models involve a vector field, known as the bumblebee field, which acquires a nonzero vacuum expectation value (VEV), thus breaking the local Lorentz symmetry by selecting a specific direction in spacetime.

Several solutions have been studied in the context of bumblebee gravity. Casana et al. [\[34\]](#page-15-14) discovered a static, spherically symmetric solution that has been extensively analyzed in relation to gravitational lensing $[35-39]$ $[35-39]$, quark stars $[40]$, Hawking radiation [\[41\]](#page-16-2) and quasinormal modes [\[42\]](#page-16-3). Maluf et al. [\[43\]](#page-16-4) extended the work by deriving an Anti-de Sitter-Schwarzschildlike solution. Xu et al. [\[44\]](#page-16-5) identified new classes of static spherical bumblebee black holes. Investigations into rotating bumblebee black holes [\[45,](#page-16-6) [46\]](#page-16-7) and their associated phenomena, such as gravitational wave propagation [\[47,](#page-16-8) [48\]](#page-16-9), have provided crucial insights into the effects of spontaneous LSB on gravitational behavior.

In addition to vector fields, rank-two antisymmetric tensor fields, such as the Kalb-Ramond (KR) field, have been explored as potential sources of LSB [\[49\]](#page-16-10). The KR field, which arises in the context of bosonic string theory [\[50\]](#page-16-11), has been examined in various areas, including black hole physics $[51–64]$ $[51–64]$, cosmology $[65]$, and braneworld scenarios $[66, 67]$ $[66, 67]$ $[66, 67]$. When the KR field nonminimally couples to gravity and acquires a nonzero VEV, Lorentz symmetry is spontaneously broken. Lessa et al. [\[68\]](#page-16-17) provided a static, spherically symmetric solution within this framework, which was later explored for the motion of massive and massless particles [\[69\]](#page-16-18). The gravitational deflection of light and the shadow of rotating KR black holes were further studied by Kumar et al. [\[70\]](#page-16-19). Solutions for traversable wormholes [\[71,](#page-16-20) [72\]](#page-16-21) and their implications for Bianchi

[∗] mohsen.fathi@ucentral.cl

[†] ali.ovgun@emu.edu.tr

type I cosmology [\[73\]](#page-17-0) have also been investigated. Recently, new exact solutions have been found for static and spherically symmetric spacetimes, both with and without the cosmological constant, in the presence of a nonzero VEV of the KR field, as reported in Refs. [\[74](#page-17-1)[–76\]](#page-17-2).

In this study, we build upon the aforementioned works by incorporating a nonzero VEV of the KR field and examining its interaction with a global monopole charge. Global monopoles, which arise as topological defects due to the spontaneous breaking of global symmetries, particularly in the context of early universe phase transitions, have been extensively explored in cosmology and black hole physics [\[77–](#page-17-3)[80\]](#page-17-4). These monopoles, resulting from an $O(3) \to U(1)$ symmetry breaking, are typically associated with spacetime singularities. However, when gravitational effects are taken into account, the properties of global monopoles are modified. The introduction of self-gravity resolves the self-energy divergence of monopoles, enhancing their physical relevance, especially in astrophysical contexts [\[81\]](#page-17-5). Additionally, global monopoles formed during early universe phase transitions have been proposed as potential contributors to cosmic inflation [\[82,](#page-17-6) [83\]](#page-17-7).

In the present work, we investigate the combined effects of spontaneous LSB in the KR field and the presence of global monopoles. We present a non-asymptotically flat solution that incorporates both phenomena, focusing on their implications for black hole thermodynamics and astrophysical observations. The interaction between these two phenomena provides valuable insights into the behavior of light and particles near black holes, offering potential observational consequences that can be tested in astrophysical settings.

This paper is organized as follows: In Sect. [II,](#page-1-0) we present the field equations for the self-interacting KR field, followed by assigning the Lagrangian density of the global monopole as the matter Lagrangian. We then solve the field equations within a static, spherically symmetric metric ansatz to obtain the exterior solution of a static black hole in the KR background. Additionally, we provide a detailed analysis of the spacetime structure and its sensitivity to the spacetime parameters. In Sect. [III,](#page-5-0) we explore various thermodynamical aspects of the spacetime for the specific case where the black hole possesses only one horizon and derive corrections to the relations characteristic of the Schwarzschild black hole (SBH). In Sect. [IV,](#page-8-0) we perform the four standard Solar System tests on our newly obtained black hole spacetime. Within this context, we provide constraints on the orders of magnitude for the black hole parameters related to the Lorentz-violating and monopole charge parameters. We conclude in Sect. [V.](#page-14-1)

Throughout this study, we adopt the natural system of units by setting $\kappa = 8\pi G = c = \hbar = 1$, and we work with the sign convention (−, +, +, +). Furthermore, primes denote differentiation with respect to the argument of the corresponding functions wherever they appear.

II. NEUTRAL BLACK HOLE SOLUTION IN KR THEORY WITH GLOBAL MONOPOLE CONSTITUENT

The Einstein-Hilbert action for a gravity theory minimally coupled to the KR field is expressed as [\[49,](#page-16-10) [84\]](#page-17-8)

$$
S = \frac{1}{2} \int d^4x \sqrt{-g} \left[R - \frac{1}{6} H^{\mu\nu\rho} H_{\mu\nu\rho} - V \left(B^{\mu\nu} B_{\mu\nu} \right) + \xi_2 B^{\rho\mu} B^{\nu}{}_{\mu} R_{\rho\nu} + \xi_3 B^{\mu\nu} B_{\mu\nu} R \right] + \int d^4x \sqrt{-g} \mathcal{L}_M,
$$
 (1)

where ξ_2 and ξ_3 are coupling constants that describe the interaction between gravity and the KR field. The term $H_{\mu\nu\rho}\equiv\partial_{[\mu}B_{\nu\rho]}$ represents the strength of the KR field, with $B_{\mu\nu}=\partial_\mu B_\nu-\partial_\nu B_\mu$ being the field strength tensor associated with the field B^μ . The self-interaction potential $V(X)$, with $X=B^{\mu\nu}B_{\mu\nu}$, ensures the theory's invariance under local Lorentz transformations. Additionally, \mathcal{L}_{M} denotes the matter field Lagrangian density.

By varying the action in Eq. [\(1\)](#page-1-1) with respect to the metric $g^{\mu\nu}$, the gravitational field equations are derived as

$$
R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R = T_{\mu\nu}^{\text{M}} + T_{\mu\nu}^{\text{KR}} = T_{\mu\nu}^{\text{tot}},
$$
\n(2)

where $T_{\mu\nu}^{\rm tot}$ is the total energy-momentum tensor, comprising the matter field energy-momentum tensor $T_{\mu\nu}^{\rm M}$ and the KR field energy-momentum tensor $T_{\mu\nu}^{\rm KR}$. The KR field energy-momentum tensor is given by

$$
T_{\mu\nu}^{\text{KR}} = \frac{1}{2} H_{\mu\alpha\beta} H_{\nu}^{\alpha\beta} - \frac{1}{12} g_{\mu\nu} H^{\alpha\beta\rho} H_{\alpha\beta\rho} + 2V'(X) B_{\alpha\mu} B^{\alpha}{}_{\nu} - g_{\mu\nu} V(X) + \xi_2 \left[\frac{1}{2} g_{\mu\nu} B^{\alpha\gamma} B^{\beta}{}_{\gamma} R_{\alpha\beta} - B^{\alpha}{}_{\mu} B^{\beta}{}_{\nu} R_{\alpha\beta} - B^{\alpha\beta} B_{\nu\beta} R_{\mu\alpha} - B^{\alpha\beta} B_{\mu\beta} R_{\nu\alpha} + \frac{1}{2} \nabla_{\alpha} \nabla_{\mu} (B^{\alpha\beta} B_{\nu\beta}) + \frac{1}{2} \nabla_{\alpha} \nabla_{\nu} (B^{\alpha\beta} B_{\mu\beta}) - \frac{1}{2} \Box (B_{\mu}{}^{\gamma} B_{\nu\gamma}) - \frac{1}{2} g_{\mu\nu} \nabla_{\alpha} \nabla_{\beta} (B^{\alpha\gamma} B^{\beta}{}_{\gamma}) \right],
$$
(3)

where $\Box\equiv\nabla^\alpha\nabla_\alpha.$ Conservation of the total energy-momentum tensor, $T_{\mu\nu}^{\rm tot}$, can be verified using the Bianchi identities.

To allow for a non-vanishing VEV of the KR field, i.e., $\langle B_{\mu\nu}\rangle=b_{\mu\nu}$, we assume the potential takes the form $V=$ $V(B^{\mu\nu}B_{\mu\nu}\pm b^2)$, where the \pm sign ensures the positiveness of b^2 [\[49,](#page-16-10) [84,](#page-17-8) [85\]](#page-17-9). The VEV configuration is determined by the constant norm condition $b^{\mu\nu}b_{\mu\nu}=\mp b^2.$ Under this configuration, the field equations can be rewritten as [\[74–](#page-17-1)[76\]](#page-17-2)

$$
R_{\mu\nu} = T_{\mu\nu}^{\text{M}} - \frac{1}{2} g_{\mu\nu} T^{\text{M}} + V'(Y) + \xi_2 \left[g_{\mu\nu} b^{\alpha\gamma} b^{\beta}{}_{\gamma} R_{\alpha\beta} - b^{\alpha}{}_{\mu} b^{\beta}{}_{\nu} R_{\alpha\beta} \right]
$$

$$
-b^{\alpha\beta} b_{\mu\beta} R_{\nu\alpha} - b^{\alpha\beta} b_{\nu\beta} R_{\mu\alpha} + \frac{1}{2} \nabla_{\alpha} \nabla_{\mu} (b^{\alpha\beta} b_{\nu\beta}) + \frac{1}{2} \nabla_{\alpha} \nabla_{\nu} (b^{\alpha\beta} b_{\mu\beta}) - \frac{1}{2} \Box (b_{\mu}{}^{\gamma} b_{\nu\gamma}) \right], \tag{4}
$$

where $T^{\rm M}=g^{\mu\nu}T^{\rm M}_{\mu\nu}$ and $Y=2b_{\mu\alpha}{b_{\nu}}^{\alpha}+b^2g_{\mu\nu}$.

In this work, the matter Lagrangian density \mathcal{L}_{M} in Eq. (1) corresponds to a global monopole, defined as [\[79\]](#page-17-10)

$$
\mathcal{L}_{\rm M} \equiv \mathcal{L}_{\rm (GM)} = \frac{1}{2} \partial_{\mu} \varphi^a \partial^{\mu} \varphi^a - \frac{\lambda}{4} \left(\varphi^a \varphi^a - \eta^2 \right)^2, \tag{5}
$$

where φ^a is a scalar triplet field $(a=1,2,3)$ representing the monopole configuration. The model exhibits global ${\rm O}(3)$ symmetry, spontaneously broken to U(1). Here, λ is the self-coupling constant, and η is the symmetry-breaking scale (monopole charge) with dimensions $[\eta] = \text{length}^{-1}$. The corresponding energy-momentum tensor is given by

$$
T^{\rm M}_{\mu\nu} \equiv T^{\rm (GM)}_{\mu\nu} = \partial_{\mu}\varphi^{a}\partial_{\nu}\varphi^{a} - g_{\mu\nu}\left[\frac{1}{2}\partial^{\rho}\varphi^{a}\partial_{\rho}\varphi^{a} - \frac{\lambda}{4}\left(\varphi^{a}\varphi^{a} - \eta^{2}\right)^{2}\right].
$$
 (6)

Focusing on a static, spherically symmetric spacetime, we adopt the metric ansatz

$$
ds^{2} = -A(r)dt^{2} + B(r)dr^{2} + r^{2}d\theta^{2} + r^{2}\sin^{2}\theta d\phi^{2},
$$
\n(7)

in Schwarzschild coordinates (t, r, θ, ϕ) . Assuming a spherically symmetric global monopole configuration, the scalar field is parametrized as $\varphi^a=\eta f(r)x^a/r$, with $x^ax^a=r^2$ and $f(r)$ being an arbitrary radial function. In this spacetime, the components of the energy-momentum tensor in Eq. [\(6\)](#page-2-0) are obtained as

$$
T_{tt}^{(\text{GM})} = -\frac{1}{4}\eta^2 A(r) \left[\frac{2f'(r)^2}{B(r)} + \frac{4f(r)^2}{r^2} + \eta^2 \lambda \left(f(r)^2 - 1\right)^2 \right],\tag{8a}
$$

$$
T_{rr}^{(\text{GM})} = \frac{1}{4} \eta^2 B(r) \left[\frac{2f'(r)^2}{B(r)} + \frac{4f(r)^2}{r^2} + \eta^2 \lambda \left(f(r)^2 - 1 \right)^2 \right],\tag{8b}
$$

$$
T_{\theta\theta}^{(\text{GM})} = \csc^2\theta \, T_{\phi\phi}^{(\text{GM})} = \frac{1}{4} \eta^2 r^2 \left[\frac{2f'(r)^2}{B(r)} + \eta^2 \lambda \left(f(r)^2 - 1\right)^2 \right]. \tag{8c}
$$

For the specific case $f(r)=1$, the above tensor simplifies to $T_{\mu\nu}^{\rm (GM)}={\rm diag}\left(-\eta^2A(r)/r^2,\eta^2B(r)/r^2,0,0\right)$, and $T^{\rm (GM)}=$ $2\eta^2/r^2$. Using this, we find $T^{(\rm GM)}_{\mu\nu}-\frac{1}{2}g_{\mu\nu}T^{(\rm GM)}=(0,0,-\eta^2,-\eta^2\sin^2\theta).$ With the help of Eqs. [\(4\)](#page-2-1) and the spacetime metric (7) , we derive the following field equations:

$$
\frac{2A''(r)}{A(r)} - \frac{A'(r)}{A(r)} \frac{B'(r)}{B(r)} - \frac{A'(r)^2}{A(r)^2} + \frac{4}{r} \frac{A'(r)}{A(r)} = 0,
$$
\n(9)

$$
\frac{2A''(r)}{A(r)} - \frac{A'(r)}{A(r)} \frac{B'(r)}{B(r)} - \frac{A'(r)^2}{A(r)^2} - \frac{4}{r} \frac{B'(r)}{B(r)} = 0,
$$
\n(10)

$$
\frac{2A''(r)}{A(r)} - \frac{A'(r)}{A(r)} \frac{B'(r)}{B(r)} - \frac{A'(r)^2}{A(r)^2} + \frac{1+\ell}{\ell r} \left[\frac{A'(r)}{A(r)} - \frac{B'(r)}{B(r)} \right] - \left[1 - b^2 r^2 V'(Y) \right] \frac{2B(r)}{\ell r^2} + \frac{2(1-\ell)}{\ell r^2} + \eta^2 = 0, \tag{11}
$$

where $\ell\equiv \xi_2b^2/2$ is dimensionless. Following Ref. [\[74\]](#page-17-1), we assume $V'(Y)=0$, which corresponds to the VEV being at the local minimum of the potential. For instance, this is achieved when $V(X)=\frac{1}{2}\alpha X^2$ with $X=B^{\mu\nu}B_{\mu\nu}+b^2$, where α is a real coupling constant [\[85\]](#page-17-9).

Under these conditions, subtracting Eq. [\(10\)](#page-2-3) from Eq. [\(9\)](#page-2-3) yields $A'(r)/A(r) = -B'(r)/B(r)$, leading to $A(r) = B(r)^{-1}$. Subtracting Eq. (11) from Eq. (9) provides the solution

$$
A(r) = \frac{e^{-\frac{\ell\eta^2 r^2}{4(1-\ell)}}}{\eta(1-\ell)r} \left[\eta(1-\ell)c_1 + \sqrt{\pi\left(\frac{1}{\ell}-1\right)} \operatorname{erf}_i\left(\frac{\eta r}{2\sqrt{\frac{1}{\ell}-1}}\right)\right],\tag{12}
$$

where $\text{erf}_1(z) \equiv \text{erf}(iz)/i$ is the imaginary error function, and c_1 is an integration constant. It has been shown that $c_1/2 = M$ [\[74\]](#page-17-1). Expanding the solution up to the second order of the monopole charge, we obtain

$$
A(r) \approx \frac{1}{1-\ell} - \frac{2M}{r} + \frac{\ell M \eta^2 r}{2(1-\ell)} - \frac{\ell \eta^2 r^2}{6(1-\ell)^2} + \mathcal{O}(\eta^4). \tag{13}
$$

The solution is independent of the sign of η , while the parameter ℓ significantly impacts it. For $\eta = 0$, the solution reduces to

$$
A(r) \approx \frac{1}{1-\ell} - \frac{2M}{r},\tag{14}
$$

which corresponds to a static uncharged black hole of mass M in a self-interacting KR field [\[74\]](#page-17-1). This further simplifies to the Schwarzschild metric when the Lorentz-violating term vanishes. Due to experimental constraints on Lorentz-violating effects, ℓ is expected to be small.

The Kretschmann scalar is given by:

$$
R^{\alpha\beta\gamma\delta}R_{\alpha\beta\gamma\delta} = \frac{2\eta^4\ell^2}{3(\ell-1)^4} + \frac{2\eta^4\ell^2 M}{(\ell-1)^3 r} + \frac{2\eta^2\ell^2 \left[3\eta^2(\ell-1)M^2 + 2\right]}{3(\ell-1)^3 r^2} + \frac{4\eta^2\ell^2 M}{(\ell-1)^2 r^3} + \frac{4\ell^2}{(\ell-1)^2 r^4} + \frac{16\ell M}{(\ell-1)r^5} + \frac{48M^2}{r^6},
$$
 (15)

which diverges at $r=0$, indicating an intrinsic and non-removable singularity. The terms $\sim r$ and $\sim r^2$ in $A(r)$ resemble solutions with quintessential and cosmological terms (e.g., Ref. $[86]$), though these arise from KR field contributions rather than cosmological effects. The general lapse function can be approximated as

$$
A(r) \approx 1 - \frac{2M}{r} + l + \gamma r - kr^2,\tag{16}
$$

mimicking the Mannheim-Kazanas solution in conformal Weyl gravity [\[87\]](#page-17-12). However, these terms reflect spacetime curvature modifications due to the KR field and monopole charge, rather than cosmological contributions. To explore this further, we study the black hole's causal structure.

To examine the causal structure of the spacetime characterized by the lapse function (13) , the horizon locations can be identified by solving the equation $g^{rr} = A(r) = 0$. This equation yields three solutions:

$$
r_1 = (1 - \ell)M - \frac{24(1 - \ell)^2}{\ell \eta^2} \sqrt{\frac{\zeta_2}{3}} \cos\left(\frac{1}{3} \arccos\left(\frac{3\zeta_3}{\zeta_2}\sqrt{\frac{3}{\zeta_2}}\right)\right),\tag{17}
$$

$$
r_2 = (1 - \ell)M - \frac{24(1 - \ell)^2}{\ell \eta^2} \sqrt{\frac{\zeta_2}{3}} \cos\left(\frac{1}{3} \arccos\left(\frac{3\zeta_3}{\zeta_2}\sqrt{\frac{3}{\zeta_2}}\right) - \frac{4\pi}{3}\right),\tag{18}
$$

$$
r_3 = (1 - \ell)M - \frac{24(1 - \ell)^2}{\ell \eta^2} \sqrt{\frac{\zeta_2}{3}} \cos \left(\frac{1}{3} \arccos \left(\frac{3\zeta_3}{\zeta_2} \sqrt{\frac{3}{\zeta_2}} \right) - \frac{2\pi}{3} \right),\tag{19}
$$

where

$$
\zeta_2 = \frac{\ell \left[\eta^2 (1 - \ell) \ell M^2 + 2 \right] \eta^2}{48 (1 - \ell)^3},\tag{20a}
$$

$$
\zeta_3 = -\frac{\ell^2 \left[\eta^2 (1-\ell)\ell M^2 - 3 \right] M \eta^4}{1728 (1-\ell)^4}.
$$
\n(20b)

For $\ell \leq 0$, the conditions $r_1 > 0$ and $r_2 = r_3^* \in \mathbb{C}$ hold, indicating that the black hole possesses a single horizon, $r_+ = r_1$. Conversely, when $\ell > 0$, we find $r_1 < 0$ and $0 < r_3 < r_2$. In this case, the black hole has an event horizon at $r_+ = r_3$ and an outer horizon at $r_{++} = r_2$. Notably, since the theory lacks a cosmological constant, the existence of r_{++} arises from the $\sim r^2$ terms in the lapse function. This behavior results from the interplay between the monopole charge, the KR field, and their interaction with spacetime, mimicking the effects of a cosmological constant. At the r_+ surface, infinite redshift occurs, whereas infinite blueshift is observed at r_{++} . Therefore, r_{++} can be interpreted as an exterior Cauchy horizon, beyond which spacetime predictability fails. These aspects can be further illustrated by examining the radial profile of $g^{rr} = A(r)$, as shown in Fig. [1.](#page-4-0) The plots reveal that for $\ell < 0$, the SBH represents the lower bound, and the black hole becomes larger than the SBH. For $\ell \geq 0$, the SBH serves as the upper bound, with $r_+ \leq r_s = 2M$. Additionally, the spacetime asymptotically resembles Anti-de Sitter (AdS) spacetime for $\ell < 0$ and de Sitter (dS) spacetime for $\ell > 0$. The

FIG. 1. Radial profile of $g^{rr} = A(r)$ for $\eta = 0.3$, with (a) $\ell \leq 0$ and an additional curve for $\eta = 0$ (SBH with a topological defect), and (b) $\ell > 0$. Unless otherwise noted, axes lengths are measured in units of the black hole mass M.

FIG. 2. Profiles of r_+ versus ℓ for $0 \leq \eta \leq 1$.

event horizon's dependence on ℓ and the monopole charge is shown in Fig. [2.](#page-4-1) The profiles demonstrate that as ℓ transitions from negative to positive values, the black hole size diminishes continuously, with the SBH being the limiting case for $\ell < 0$ and $\ell > 0$. Moreover, for $\ell < 0$, increasing η enlarges the black hole, whereas for $\ell > 0$, the opposite trend is observed.

For $\ell \leq 0$, a black hole exists for all values of the monopole charge. In contrast, for $\ell > 0$, the horizons can merge into an extremal black hole (EBH) or vanish entirely, leaving a naked singularity. This occurs when the discriminant $\Delta=16(\zeta_2^3-27\zeta_3^2)$ of the cubic $A(r)=0$ for $\ell>0$ satisfies $\Delta=0$. When $\Delta>0$, the cubic equation has three real roots, with one negative and two positive. For $\Delta = 0$, the positive roots degenerate, forming an EBH with a single horizon. If Δ < 0, the cubic equation yields one real negative root and two complex conjugates, eliminating the horizons and leaving a naked singularity. Figure [3](#page-5-1) illustrates Δ as a function of η and ℓ for $\ell > 0$. The curve corresponding to $\Delta = 0$ identifies the EBH. Solving $\Delta = 0$ yields the critical value of η for the EBH:

$$
\eta_*^2 = \frac{3 - 4\sqrt{3}M(1 - \ell)^2 - \sqrt{8M(1 - \ell)^2 \left[6M(1 - \ell)^2 - 7\sqrt{3}\right] + 9}}{2M^2(1 - \ell)\ell},\tag{21}
$$

which denotes the value of η at the EBH. However, as shown in Fig. [3,](#page-5-1) this condition corresponds to larger ℓ values that lack physical relevance in the theory.

FIG. 3. Relationship between ℓ and η for $\Delta > 0$ (blue region), with the $\Delta = 0$ curve (EBH) separating it from the naked singularity region (Δ < 0).

III. THERMODYNAMICS OF THE BLACK HOLE

Black hole thermodynamics reveals that black holes follow the four thermodynamic laws [\[88,](#page-17-13) [89\]](#page-17-14) and exhibit phase structures akin to classical thermodynamic systems [\[90–](#page-17-15)[92\]](#page-17-16), providing important insights into gravity and black hole physics. Asymptotically AdS-like black holes are particularly significant due to their connection to the AdS/CFT correspondence and their various phase transitions. In contrast, asymptotically dS-like black holes, which are characterized by two distinct temperatures, remain in non-equilibrium states, presenting unique challenges. Although some progress has been made in studying their thermodynamics [\[93\]](#page-17-17), many aspects are still not fully understood. In this section, we focus on the fundamental thermodynamic properties of the asymptotically AdS-like black hole corresponding to the case of $\ell \leq 0$, for simplicity in our analysis.

To investigate this, we begin by solving the equation $A(r_+) = 0$ for the lapse function [\(13\)](#page-3-0) to determine the black hole mass, which gives

$$
M = \frac{r_+ \left[\ell \left(\eta^2 r_+^2 + 6 \right) - 6 \right]}{3(1 - \ell) \left[\ell \left(\eta^2 r_+^2 + 4 \right) - 4 \right]}.
$$
\n(22)

Since the black hole is static and spherically symmetric with an effective long-distance term $l_{\text{eff}}=\frac{1}{2}\ell\eta^2/(1-\ell)^2$, we can associate the black hole mass M with the enthalpy of the black hole. In this case, the thermodynamic pressure is given by $P=-\frac{1}{8\pi}l_{\rm eff}$, and thus, the enthalpy is related to the $\ell\eta^2$ coefficient, which accounts for both the Lorentz-violating parameter and the monopole charge. Since ℓ is dimensionless, we can express the enthalpy as a function of entropy S and pressure P, in the form $M \equiv M(S, P)$. Consequently, the first law of thermodynamics for the AdS-like black hole is written as

$$
dM = T_H^+ dS + VdP,\tag{23}
$$

where $T_{\rm H}^+$ is the Hawking temperature of the horizon and V represents the thermodynamic volume. Using the line element (7) along with Eqs. (13) and (22) , the Hawking temperature can be computed as

$$
T_{\rm H}^+ = \frac{A'(r_+)}{4\pi} = \frac{6\eta^2(1-\ell)\ell r_+^2 - 24(1-\ell)^2 - \eta^4 \ell^2 r_+^4}{24\pi(1-\ell)^2 r_+ \left[\ell\left(\eta^2 r_+^2 + 4\right) - 4\right]}.
$$
\n(24)

For $\ell=0$, the SBH's Hawking temperature is recovered, which is given by $T_{\rm H}^+=1/(4\pi r_s)$. In Fig. [4,](#page-6-0) we plot the behavior of $T_{\rm H}^+$ as a function of r_+ for specific values of ℓ and η , considering $\ell\leq 0$. The impact of the Lorentz-violating parameter on the Hawking temperature is evident from the diagrams. It can be inferred that for fixed η , increasing the ℓ -parameter leads to an increase in temperature. Consequently, the SBH (i.e., $\ell=0$) has the highest temperature. Similarly, for fixed ℓ , an increase in the monopole charge results in a higher temperature. In general, all profiles show a significant decrease in temperature as the black hole size increases.

FIG. 4. The behavior of the Hawking temperature for the AdS-like black hole within $\ell \le 0$, plotted for (a) $\eta = 0.3$, and (b) $\ell = -0.2$.

Using the first law of thermodynamics in Eq. [\(23\)](#page-5-3) and the Hawking temperature in Eq. [\(24\)](#page-5-4), one can derive the black hole's entropy as

$$
S = \int \left(\frac{dM}{T_{\rm H}^{+}}\right)_{P} = \int \frac{1}{T_{\rm H}^{+}} \left(\frac{\partial M}{\partial r_{+}}\right)_{P} dr_{+}
$$

$$
= -\frac{4\pi (1 - \ell) \ln \left(\eta^{2} \ell r_{+}^{2} + 4 - 4\ell\right)}{\eta^{2} \ell}
$$

$$
\approx \frac{\mathcal{A}_{+}}{4} - \frac{4\pi (1 - \ell) \ln(4 - 4\ell)}{\eta^{2} \ell} + \mathcal{O}(r_{+}^{3}),
$$
 (25)

where ${\cal A}_+=4\pi r_+^2$ is the event horizon's area. This indicates that the Bekenstein-Hawking (B-H) area-entropy relation is not exactly satisfied, which is a consequence of the global monopole's presence. If we consider $\eta=0$, the entropy reduces to $S = A_{+}/4$, which aligns with the B-H formula. The behavior of entropy as a function of r_{+} is depicted in Fig. [5](#page-6-1) for variations in the ℓ and η parameters. As expected from the diagram, the SBH possesses the largest entropy. For fixed η , a

FIG. 5. Entropy behavior for the AdS-like black hole with $\ell \leq 0$ values, plotted for (a) $\eta = 0.3$, and (b) $\ell = -0.2$.

decrease in the ℓ -parameter leads to a decrease in entropy. In contrast, for a fixed ℓ , a decrease in the η -parameter increases the entropy. The thermodynamic volume is calculated as

$$
V = \left(\frac{\partial M}{\partial P}\right)_S = \left(\frac{\partial M}{\partial l_{\text{eff}}}\right)_S \left(\frac{\partial l_{\text{eff}}}{\partial P}\right)_S
$$

=
$$
\frac{16\pi (1 - \ell)r_+^3}{3\left[4 - \ell \left(\eta^2 r_+^2 + 4\right)\right]}
$$

$$
\approx \frac{4\pi}{3}r_+^3 + \frac{\ell\eta^2 \pi}{3}r_+^5 + \mathcal{O}\left(\ell^2, r_+^7\right),
$$
 (26)

which reduces to the volume of a sphere of radius r_+ for $\eta \to 0$, as expected from the B-H criteria. Consequently, the Smarr

formula is corrected as

$$
M \approx 2(T_{\rm H^+}S - VP) + \frac{4\ln(2)}{\ell\eta^2 r_+} - \frac{2}{\eta^2 r_+} + \mathcal{O}\left(\ell^2\right),\tag{27}
$$

for the black hole with monopole charge. It is evident that this result becomes singular for $\eta \to 0$. Therefore, to verify the Smarr formula for a neutral black hole in the KR field, we first set $\eta=0$ in the integral of Eq. [\(25\)](#page-6-2). This yields $S=\pi r_+^2$, $V=4\pi r_+^3/3$, and $P=0$, leading to $M=r_+/(2-2\ell)$, which corresponds to the mass of a neutral black hole in KR gravity [\[74\]](#page-17-1), satisfying the Smarr formula.

Another thermodynamic quantity is the specific heat, which is important in analyzing the local stability of the black hole. This quantity is calculated as

$$
C_p = \left(\frac{\partial M}{\partial T_{\rm H^+}}\right)_P = \left(\frac{\partial M}{\partial r_+}\right)_P \left(\frac{\partial r_+}{\partial T_{\rm H^+}}\right)_P
$$

=
$$
\frac{8\pi (1 - \ell)r_+^2 \left[6\eta^2 (1 - \ell)\ell r_+^2 - \eta^4 \ell^2 r_+^4 - 24(1 - \ell)^2\right]}{\eta^6 \ell^3 r_+^6 - 6\eta^4 (1 - \ell)\ell^2 r_+^4 - 48\eta^2 (1 - \ell)^2 \ell r_+^2 + 96(1 - \ell)^3}
$$

$$
\approx -2\pi r_+^2 - \frac{1}{2}\pi \ell \eta^2 r_+^4 + \mathcal{O}(\ell^2),
$$
 (28)

for the black hole with monopole charge, which results in $C_p=-2\pi r_+^2$ in the limit of $\eta\to0$, corresponding to the neutral black hole in the KR field [\[74\]](#page-17-1). It is interesting to note that the contribution of the Lorentz-violating term only appears as an interaction with the monopole charge. Hence, for a neutral black hole, the ℓ -parameter does not contribute to the heat capacity, although it appears in both the mass and the Hawking temperature. In Fig. [6,](#page-7-0) the behavior of the heat capacity has been plotted versus changes in r_+ , for different values of ℓ and η , within the domain $\ell \leq 0$. As shown in the diagrams,

FIG. 6. The behavior of the specific heat within $\ell \leq 0$ values, plotted for (a,b) general relativistic black hole size range, and (c,d) larger black holes. The diagrams correspond to (a,c) $\eta = 0.3$, and (b,s) $\ell = -0.2$.

the specific heat remains negative for black hole sizes within the range typically considered reasonable in general relativity, indicating local instability, akin to the behavior of the SBH. However, for sufficiently large black holes ($r_{+} \gtrsim 5M$), the specific heat becomes positive $(C_p>0)$, signifying stability. Notably, when $C_p < 0$, increasing the ℓ -parameter leads to a decrease in C_p , while an increase in η causes C_p to rise. Conversely, when $C_p>0$, an increase in ℓ results in an increase in C_p , while increasing η causes C_p to decrease.

To analyze the global stability of black holes, one can consider the Gibbs free energy F, in the sense that for $F < 0$, the black hole is globally stable, whereas for $F > 0$, it is globally unstable. The Gibbs free energy for the black hole under consideration is calculated as

$$
F = M - T_{\rm H}^{+} S
$$

=
$$
\frac{\left[24(1 - \ell)^{2} + \eta^{4}\ell^{2}r_{+}^{4} - 6\eta^{2}(1 - \ell)\ell r_{+}^{2}\right] \ln\left(\eta^{2}\ell r_{+}^{2} + 4 - 4\ell\right) + 2\eta^{2}\ell r_{+}^{2}\left[6 - \ell\left(\eta^{2}r_{+}^{2} + 6\right)\right]}{6\eta^{2}(1 - \ell)\ell r_{+}\left[4 - \ell\left(\eta^{2}r_{+}^{2} + 4\right)\right]}
$$

$$
\approx \frac{r_{+}}{4(1 - \ell)} + \frac{\ln(4 - 4\ell)}{\eta^{2}\ell r_{+}} + \mathcal{O}(\ell^{2}).
$$
 (29)

Again, for $S=\pi r_+^2$, corresponding to $\eta=0$, the above relation results in the Gibbs free energy for a neutral black hole in the KR field, which is $F = r_+/(4 - 4\ell)$ [\[74\]](#page-17-1). In Fig. [7,](#page-8-1) the behavior of the Gibbs free energy has been plotted versus changes in the event horizon, for different values of ℓ and η . As observed, the Gibbs free energy remains negative across the

FIG. 7. The behavior of the Gibbs free energy within $\ell \leq 0$ values, plotted (a) $\eta = 0.3$, and (b) $\ell = -0.2$.

entire range of black hole sizes, suggesting that the black hole is globally stable. Additionally, we find that an increase in the ℓ -parameter leads to a decrease in the free energy, while an increase in the monopole charge results in an increase in the free energy. It is worth mentioning that the SBH is not only locally unstable but also globally unstable, as its free energy is always positive. However, despite its presence, the topological defect, which manifests itself by the Lorentz-violating parameter ℓ , cannot affect this instability for a Schwarzschild-like black hole in the KR field, as the free energy for this black hole remains positive.

IV. SOLAR SYSTEM TESTS

To analyze the observational implications of the obtained spacetime in the context of the solar system, it is essential to consider the weak-field approximation of the metric. In this regime, the radial coordinate r is significantly larger than the characteristic scale of the black hole, making higher-order corrections in r negligible. Therefore, we approximate the lapse function $A(r)$ as:

$$
A(r) \approx 1 + \ell - \frac{2M}{r} + \frac{\ell M \eta^2}{2} r + \mathcal{O}(\ell^2, r^2).
$$
 (30)

This approximation is justified for the following reasons: The term $-2M/r$ represents the dominant Schwarzschild potential, which governs gravitational interactions within the solar system. The additional constant term ℓ introduces a small deviation due to Lorentz violation, which can be constrained by precise observations. The linear correction $\ell M\eta^2r/2$ reflects the first-order effect of the monopole charge η , which remains significant in the weak-field regime. Higher-order terms, such as those proportional to r^2 , are negligible within the solar system due to the small values of ℓ , and the relatively small scales involved compared to cosmological distances. In fact, given the smallness of the parameters, approximate approaches and perturbative methods can be applied to this black hole in the context of the solar system. Accordingly, using the above simplified form of the lapse function, we will now investigate the solar system tests, such as the perihelion precession, bending of light, and time delay of signals.

A. Perihelion precession

An intuitive method to investigate this effect was introduced in Ref. [\[94\]](#page-17-18), which funds our mathematical approach within this subsection. The core concept involves comparing Keplerian elliptic orbits in the Minkowski spacetime, described using Lorentzian coordinates, with those defined in Schwarzschild coordinates. This approach naturally highlights the general relativistic corrections. Consider the unperturbed Lorentzian metric

$$
ds^{2} = -dt^{2} + dr^{2} + r^{2}d\theta^{2} + r^{2}\sin^{2}\theta d\phi^{2},
$$
\n(31)

defined in the (t,r,θ,ϕ) coordinates. We compare this with the metric [\(7\)](#page-2-2), now assumed to be expressed in the (t',r',θ,ϕ) coordinates. The relationship between (t,r) and (t^{\prime},r^{\prime}) is approximated as

$$
dt' = \left(1 + \frac{\ell}{2} - \frac{M}{r} + \frac{1}{4}\eta^2 \ell Mr\right) dt,\tag{32a}
$$

$$
dr' = \left(1 - \frac{\ell}{2} + \frac{M}{r} - \frac{1}{4}\eta^2 \ell Mr\right) dr.
$$
 (32b)

In the invariant plane $\theta=\pi/2$, the area element in the Lorentzian framework is $d\mathcal{A}=\int_0^R r dr d\phi=\frac{1}{2}R^2d\phi$, where R represents the areal distance from the planet to the central mass. Thus, Kepler's second law can be written as

$$
\frac{d\mathcal{A}}{dt} = \frac{1}{2}R^2\frac{d\phi}{dt}.\tag{33}
$$

In Schwarzschild coordinates, we have

$$
d\mathcal{A}' = \int_0^R r dr' d\phi = \int_0^R \left(r - \frac{\ell}{2} r + M - \frac{1}{4} \eta^2 \ell M r^2 \right) dr d\phi \tag{34}
$$

$$
= \frac{R^2}{2} \left(1 - \frac{\ell}{2} + \frac{2M}{R} - \frac{1}{6} \eta^2 \ell MR \right) d\phi.
$$
 (35)

Using the transformations [\(32\)](#page-9-0), Kepler's second law becomes

$$
\frac{d\mathcal{A}'}{dt'} = \frac{1}{2}R^2 \left(1 - \frac{\ell}{2} + \frac{2M}{R} - \frac{1}{6}\eta^2 \ell MR\right) \frac{d\phi}{dt'}
$$
\n
$$
= \frac{1}{2}R^2 \left(1 - \frac{\ell}{2} + \frac{2M}{R} - \frac{1}{6}\eta^2 \ell MR\right) \left(1 - \frac{\ell}{2} + \frac{M}{R} - \frac{1}{4}\eta^2 \ell MR\right) \frac{d\phi}{dt}
$$
\n
$$
\simeq \frac{1}{2}R^2 \left(1 - \ell + \frac{3M}{R} - \frac{2}{3}\eta^2 \ell M^2\right) \frac{d\phi}{dt}.
$$
\n(37)

Since this law must hold covariantly in all coordinate systems, Eqs. [\(33\)](#page-9-1) and [\(37\)](#page-9-2) imply $d\phi'=(1-\ell+3M/R-2\eta^2\ell M^2/3)d\phi$. For an angular increment $\Delta \phi'$, we find

$$
\int_0^{\Delta \phi'} d\phi' = \int_0^{\Delta \phi = 2\pi} \left(1 - \ell + \frac{3M}{R} - \frac{2}{3} \eta^2 \ell M^2 \right) d\phi,
$$
 (38)

for one orbit. Given $R = l/(1 + \varepsilon \cos \phi)$, where ε is the eccentricity and l the semi-latus rectum, this becomes

$$
\Delta \phi' = 2\pi \left(1 - \ell - \frac{2}{3} \eta^2 \ell M^2 \right) + \frac{3M}{l} \int_0^{2\pi} (1 + \varepsilon \cos \phi) d\phi
$$

=
$$
2\pi + \Delta \phi_{\rm gr} + \Delta \phi_{\rm KR} + \Delta \phi_{\eta},
$$
 (39)

where

$$
\Delta \phi_{\rm gr} = \frac{6\pi M}{l},\tag{40a}
$$

$$
\Delta \phi_{\rm KR} = -2\pi \ell, \tag{40b}
$$

$$
\Delta \phi_{\eta} = -\frac{4\pi}{3} \ell \eta^2 M^2, \tag{40c}
$$

represent the general relativistic term and the corrections due to the KR field and the KR-monopole charge interaction. Using $M = M_{\odot} = 1476.112$ m in our unit system, the perihelion advance in arcseconds per century is

$$
\delta \equiv \Delta \phi' - 2\pi = 5.73912 \frac{\nu}{l} - 1.296 \nu \ell - 1.88258 \nu \ell \eta^2,\tag{41}
$$

where v is the number of orbits per year and l is approximately 10^9 m. Figure [8](#page-10-0) constrains the black hole parameters ℓ and η based on perihelion advance observations. From Fig. [8,](#page-10-0) the optimal range for ℓ is $-0.0001\leq\ell\leq 0.0001$ for $\eta\sim 10^{-6}\,\rm m^{-1}$.

FIG. 8. Constraints on ℓ and η based on perihelion precession data for Mercury (blue), Venus (green), and Earth (red) (see Ref. [\[94\]](#page-17-18) for data).

Additionally, since η enters as a squared term, its sign does not affect the constraints, and for $\eta < 0$, a mirrored domain is obtained.

B. Gravitational redshift

The frequency shift experienced by photons as they traverse a static gravitational source can be derived using the relation [\[95\]](#page-17-19)

$$
\frac{\nu}{\nu_i} = \sqrt{\frac{A(r)}{A(r_i)}},\tag{42}
$$

which applies to the spacetime metric given in Eq. [\(7\)](#page-2-2). This equation arises from the presence of a time-like Killing vector field that characterizes the spacetime geometry. Here, (r_i,ν_i) and (r,ν) correspond to the source's initial and the observer's radial distance and frequency, respectively. For scenarios near Earth's surface, the conditions $\ell\ll1$ and $\frac12\eta^2\ell Mr\ll 2M/r$ are satisfied. Under these approximations, Eq. (42) can be expanded as

$$
\frac{\nu}{\nu_i} \simeq \left(\frac{\nu}{\nu_i}\right)_{\rm gr} - \left(\frac{r - r_i}{r_i r}\right) M\ell + \frac{1}{4} \eta^2 \ell M(r - r_i),\tag{43}
$$

where

$$
\left(\frac{\nu}{\nu_i}\right)_{\rm gr} \equiv 1 - \frac{M}{r} + \frac{M}{r_i},\tag{44}
$$

represents the frequency shift due to general relativistic effects induced by the gravitational field of the source. This relation has been verified through the Gravity Probe A (GP-A) redshift experiment using a hydrogen maser, achieving an experimental accuracy of approximately 10^{-14} [\[96\]](#page-17-20). As a result, the following inequality must hold:

$$
\left| \left(\frac{r - r_i}{r_i r} \right) M \ell - \frac{1}{4} \eta^2 \ell M (r - r_i) \right| \lesssim 10^{-14}.
$$
\n(45)

Assuming the source is located at $r_i = r_{\oplus}$, corresponding to Earth's radius and mass $M = M_\oplus = 4.453 \times 10^{-3}$ m, and the observer is positioned on a satellite orbiting 15000 km above Earth's surface, Eq. [\(45\)](#page-10-2) imposes the constraint:

$$
\left|4.877\ell - 3.75\ell M\eta^2\right| \lesssim 1.\tag{46}
$$

This restriction yields approximate bounds of $|\ell| \sim 10^{-4}$ and $\eta \sim 10^{-6}\,\mathrm{m}^{-1}$ (see Fig. [9\)](#page-11-0).

FIG. 9. The confidence intervals for ℓ and η derived from the GP-A redshift measurements (specific parameter values are provided in Ref. [\[96\]](#page-17-20)).

C. Deflection of light

In this section, we adopt the approach outlined in Ref. [\[97\]](#page-17-21) to compute the deflection angle of light passing near the Sun. This methodology leverages the Gauss-Bonnet theorem (GBT) and has been extended to accommodate non-asymptotically flat spacetimes. Introducing $\dot{x}^\mu \equiv dx^\mu/ds$, we arrive at the following equation:

$$
\epsilon = -\frac{E^2}{A(r)}\dot{t}^2 + \frac{\dot{r}^2}{A(r)} + \frac{L^2}{r^2},\tag{47}
$$

where $E\equiv A(r)\dot{t}$ and $L\equiv r^2\dot{\phi}$ are constants of motion. Consistent with prior discussions, equatorial plane motion $(\theta=\pi/2)$ is assumed. The parameter ϵ characterizes the nature of the geodesics, with $\epsilon = 0$ representing null trajectories and $\epsilon = -1$ corresponding to time-like ones. For light rays (photons) traversing the black hole, the first-order angular equation of motion becomes [\[98\]](#page-17-22)

$$
\left(\frac{\dot{r}}{\dot{\phi}}\right)^2 = \left(\frac{dr}{d\phi}\right)^2 = \frac{r^4}{b^2} - (1+\ell)r^2 + 2Mr - \frac{1}{2}\eta^2Mr^3,\tag{48}
$$

where $b \equiv L/E$ denotes the impact parameter. Substituting $r = 1/u$, the equation transforms into

$$
\left(\frac{du}{d\phi}\right)^2 = \frac{1}{b^2} - (1+\ell)u^2 + 2Mu^3 - \frac{1}{2}\eta^2 M\ell u,\tag{49}
$$

which reduces to the standard Schwarzschild case as $\ell \to 0$. Differentiating Eq. [\(49\)](#page-11-1) with respect to ϕ yields

$$
u'' + u = 3Mu^2 - \ell u - \frac{1}{4}\eta^2 M\ell,
$$
\n(50)

where primes denote derivatives with respect to ϕ . Employing an iterative solution method, we find

$$
u(\phi) \approx \frac{\sin \phi}{b} + \frac{M}{b^2} (1 + \cos^2 \phi) - \frac{1}{4} M \ell \eta^2 + \mathcal{O}(\ell^2). \tag{51}
$$

For the optical metric $\gamma_{ij}=\mathrm{diag}(A(r)^{-2},r^2A(r)^{-1}),$ with $i,j=r,\phi,$ the area element is $d\mathcal{S}=\sqrt{\det(\gamma_{ij})}\,dr d\phi=0$ $rA(r)^{-3/2}drd\phi$. The Gaussian curvature K on this surface, involving the lens, source, and observer, can then be expressed as

$$
K = \frac{R_{r\phi r\phi}}{\gamma_{ij}},\tag{52}
$$

and under the weak lensing approximation $M\ll b \ll (r_O,r_S)$ and $(r_O,r_S)\ll (\frac{1}{2}\eta^2M\ell)^{-1}$, the curvature simplifies to

$$
K \approx -\frac{2M}{r^3} - \frac{3}{2} \frac{M^2 \ell \eta^2}{r^2} + \mathcal{O}(\ell^2).
$$
 (53)

Using the formulation of Ref. [\[97,](#page-17-21) [99–](#page-17-23)[101\]](#page-17-24), the deflection angle is given as

$$
\hat{\alpha} = \iint_{D_O + D_S} K \, dS + \int_{P_O}^{P_S} \kappa_g \, d\mathfrak{l} + \phi_{OS},\tag{54}
$$

where D_O and D_S denote the observer and source regions, containing P_O and P_S , respectively. Here, κ_q is the geodesic curvature along the boundary and ℓ is the line element on this boundary. Substituting Eq. [\(51\)](#page-11-2) and simplifying, we derive

$$
\hat{\alpha} \approx \frac{2M}{b} \left(\sqrt{1 - b^2 u_S^2} + \sqrt{1 - b^2 u_O^2} \right) + \frac{1}{2} M^2 \ell \eta^2 \left(\frac{b u_S}{\sqrt{1 - b^2 u_S^2}} + \frac{b u_O}{\sqrt{1 - b^2 u_O^2}} \right) + \mathcal{O}(\ell^2). \tag{55}
$$

For large $r_{O,S}$, the $\ell\eta^2$ term vanishes, recovering the standard weak deflection angle $\hat\alpha\approx4M/b$ for the Schwarzschild black hole. Observations near the Sun confirm $\hat\alpha_\odot\approx1.7520$ arcsec (prograde) and $\hat\alpha_\odot\approx1.7519$ arcsec (retrograde) [\[102\]](#page-17-25), leading to parameter constraints $\ell \sim -10^{-9}$ and $\eta \sim 10^{-7} \mathrm{~m^{-1}}$ (see Fig. [10\)](#page-12-0).

FIG. 10. Parameter constraints on ℓ and η based on solar deflection angle measurements.

D. Gravitational time delay

The Shapiro time delay, often referred to as the fourth test of general relativity, represents an intriguing phenomenon with significant observational relevance. This effect, describing the delay in radar echoes of electromagnetic signals traveling near massive objects, was experimentally verified around the time it was first proposed [\[103](#page-17-26)[–105\]](#page-17-27). Additionally, recent astrophysical observations indicate that this delay also occurs for two other massless energy carriersneutrinos and gravitational wavesproviding further support for the presence of dark matter [\[106\]](#page-17-28).

In this subsection, we aim to calculate the Shapiro effect for photons passing near a black hole. Specifically, we derive the time difference between the emission and observation of a light ray sent from the point $P_1 = (t_1, r_1)$, traveling to $P_2 = (t_2, r_2)$, and returning to P_1 . The total time interval can be expressed as

$$
t_{12} = 2t(r_1, r_0) + 2t(r_2, r_0),
$$
\n(56)

where r_0 represents the point of closest approach to the central mass. Utilizing the definitions from the previous subsection, the radial velocity can be expressed as

$$
\dot{r} = \dot{t}\frac{dr}{dt} = \frac{E}{A(r)}\frac{dr}{dt},\tag{57}
$$

which allows Eq. (47) to be rewritten as:

$$
\frac{E}{A(r)}\frac{dr}{dt} = \sqrt{E^2 - \frac{L^2}{r^2}A(r)},\tag{58}
$$

for massless particles. At $r=r_0$, where the radial velocity vanishes, one finds that $b^{-2}=A(r_0)/r_0^2$. Thus, the coordinate time is given by

$$
t(r,r_0) = \int_{r_0}^r \frac{dr}{A(r)\sqrt{1 - \frac{r_0^2}{A(r_0)}\frac{A(r)}{r^2}}},
$$
\n(59)

for the segment of the journey between r_0 and r. To first-order corrections, this reduces to

$$
t(r,r_0) \approx \sqrt{r^2 - r_0^2} + t_M(r,r_0) + t_\ell(r,r_0) + t_\eta(r,r_0),
$$
\n(60)

where:

$$
t_M(r,r_0) = M \left[\sqrt{\frac{r - r_0}{r + r_0}} + 2 \ln \left(\frac{r + \sqrt{r^2 - r_0^2}}{r_0} \right) \right],
$$
\n(61a)

$$
t_{\ell}(r,r_0) = -\ell \sqrt{r^2 - r_0^2},\tag{61b}
$$
\n
$$
1 \qquad 1 \qquad \qquad \frac{1}{r-r_0} \qquad \left(\frac{r}{r} + \sqrt{r^2 - r_0^2}\right) \qquad 1 \qquad \sqrt{r} \qquad \qquad \frac{1}{r} \qquad \frac{1}{r} \qquad \qquad
$$

$$
t_{\eta}(r,r_0) = -\frac{1}{2}\ell M \eta^2 r_0^2 \left[\sqrt{\frac{r-r_0}{r+r_0}} - \ln \left(\frac{r+\sqrt{r^2-r_0^2}}{r_0} \right) \right] - \frac{1}{4}\ell M \eta^2 \left[r\sqrt{r^2-r_0^2} + r_0^2 \ln \left(\frac{r+\sqrt{r^2-r_0^2}}{r_0} \right) \right].
$$
 (61c)

The time delay Δt between the journey $P_1\to P_2\to P_1$ is defined as $\Delta t:=t_{12}-t_{12}^E$, where $t_{12}^E=2\left(\sqrt{r_1^2-r_0^2}+\sqrt{r_2^2-r_0^2}\right)$ is the travel time in Euclidean space. Substituting these expressions, we find

$$
\Delta t = \Delta t_M + \Delta t_\ell + \Delta t_\eta, \tag{62}
$$

where

$$
\Delta t_M = 2M \left[\sqrt{\frac{r_1 - r_0}{r_1 + r_0}} + \sqrt{\frac{r_2 - r_0}{r_2 + r_0}} + 2 \ln \left(\frac{\tilde{\mathfrak{t}}_{12}^E}{r_0^2} \right) \right],\tag{63a}
$$

$$
\Delta t_{\ell} = -\ell t_{12}^{E},\tag{63b}
$$

$$
\Delta t_{\eta} = -\ell M \eta^2 r_0^2 \left[\sqrt{\frac{r_1 - r_0}{r_1 + r_0}} + \sqrt{\frac{r_2 - r_0}{r_2 + r_0}} - \ln \left(\frac{\tilde{t}_{12}^E}{r_0^2} \right) \right] - \frac{1}{2} \ell M \eta^2 \left[r_1 \sqrt{r_1^2 - r_0^2} + r_2 \sqrt{r_2^2 - r_0^2} + r_0^2 \ln \left(\frac{\tilde{t}_{12}^E}{r_0^2} \right) \right], \tag{63c}
$$

and $\tilde{\mathfrak{t}}_{12}^E = \left(r_1 + \sqrt{r_1^2 - r_0^2}\right)\left(r_2 + \sqrt{r_2^2 - r_0^2}\right).$

Focusing on the solar system with $r_0 \ll r_1, r_2$, the time delay approximates to

$$
\Delta t_{\odot} \approx 4M \left[1 + \ln \left(\frac{4r_1 r_2}{r_0^2} \right) \right] - 2\ell \left(r_1 + r_2 \right) - \frac{1}{2} \ell M \eta^2 \left[r_1^2 + r_2^2 - r_0^2 \ln \left(\frac{4r_1 r_2}{r_0^2} \right) \right]. \tag{64}
$$

Substituting $M=M_\odot$ and $\ell=0$, the classical Schwarzschild limit $\Delta t_{\rm Sch}=4M_\odot\left[1+\ln\left(\frac{4r_1r_2}{r_0^2}\right)\right]$ is recovered. For typical distances, such as the Earth-Sun and Sun-Mars separations, and $r_0\,\approx\,R_\odot+(5\times10^6)$ m, $\Delta t_{\rm Sch}\,\approx\,246\,\mu\rm s.$ Measurements during the Viking mission reported an observational error of approximately $10\,\rm{ns}$ [\[107\]](#page-17-29), constraining $\ell\sim10^{-9}$ and $\eta \sim 10^{-9}\,\text{m}^{-1}$ (see Fig. [11\)](#page-14-2).

Through these results, the positive domain of the Lorentz-violating parameter ℓ aligns with the observational data. While weak gravitational lensing favors negative ℓ , the Shapiro delay supports positive ℓ , yet both yield similar orders of magnitude for their constraints.

FIG. 11. Constraints on ℓ and η from solar system time delay observations.

V. CONCLUSIONS

In this paper, we investigated the properties of a static, spherically symmetric black hole solution in a self-interacting KR field theory, minimally coupled with a global monopole constituent. The derived spacetime metric, characterized by the Lorentz-violating parameter ℓ and the monopole charge η , revealed several intriguing features, including deviations from Schwarzschild geometry and the emergence of effective topological and cosmological-like terms. Notably, the analysis of the causal structure revealed that for $\ell \leq 0$, the black hole always possesses an event horizon for any value of η , ensuring stability against horizon disappearance. However, for $\ell > 0$, horizons can merge, leading to the formation of extremal black holes, and eventually disappear, yielding naked singularities. This emphasizes the importance of ℓ in regulating the spacetime's physical structure. We then analyzed the thermodynamic behavior of the black hole for $\ell \leq 0$, observing that the contributions from the KR field and the monopole charge lead to modifications in the Hawking temperature, entropy, and Gibbs free energy. The interplay between ℓ and η was found to significantly influence the thermodynamic stability. Specifically, larger values of η enhance the Hawking temperature while decreasing the entropy for a fixed ℓ , whereas ℓ impacts the temperature and entropy in opposite ways, depending on its sign. Our solar system tests provided observational constraints on ℓ and η . These constraints were derived from, the perihelion precession of planetary orbits, where ℓ and η must satisfy the range $-0.0001\leq\ell\leq 0.0001$ for $\eta\sim 10^{-6}\,\rm m^{-1}$, gravitational redshift data, which constrained ℓ to $\sim 10^{-4}$ and η to $\sim 10^{-6}\,\rm m^{-1}$, deflection of light near the Sun, with $\ell\sim-10^{-9}$ and $\eta\sim10^{-7}\,\rm m^{-1}$, and the Shapiro time delay measurements, which aligned ℓ to $\sim10^{-9}$ and η to $\sim10^{-9}\,\rm m^{-1}.$ The results consistently demonstrated that the Lorentz-violating parameter ℓ must be exceedingly small, aligning with existing constraints on deviations from Lorentz invariance. Meanwhile, the monopole charge η , though also tightly constrained, exhibited behavior that depended critically on its interplay with ℓ . Our findings highlight the phenomenology introduced by the Lorentz-violating term and the monopole charge. The interplay of these parameters not only modifies the spacetime geometry but also imposes testable constraints, bridging theoretical predictions with astrophysical observations. In future work, we will focus on the constraints directly inferred from the black hole shadow and analyze the features imposed by incorporating an associated topological charge into the obtained black hole solution in the KR field. This study can deepen our understanding of the interplay between black hole geometry and the KR field's influence on observable phenomena.
