(Dated: January 22, 2025)

Theoretical models of self-interacting dark matter offer a promising solution to several unresolved issues within the collisionless cold dark matter framework. For asymmetric dark matter, these self-interactions may encourage gravitational collapse, potentially leading to the creation of compact objects primarily composed of dark matter. By considering both fermionic and bosonic equations of state, we analyze the equilibrium structure of non-rotating dark stars, examining their bulk properties and comparing them with baryonic neutron stars. We show that the frequency and damping rate of f-mode oscillations of dark compact stars can be expressed in terms of universal functions of stellar mass, radius and moment of inertia. Finally, by employing the universality in the f-mode, we propose a scheme to infer accurate values of the physical parameters of dark compact stars from their f-mode gravitational wave signal.

I. INTRODUCTION

The possibility that dark matter (DM) exists as particles that experience significant self-interactions is a compelling hypothesis, supported by both theoretical considerations and observational evidence. Theoretically, if the dark sector is part of a unified framework in theories extending beyond the Standard Model, it is plausible that DM particles interact among themselves through certain gauge bosons. Additionally, DM self-interactions might be necessary given that the current collisionlesss cold dark matter (CCDM) paradigm appears to be inconsistent with some observations.

There are three primary challenges facing the CCDM model. Firstly, the DM density profile at the centers of dwarf galaxies tends to be flat, whereas CCDM simulations predict a cuspy profile [1, 2]. Observations of rotation curves in these galaxies suggest a discrepancy. Secondly, CCDM simulations forecast a greater number of satellite galaxies around the Milky Way than what is observed, as pointed out in Refs. [1, 3, 4]. Thirdly, there is the *too big to fail* problem, where simulations predict massive dwarf galaxies that should have formed observable stars, yet these galaxies are not detected [5].

In Refs. [6–8], the authors explore how these discrepancies might be mitigated by considering DM-baryon interactions or statistical anomalies in the Milky Way's satellite population. Another plausible solution is substantial DM self-interactions, which could address all three problems [9–11]. For instance, DM self-interactions could enhance self-scattering rates in regions with high DM density, leading to flattened density profiles in dwarf galaxy cores.

The study of DM self-interactions has been extensive, with research exploring various contexts (cf., e.g., Refs. [10–14]). Generally, it is believed that DM selfinteraction cross-sections within the range of $0.1 \text{ cm}^2/\text{g}$ $< \sigma_{\rm XX}/m_{\rm X} < 10 \ {\rm cm}^2/{\rm g}$ (where $\sigma_{\rm XX}$ is the DM selfinteraction cross section and $m_{\rm X}$ is the DM particle mass) are sufficient to resolve the challenges faced by the CCDM paradigm.

DM self-interactions can be a valuable feature, potentially aiding the clumping of DM and the formation of compact objects, especially if these interactions are dissipative or accelerate gravothermal evolution [15]. Two primary scenarios arise based on the nature of DM annihilation events: one involves DM with significant annihilation events, and the other involves DM with minimal annihilation events. The weakly interacting massive particle (WIMP) paradigm fits into the first category. In this model, the DM relic density in the Universe is determined by DM annihilations. Initially, DM is in thermal equilibrium with the primordial plasma until the rate of annihilations falls below the Universe's expansion rate. In the WIMP framework, DM particles and antiparticles are present in equal numbers. Gravitational collapse in this scenario could lead to the formation of dark stars, which, according to Refs. [16–18], counteract further collapse through radiation pressure. However, such stars likely no longer exist because DM annihilations would have significantly reduced the DM population, causing these dark stars to vanish over time.

Conversely, asymmetric DM presents a viable pathway for forming compact, stable starlike objects. This scenario serves as a compelling alternative to the WIMP paradigm, and it is well motivated [19–27]. In asymmetric DM models, a conserved quantum number, analogous to the baryon number, plays a crucial role. A mechanism similar to that which generated the baryon asymmetry in the Universe could also produce a particle-antiparticle asymmetry in the DM sector. Annihilations in this scenario would eliminate the species with fewer numbers, leaving an excess population that accounts for the DM relic density. In the asymmetric DM framework, substantial annihilations do not occur today due to the absence of DM antiparticles. Therefore, if DM self-interactions can promote collapse, asymmetric DM could form stable compact objects that might still be detectable today.

The potential for asymmetric DM to form com-

pact objects has been explored for both fermionic and bosonic DM, for example in Refs. [28–30]. These papers have investigated the mass-radius relations, density profiles, and maximum Chandrasekhar mass limits across a broad spectrum of DM particle masses and self-coupling strengths, considering both attractive and repulsive interactions. An equation of state (EoS) for asymmetric dark matter, incorporating both attractive and repulsive interactions, has also been constructed in Ref. [31]. In that work, equilibrium sequences and maximum masses of asymmetric dark matter stars are identified, and the stability of neutron stars containing fermionic asymmetric dark matter with an attractive force is evaluated. Additionally, Maselli et al. [32] investigate the structure of slowly rotating and tidally deformed stars, modeled with a DM equation of state based on fermionic and bosonic DM particles, and they show that these dark objects admit the I-Love-Q universal relations, which link their moment of inertia, tidal deformabilities and quadrupole moments.

In particular, tidal effects on binary stars are measurable in the late inspiral stage [33–35]. Further, the measurement of tidal deformations can be used to extract information about the internal structure of NSs [36–39]. Wahidin and Sulaksono study the tidal deformation of binary dark stars composed of fermionic dark matter, exploring the effect of dark particle mass and scalar boson coupling exchange on the EoS, mass-radius relation and tidal Love number properties [40].

The effects of dark matter on the tidal deformability have been explored also in the case of admixed neutron stars. The presence of a DM core with a mass fraction 5% could affect significantly the interpretation of NS data as constraints on the nuclear EoS [41]. A more recent work on the tidal deformability of dark matter admixed neutron stars can be found in Ref. [42]. The impact of asymmetric fermionic dark matter on the thermal evolution of dark matter admixed neutron stars is discussed in Ref. [43].

Ellis *et al.* [44] analyse the impact of dark matter on gravitational wave signals from a binary merger and find that dark matter cores in merging neutron stars may yield an observable supplementary peak in the gravitational wave power spectral density following the merger.

In astrophysics, it is customary to develop models of compact stars and establish correlations among various physical quantities deducible from astronomical observations which are known as *universal relations* or *asteroseismological relations* (in case they contain seismological quantities such as mode frequency and/or damping time). This approach is motivated by the potential to constrain the EoS for nuclear matter and extract physical parameters of compact stars. Andersson and Kokkotas [45] published the seminal paper opening up the field of gravitational wave asteroseismology in which they propose the first asteroseismological relations for oscillation modes of neutron stars. Similar universal relations involving the f-mode frequency and damping time have been proposed subsequently [46–48], some of which also were concerned with rotating neutron stars [49–52]. Numerous universal relations that correlate bulk quantities other than mode properties have also been discovered, see, e.g., Refs. [53–59].

There are several avenues for measuring f-mode characteristics in compact stars. For example, it is expected that third-generation detectors such as Einstein Telescope [60] or Cosmic Explorer [61] will have the necessary sensitivity for such observations [62, 63]. At the current time, an estimate for the f-mode frequency may be obtained via the f-Love relations [64], as the tidal deformability Λ is accessible during the late inspiral of a binary system [65, 66]. Furthermore, the f-mode frequency and damping time can be linked to the moment of inertia I; this quantity may be measurable, e.g., by analyzing spinorbit coupling effects in double pulsar systems [54, 67].

In this paper we present previously proposed relations for NSs involving the f-mode characteristics, which have been reconsidered in different contexts due to being fundamental to the field [45–47, 68], and we investigate the accuracy of these relations for isolated stars composed of DM. We consider static, spherically symmetric objects, modeled with a DM EoS based on fermionic and bosonic DM particles. We show that these dark stars do not follow the same universal relations that hold true for a large variety of NS EoSs, and consequently we propose new universal relations for dark stars. Based on these universal relations, we propose a scheme to determine the mass, radius and moment of inertia of a dark compact star once its f-mode frequency is found from GW observations.

The paper is organized as follows: In Sec. II we describe the main properties of the two classes of EoSs considered, and we analyze the bulk properties of the stellar models, such as masses and radii, through their massradius profiles. In Sec. III A we investigate the accuracy of previously proposed relations between stellar pulsation frequencies and stellar parameters, and we propose new universal relations for dark stars. In Sec. III B we do the same as in the previous section, but for relations involving stellar pulsation damping times and stellar parameters. In Sec. III C we consider the two universal relations proposed by Chan et al. [64] and Kuan et al. [69], which relate the f-mode frequency to the tidal deformability Λ , testing their applicability to DM stars and, consequently, proposing alternative relations for these models. In Sec. IV we suggest a feasible scheme to apply our findings reported in Sec. III to estimate the mass, radius and moment of inertia of a dark compact star if its f-mode GW signal is detected. We finally summarize our paper in Sec. V and provide some conclusions. Throughout the whole work we use units in which c = G = 1, unless otherwise specified.

FIG. 1. Mass-radius profiles for the neutron star EoSs used in this work. The curves start at $M = 0.5 M_{\odot}$, and extend to the last stable or causal model. For some EoSs, the maximal mass model is not determined by stability, i.e. $\frac{\partial M}{\partial \epsilon_c} = 0$, but by causality as the speed of sounds becomes superluminal already at lower ϵ_c (in our case APR4, ENG, and WFF1).

II. DARK MATTER EQUATION OF STATE

In this section, we describe the most important features of the dark matter EoS used in this paper to model fermion and boson stars. In particular, we adopt the same EoSs considered by Maselli *et al.* [32].

Moreover, in our analysis we will also consider the piecewise polytropic approximations [70] to 6 neutron star EoSs (APR4 [71], SLy [72], H4 [73], WFF1 [74], ALF2 [75], ENG [76]), which will allow one to make a direct comparison between the macroscopic features of baryonic and dark objects. The mass-radius profiles obtained by using the aforementioned EoSs are shown in Fig. 1. The curves start from light stars with a mass of $M = 0.5 M_{\odot}$, and extend to the last stable model. However, with some EoSs, the curves do not reach the neutron star model for which $\frac{\partial M}{\partial \epsilon_c} = 0$, because the EoS becomes acausal already at lower energy densities. We show the pressure vs. energy density relations of these EOSs in Figs. 2 and 4 along with the dark matter relations; see the following two subsections.

A. Fermion star

We consider a fermionic particle interacting via a repulsive Yukawa potential, e.g., due to a massive dark photon [29]

$$V(r) = \alpha_{\rm X} \frac{e^{-\hbar m_{\phi} r}}{r},\tag{1}$$

where α_X is the dark fine structure constant, \hbar the reduced Planck constant and m_{ϕ} is the mass of the mediator.

FIG. 2. Relation between pressure p and energy density ϵ for the fermionic dark matter EOSs employed in this study, which are shown in different shades of yellow and red. For comparison, we also show the relations of six nuclear matter EOSs in shades of blue with dashed lines.

Models incorporating a Yukawa potential are particularly valuable in the study of self-interacting DM, as they effectively suppress the scattering cross section at high relative velocities, as shown in Ref. [77]. This characteristic preserves the viability of collisionless cold DM on supergalactic scales while simultaneously addressing the flattening of subgalactic structures.

Pressure in fermion stars has two contributions: one from Fermi repulsion and one due to the Yukawa interactions. By calculating the energy density and pressure due to Yukawa interactions in the mean field approximation, the EoS is given by two implicitly related equations:

$$\epsilon(x) = \frac{m_{\rm X}^4 c^3}{\hbar^3} \left[\xi(x) + \frac{2}{9\pi^3} \frac{\alpha_{\rm X}}{\hbar c} \frac{m_{\rm X}^2}{m_{\phi}^2} x^6 \right], \qquad (2)$$

$$P(x) = \frac{m_{\rm X}^4 c^5}{\hbar^3} \left[\chi(x) + \frac{2}{9\pi^3} \frac{\alpha_{\rm X}}{\hbar c} \frac{m_{\rm X}^2}{m_{\phi}^2} x^6 \right], \qquad (3)$$

where $x \equiv p_{\rm F}/(m_{\rm X}c)$ is a dimensionless quantity that measures the Fermi momentum compared to the DM mass. The functions ξ and χ are the contributions from Fermi repulsion, given by

$$\xi(x) = \frac{1}{8\pi^2} \left[x\sqrt{1+x^2}(2x^2+1) - \ln\left(x+\sqrt{1+x^2}\right) \right],$$

$$\chi(x) = \frac{1}{8\pi^2} \left[x\sqrt{1+x^2}(2x^2/3-1) + \ln\left(x+\sqrt{1+x^2}\right) \right].$$

Both pressure and density are smooth monotonic functions of the parameter x. We show the resulting pressure vs. energy density relations in Fig. 2.

Hereafter, we will vary the three parameters that fully specify fermion stars in the ranges $\alpha_{\rm X}/(\hbar c) \equiv \alpha =$ $(10^{-3}, 10^{-2}), m_{\phi} = (8, 10, 12)$ MeV and $m_{\rm X} = (1, 2)$

FIG. 3. Mass-radius profiles for fermionic dark matter stars with $\alpha = (10^{-3}, 10^{-2})$, dark particle mass $m_{\rm X} = (1,2)$ GeV, and mediator mass $m_{\phi} = (8, 10, 12)$ MeV. The curves start at $M = 0.5 M_{\odot}$, and extend to the last stable model; they are shown in different shades of yellow and red. For comparison, we also show the mass-radius curves of six nuclear matter EoS in shades of blue.

GeV. The mass-radius relations for all our models are presented in Fig. 3. We use a specific identifier for fermionic EoS that contains the three parameters $m_{\rm X}$, m_{ϕ} , and α . Exemplarity, the EoS specified by the parameter set $m_{\rm X} = 1 \,{\rm GeV}, m_{\phi} = 10 \,{\rm MeV}$ and $\alpha = 10^{-2}$ will be labeled as "x1 ϕ 10 α 0.01". Each point of the plot is obtained, for a given EoS, by varying the star's central pressure and solving the well-known Tolman-Oppenheimer-Volkoff equations with that value of the central pressure and the corresponding central energy density. It can be seen that, for a fixed value of the radius, increasing values of $m_{\rm X}$ significantly reduce the mass, resulting in less compact objects. Similarly, variations in the mediator mass m_{ϕ} yield substantial changes in the same direction as $m_{\rm X}$. In the same plot, we include also the mass-radius profiles of the baryonic EoS considered in this study. We note that there are overlapping regions between fermion stars and baryonic matter profiles, suggesting the potential for similar configurations. However, baryonic EoSs typically exhibit steeper slopes, resulting in greater variations of the compacteness C = M/R of the corresponding neutron star models.

B. Boson star

Boson stars are inherently smaller than their fermionic counterparts because they lack Fermi pressure to counterbalance their self-gravity. In the absence of selfinteractions, boson stars rely on quantum mechanical pressure arising from the uncertainty principle for stabilization. However, unless the bosons are exceptionally lightweight, this pressure is naturally minimal and can

FIG. 4. Same as Fig. 2 but for the bosonic dark matter EoSs.

only support small concentrations of matter. Introducing self-interactions would allow a boson star to achieve a size comparable to that of a fermion star.

In this work, we consider boson star models whose EoS was first derived in Ref. [78], and it is given by

$$P = \frac{c^5}{9\hbar^3} \frac{m_{\rm X}^4}{\beta} \left(\sqrt{1 + \frac{3\hbar^3}{c^3} \frac{\beta\epsilon}{m_{\rm X}^4}} - 1 \right)^2, \qquad (4)$$

where $m_{\rm X}$ is the boson mass and β is a dimensionless coupling constant. We show the pressure vs. energy density graphs of the employed bosonic EoSs in Fig. 4 and the mass-radius profiles for bosonic dark matter stars in Fig. 5. For bosonic EoS, we use the following identifier containing $m_{\rm X}$ and β : the EoS specified by the parameter set $m_{\rm X} = 400$ MeV, $\beta = 0.5\pi$ will be labeled as "x400 $\beta 0.5\pi$ ". Two values of the boson mass are considered, $m_{\rm X} = (300, 400)$ MeV, as well as three different values of the coupling parameter $\beta = (0.5, 1.0, 1.5)\pi$. It is observed that stronger couplings result in larger radii for a given mass, thereby yielding less compact objects. A similar trend, albeit more pronounced, is evident when considering lighter dark particles. Even in the case of boson stars, the curves exhibit a smoother slope compared to those derived for standard nuclear matter. Finally, we note that stellar models constructed with the bosonic dark matter EoSs considered in this work exhibit self-similar symmetries. Namely, the shape of the massradius relation is independent of EoS parameters such as the mass of the dark particle $m_{\rm X}$ or the coupling parameter β . A proof of this feature can be found in Ref. [32] and is also outlined in App. B of the present work.

FIG. 5. Mass-radius profiles for bosonic dark matter stars with different values of the coupling constant $\beta = (0.5, 1.0, 1.5)\pi$ and boson mass $m_{\rm X} = (300, 400)$ MeV. The curves start at $M = 0.5 M_{\odot}$, and extend to the last stable model. For comparison, we also show the mass-radius curves of six nuclear matter EOS in shades of blue.

III. UNIVERSAL RELATIONS

A. Frequency relations of the *f*-mode

Compact star pulsations can lead to GW emission. Since GWs carry away energy, they act as a damping mechanism. In a perturbative approach the pulsations are treated as damped linear oscillations, which are analyzed in terms of quasi-normal modes (QNMs). This ansatz assumes an $e^{i\omega t}$ time dependency, where ω is the complex-valued eigenfrequency of the QNM. The complex nature of the eigenfrequency accounts for the damping. It reads

$$\omega = 2\pi f + \frac{i}{\tau},\tag{5}$$

where f is the pulsation frequency and τ the damping time of the oscillation.

We focus on the fundamental f-mode whose frequencies we determine using the code presented in Ref. [79].

In the considered case of isolated, static stars, many relations have been proposed relating the fundamental frequency f to stellar parameters such as the mass M, radius R, moment of inertia I and tidal deformability $\Lambda = \frac{2}{3}k_2(\frac{c^2R}{GM})^5$. They exhibit a different level of accuracy.

A very well known relation was proposed by Andersson and Kokkotas [45] between f and the mean density of the star, and reads

$$\frac{f}{\mathrm{kHz}} \approx 0.22 + 32.16\sqrt{\frac{M}{R^3}}.$$
(6)

This relation is shown as a light-blue dashed-dotted line in Fig. 6. Years later, Lioutas, Bauswein and Stergioulas

FIG. 6. The numerically obtained f-mode frequencies plotted as a function of the mean stellar density. Orange symbols represent fermionic dark matter stars with $\alpha = 10^{-3}$, dark particle mass $m_{\rm X} = (1,2)$ GeV, and mediator mass $m_{\phi} = (8,10,12)$ MeV. Green symbols stand for bosonic dark matter stars with coupling constant $\beta = (0.5, 1.0, 1.5)\pi$ and boson mass $m_{\rm X} = (300, 400)$ MeV. Light-blue symbols show the behaviour of the NS stellar models chosen for comparison. The light-blue dashed-dotted curve corresponds to the universal relation for the f-mode frequency of Andersson and Kokkotas [45] described in Eq. (6), while the relation by Lioutas *et al.* [51] reported in Eq. (7) is shown with a light-blue solid curve. Our best linear fits to fermionic (Eq. (9)) and bosonic (Eq. (8)) dark matter models are represented by an orange and a green line, respectively.

proposed a relation also employing the star's average density in Ref. [51], but based on a second-order fit to their data for NSs, namely

$$\frac{f}{\rm kHz} \approx -0.133 + 47.23\sqrt{\frac{M}{R^3}} - 173.2\frac{M}{R^3}.$$
 (7)

Equation (7) is represented with a light-blue solid line in Fig. 6. In the same figure, we include some NS data points (light-blue) with the purpose of getting a visual impression of how the NS data scatter around the corresponding universal relations. Green points represent instead bosonic dark matter stars obtained by varying the stellar central energy density, as well as the EoS parameters. Specifically, the dark boson mass is varied in the range $m_{\rm X} = (300, 400)$ MeV, while the coupling constant assumes the values $\beta = (0.5, 1.0, 1.5)\pi$. Finally, orange data points correspond to fermionic dark matter stars whose EoSs is determined by a dark particle mass $m_{\rm X} =$ (1.0, 2.0) GeV, a mediator mass $m_{\phi} = (8, 10, 12)$ MeV and a fixed value of the dark fine structure constant, set to $\alpha_{\rm X}/(\hbar c) \equiv \alpha = 10^{-3}$. From these results we can infer that the dark matter EoSs considered in this work do not follow the relation proposed by Andersson and Kokkotas for NSs, but they seem instead to distribute along straight lines, with two well-defined slopes, one for bosonic models and one for fermionic ones. Consequently, we perform a linear fit on our bosonic dark matter's data points, obtaining

$$\frac{f}{\rm kHz} \approx -0.01461 + 42.11 \sqrt{\frac{M}{R^3}}.$$
 (8)

As regards fermionic dark matter models, the result of a linear fit is

$$\frac{f}{\rm kHz} \approx 0.06661 + 38.97 \sqrt{\frac{M}{R^3}}.$$
 (9)

Both the equations fit the given data points with a relative error smaller than 2%. As shown in Table I, comparing the values of the *f*-mode frequency with the estimates given by the universal relations (6) and (7) for a variable mean stellar density in the range $\sqrt{M/R^3} \in$ [0.055, 0.075], the DM values deviate from the fit by Andersson and Kokkotas [45] by more than 10%, and by more than 14% in the case of the fit by Lioutas *et al.* [51].

Another relation exploring the connection between the f-mode frequency and the star's moment of inertia was discussed by Lau *et al.* [46]. In particular, arguing that the moment of inertia I is sensitive to the matter distribution within the star, they defined an effective compactness $\eta \equiv \sqrt{M^3/I}$. In this way, they accounted for the different density profiles of neutron stars and quark stars, which prevented the previously suggested relations from being applicable to quark stars. The relation proposed by Lau *et al.* is a quadratic expression in η of the form:

$$M\omega_r \approx -0.0047 + 0.133\eta + 0.575\eta^2, \tag{10}$$

where $\omega_r \equiv 2\pi f$. We note that Eq. (10) is slightly different from the corresponding Eq. (6) of Ref. [46], as the latter contained a typo in the coefficient of the quadratic term.

This relation is shown as a light-blue solid curve in Fig. 7. Comparing the curve with data points for NSs (light-blue), bosonic DM models (green) and fermionic DM models (orange) it is clear that this relation fits nicely every type of EoS considered.

B. Damping time relations of the *f*-mode

Andersson and Kokkotas [45] proposed also a universal relation for the damping time τ of the *f*-mode. They estimated the characteristic damping time based on the quadrupole formula, namely

$$\tau \sim \frac{\text{oscillation energy}}{\text{power emitted in GW}} \sim \frac{R^4}{M^3},$$

thus finding a relation which reads

$$\frac{R^4}{M^3 \tau} \approx 0.08627 - 0.2676 \frac{M}{R}.$$
 (11)

FIG. 7. The mass-scaled real part of the *f*-mode frequency $\omega_r = 2\pi f$ is plotted against the effective compactness $\eta = \sqrt{M^3/I}$. The blue curve represents the universal relation proposed by Lau *et al.* [46] and corresponds to Eq. (10). Green, orange and blue points correspond to stellar models as described in Fig. 6.

Equation (11) is represented as a light-blue dasheddotted line in Fig. 8.

In Ref. [48], Lioutas and Stergioulas extended the relation found by Andersson and Kokkotas to higher order. They found that their numerical data for τ are described very accurately by the following universal relation

$$\frac{R^4}{M^3\tau} \approx 0.112 - 0.53\frac{M}{R} + 0.628\left(\frac{M}{R}\right)^2.$$
 (12)

As can be seen in Fig. 8, although this quadratic relation in M/R (light-blue solid line) fits well the neutron stars' points, it fails to represent the behaviour of bosonic (green) and fermionic (orange) dark matter models, which clearly display, again, a linear distribution. A linear fit to the bosonic DM models gives

$$\frac{R^4}{M^3\tau} \approx 0.1105 - 0.3764 \frac{M}{R},\tag{13}$$

while in the fermionic case we find

$$\frac{R^4}{M^3\tau} \approx 0.1126 - 0.3930 \frac{M}{R}.$$
 (14)

As usual, the two new relations are represented in Fig. 8 via green and orange lines for the bosonic and fermionic dark matter case, respectively. The relative error is less than 0.5% in the former case, and less than 4% in the latter.

Another relation for the f-mode damping time was proposed by Lau et al. [46]. Their quadratic expression in η reads

$$\frac{I^2}{M^5}\omega_i \approx 0.00694 - 0.0256\eta^2 \tag{15}$$

TABLE I. Relative errors in the estimate of the f-mode frequency obtained by using universal relations. We specify the dark matter EoS in the first column, the mean stellar density $\sqrt{M/R^3}$ in the second, and the numerical value of the f-mode frequency in the third. Moreover, column four and five correspond to the estimate of f obtained by using the universal relation by Anderson and Kokkotas of Eq. (6) and its relative error with respect to the true value, respectively. The behaviour of the dark matter EoS is not well represented by this universal relation, as the relative error is always greater than 10%. In the last two columns, we show the estimate and relative error for the case of the universal relation by Lioutas *et al.* [51] of Eq. (7). The relative error in the estimate of f is grater than 14%.

EoS	$\sqrt{\frac{M}{R^3}}$	f	$f_{\rm AK}$	$\frac{ f-f_{\rm AK} }{f}$	$f_{\rm LBS}$	$\frac{ f-f_{\rm LBS} }{f}$
$x2 \phi 8 \alpha 0.001$	0.064	2.541	2.280	0.103	2.181	0.141
x2 ϕ 8 $\alpha 0.001$	0.071	2.788	2.489	0.107	2.337	0.162
x2 $\phi10~\alpha0.001$	0.069	2.749	2.424	0.118	2.290	0.167
x2 $\phi12~\alpha0.001$	0.066	2.666	2.329	0.126	2.219	0.167
x400 $\beta 0.5\pi$	0.057	2.357	2.063	0.125	2.005	0.150
x400 $\beta 0.5\pi$	0.068	2.821	2.406	0.147	2.277	0.193
x400 $\beta 1.0\pi$	0.058	2.427	2.075	0.145	2.015	0.169

FIG. 8. The normalized damping time of the *f*-mode as a function of the stellar compactness. The universal relation of Eq. (11) proposed by Andersson and Kokkotas [45] is shown as a light-blue dashed-dotted line. The blue curve corresponds to Eq. (12), namely to the universal relation of Lioutas and Stergioulas [48]. The best linear fits to our bosonic (cf. Eq. (13)) and fermionic (cf. Eq. (14)) dark matter stellar models are represented with a green and an orange line, respectively. Green, orange and blue points represent stellar models as described in Fig. 6.

where $\eta \equiv \sqrt{M^3/I}$ and $\omega_i \equiv 1/\tau$. This relation can be found in Fig. 9 as a light-blue curve, together with NS data points (blue), bosonic (green) and fermionic (orange) stellar models. While the data points referring to NSs fall on the aforementioned relation with high accuracy, the dark models seem to follow different patterns. More precisely, their distributions suggest that bosonic and fermionic EoSs might be characterised by their own linear universal relations. By performing a linear fit to the data, we find that an expression in η of the form

$$\frac{I^2}{M^5}\omega_i \approx 0.006858 - 0.03105\eta^2 \tag{16}$$

yields the best linear fit to the bosonic distribution, while the formula

$$\frac{I^2}{M^5}\omega_i \approx 0.006604 - 0.02521\eta^2 \tag{17}$$

gives the best linear fit to the fermionic data points. Eq. (16) and (17) are shown in Fig. 9 with a green and an orange line, respectively. We observe that a fit of the linear type works nicely, and with high accuracy. In particular, the relative error is less than 0.5% in the bosonic dark matter case, and less than 2% in the fermionic one.

C. Tidal Love Numbers

The dark stars considered in this study may exist also in binary systems, other than as isolated entities. These stars might generate GW signals that differ from those produced by black hole binaries. The EoS leaves a distinctive mark on the signals emitted during binary mergers, primarily influenced by adiabatic tidal interactions. These interactions are defined using a series of coefficients known as Love numbers, calculated under the assumption that tidal effects arise from an external, timeindependent gravitational field. The primary contribution k_2 , which corresponds to a quadrupolar deformation, is defined by the following relation [34, 35]

$$Q_{ij} = \frac{2}{3}k_2 R^5 \xi_{ij} = \Lambda \xi_{ij}, \qquad (18)$$

where ξ_{ij} is the external tidal tensor and Q_{ij} is the (tidally deformed) star's quadrupole tensor. The Love number k_2 or, equivalently, the tidal deformability Λ , depends solely on the star's EoS.

FIG. 9. $\omega_i I^2/M^5$ is plotted against η^2 (i.e. M^3/I). The universal relation for the imaginary part of *f*-mode proposed by Lau *et al.* [46] is shown as a blue line (see Eq.(15)). The green line represents the best linear fit to our bosonic dark matter models, namely Eq. (16). The orange line is the best linear fit to the fermionic dark matter stars and corresponds to Eq. (17). Green, orange and blue points represent stellar models as described in Fig. 6.

FIG. 10. Tidal deformability Λ vs. central energy density ϵ_c for the bosonic dark matter EoSs considered in this study. The EoSs are labelled according to the value of their coupling constant $\beta = (0.5, 1.0, 1.5)\pi$ and boson mass $m_{\rm X} = (300, 400)$ MeV. For each curve, the lowest value of Λ corresponds to the tidal deformability of the last stable model, while the highest value identifies a stellar model with mass equal to $M = 0.5 M_{\odot}$.

Figure 10 shows the behaviour of the tidal deformability Λ as a function of the central energy density ϵ_c for the bosonic dark matter EoS considered in this study. For each curve, the lowest value of Λ corresponds to the tidal deformability of the last stable model, while the highest value identifies a stellar model with mass equal

FIG. 11. Tidal deformability Λ vs. central energy density ϵ_c for the fermionic dark matter EoSs considered in this study. The EoSs are labelled according to the value of their fermion mass $m_{\rm X} = (1,2)$ GeV and the mass of the mediator $m_{\phi} = (8, 10, 12)$ MeV. The fine structure constant is fixed at $\alpha = 10^{-3}$. For each curve, the lowest value of Λ corresponds to the tidal deformability of the last stable model, while the highest value identifies a stellar model with mass equal to $M = 0.5 M_{\odot}$.

to $M = 0.5 M_{\odot}$. It can be seen that Λ decreases a lot as the central energy density of the star is increased. For a given value of ϵ_c , the tidal deformability Λ decreases as the dark matter coupling constant β is increased, while bigger values of the dark particle mass $m_{\rm X}$ give the opposite effect.

Universal relations exploring the connection between the f-mode frequency f and the tidal deformability Λ have been proposed by Chan *et al.* [64] and also by Kuan *et al.* [69]. In order to investigate the validity of those universal relations for the case of bosonic dark matter, we select values of Λ in the range from 400 to 15000. Indeed, within this range, each bosonic dark matter EoS can provide stable stellar models heavier than 0.5 M_{\odot} .

Similarly, Fig. 11 shows the behaviour of the tidal deformability Λ as a function of the central energy density ϵ_c for some fermionic dark matter EoSs. For each curve, the lowest value of Λ corresponds to the tidal deformability of the last stable model, while the highest value identifies a stellar model with mass equal to $M = 0.5 M_{\odot}$. We observe that the value of Λ increases when the mediator mass m_{ϕ} is increased. A similar behaviour for Λ is obtained by increasing the mass of the dark fermion m_X . Given the results shown in Fig. 11, we choose to investigate the validity of Chan and Kuan's relations (see Refs. [64, 69]) in a range of values of $\Lambda \in [100, 12000]$, which provides stable stellar models heavier than $M = 0.5 M_{\odot}$.

The universal relation proposed by Chan *et al.* [64] establishes a connection between the mass-scaled f-mode

FIG. 12. The mass-scaled f-mode frequency is plotted against the tidal deformability Λ . The curve represents the universal relation established by Chan *et al.* [64], and reported in Eq. (19). Green, orange and blue points represent stellar models as described in Fig. 6.

FIG. 13. The radius-scaled f-mode frequency is plotted against the tidal deformability Λ . The curve represents the universal relation established in Kuan *et al.* [69] and reported in Eq. (20). The universal relation for fermionic dark matter found in this paper is shown as an orange curve, which corresponds to Eq. (21). Bosonic dark matter is best represented by Eq. (22), which is displayed as a green curve. Green, orange and blue points represent stellar models as described in Fig. 6.

 $reads^1$

$$\log\left(\frac{f}{\rm kHz}\frac{M}{M_{\odot}}\right) = 0.814 - 0.050(\log(\Lambda)) - 0.035(\log(\Lambda))^2.$$
(19)

The relation above is shown in Fig. 12 with a purple curve. We observe that the given relation applies not only to NS models, but also fits the behavior of dark bosonic and fermionic stars nicely.

Additionally, another relation between the radiusscaled f-mode frequency and Λ was found by Kuan *et al.* [69], and this is given by

$$\log\left(\frac{f}{\rm kHz}\frac{R}{\rm km}\right) = 1.409 + 0.013(\log(\Lambda)) - 0.013(\log(\Lambda))^2.$$
(20)

Kuan's relation is shown in Fig. 13 as a light-blue curve. It can be seen that fermionic and bosonic dark matter models do not follow Eq. (20). For this reason, we propose other quadratic fits for the radius-scaled fmode frequency. The best fit to fermionic dark matter data reads

$$\log\left(\frac{f}{\mathrm{kHz}}\frac{R}{\mathrm{km}}\right) = 1.503 - 0.0311(\log(\Lambda)) - 0.00672(\log(\Lambda))^2.$$
(21)

The relative error of Eq. (21) with respect to the stellar models considered is smaller than 1%.

Bosonic dark matter data are best fitted by the following relation instead

$$\log\left(\frac{f}{\rm kHz}\frac{R}{\rm km}\right) = 1.572 - 0.0652(\log(\Lambda)) - 0.00275(\log(\Lambda))^2,$$
(22)

which reproduces the behaviour of the given data with a relative error smaller than 1%.

IV. INVERSION SCHEME

Assuming that both the oscillation frequency f and the damping time τ of the f-mode of a dark star have been obtained from GW observations, we can combine the universal relations outlined in this paper to estimate some macroscopic properties of the star. For example, by solving Eq. (10) together with Eq. (16), we might estimate the mass M and the moment of inertia I of a bosonic dark matter star. Analogously, by combining Eq. (10) and Eq. (17), an estimate of the mass M and the moment of inertia I of a fermionic dark matter star can be obtained. Let us write Eq. (10) in the general form

$$M\omega_r = a_1 + a_2\eta + a_3\eta^2, \tag{23}$$

frequency of NSs and their tidal deformability Λ , and

 $^{^1}$ Here and in the following, we denote with "log" the decadic logarithm.

FIG. 14. An illustration of how accurately the moment of inertia and the mass of a bosonic dark matter star can be inferred from detected f-mode data and universal relations of Eqs. (10) (purple curve) and (16) (green curve). The true values of the BDM model considered are represented with a black point. The universal relation for the damping time of FDM stars of Eq. (17) is also included (orange curve) for comparison, as well as Eq. (15) (light-blue curve) for the damping time of NS models.

where $a_1 = -0.0047$, $a_2 = 0.133$ and $a_3 = 0.575$. We then isolate M on the left-hand side of the equation, so that we get

$$M = \frac{a_1}{\omega_r} + \frac{a_2}{\omega_r}\eta + \frac{a_3}{\omega_r}\eta^2.$$
 (24)

Moreover, since Eq. (16) and (17) have the same structure and differ only in the values of the coefficients, let us consider the general form

$$\frac{I^2}{M^5}\omega_i = b_1 + b_2\eta^2 \tag{25}$$

where b_1 and b_2 are coefficients that depend on the specific type of matter considered, and whose values are summarized in Table II.

We isolate the mass on the left-hand side, rewriting Eq. (25) as

$$M = \frac{b_1}{\omega_i}\eta^4 + \frac{b_2}{\omega_i}\eta^6.$$
 (26)

By substituting the value of M from Eq. (24) on the left-hand side of Eq. (26), we get an estimate of the effective compactness $\eta = \sqrt{M^3/I}$, which can then be plugged back into Eq. (24) to evaluate the mass M and the moment of inertia I of the source of the measured f-mode frequency.

A graphical solution to the system of Eqs. (24) and (26) is shown in Fig. 14 for the case of a bosonic dark matter model, where the two equations are represented with a

purple and a green curve, respectively. One should note that these curves represent an ideal case, while the lines would be thicker if uncertainties were taken into account. The intersection point of the two curves corresponds to the estimates of the mass M and moment of inertia I of a bosonic source that can be achieved by using the universal relations (24) and (26), with values for the coefficients a_1, a_2, a_3, b_1, b_2 given by those of Eq. (10) and (16). In order to compare the estimates with the true values of the bosonic dark matter model of which we assume to have measured the f-mode frequency and damping time, we plot the model's mass versus effective compactness $\eta = \sqrt{M^3/I}$ as a black point. It can be seen that the inversion scheme based on the universal relations provides a very good estimate of the stellar parameters.

In principle, assuming to have measured the f-mode frequency and damping time of a source, we would like to be able to infer the type of matter it is composed of, namely to distinguish between neuron matter, bosonic and fermionic dark matter. In order to explore the feasibility of the idea, we add two more curves to Fig. 14, corresponding to the universal relation for the f-mode damping time of neutron matter of Ref. [46] (cf. Eq. (15)) in light-blue and to our newly determined Eq. (17) for the damping time of fermionic dark matter in orange, respectively. We can see from Fig. 14 that extremely accurate measurements of the f-mode are necessary in order to distinguish between the different types of matter.

So far, we have only considered the universal relations provided by Lau et al. in Ref. [46] and similar ones obtained by finding the best linear fits to bosonic and fermionic dark matter models. However, the universal relations by Andersson and Kokkotas [45] can also be used to estimate some macroscopic properties of a compact star. Indeed, assuming to have measured the fmode frequency and damping time of oscillations of a given neutron star, we might combine Eqs. (6) and (11)to estimate the radius R and the compactness M/R of the source and, consequently, also its mass M. If the source is a bosonic DM model instead, we could apply the same procedure, but considering Eqs. (8) and (13). Finally, if the source is a fermionic DM model, the inversion scheme should be applied to Eqs. (9) and (14). Since the inversion scheme is the same for all types of matter considered (i.e., neutron matter, bosonic dark matter, or fermionic dark matter), differing only in the coefficients of the universal relations that depend on the matter type, we present below a possible inversion procedure using general forms for the equations. The specific values assumed by the coefficients in case of neutron, bosonic and fermionic dark matter are then reported in Table III. The system of equations to be solved is given by the general form of the Andersson and Kokkotas universal relations of Eqs. (6) and (11), namely

$$\begin{cases} f = c_1 + c_2 \sqrt{\frac{M}{R^3}}, \\ \frac{R^4}{M^3 \tau} = d_1 + d_2 \frac{M}{R}. \end{cases}$$
(27)

TABLE II. Coefficients to be used in the proposed inversion scheme based on the universal relations of Ref. [46] in case of neutron matter, bosonic or fermioni dark matter.

EoS	b_1	b_2
NS	0.00694	-0.0256
BDM	0.006858	-0.03105
FDM	0.006604	-0.02521

By taking R out of the square root on the right-hand side of the first equation, and isolating R on the left hand side of the second, we get

$$\begin{cases} f = c_1 + c_2 \frac{1}{R} \sqrt{\frac{M}{R}}, \\ R \left(\frac{R}{M}\right)^3 \frac{1}{\tau} = d_1 + d_2 \frac{M}{R}. \end{cases}$$
(28)

Finally, by reshuffling the terms, we can express R in terms of the stellar compactness M/R in the following way

$$\begin{cases} R = \frac{c_2}{f - c_1} \sqrt{\frac{M}{R}}, \\ R = d_1 \tau \left(\frac{M}{R}\right)^3 + d_2 \tau \left(\frac{M}{R}\right)^4. \end{cases}$$
(29)

The aforementioned system of Eq. (29) can be solved graphically. An example of that is shown in Fig. 15 for the case of a bosonic DM model. The true values of the radius R and compactness M/R of the chosen model are displayed with a black point. By plotting the system of Eq. (29) with the correct coefficients for BDM, we find the green solid and dashed-dotted curves for the first and the second equation, respectively. Similar to the case of the inversion scheme based on Lau et al.-like universal relations, these curves show an ideal case, but the lines would be thicker if uncertainties were considered. It can be stated that the proposed inversion scheme works very well for estimating the stellar macroscopic parameters involved. For comparison, we also include, in the same plot, the curves that we would get by considering the same measured values of the f-mode frequency and damping time, but assuming that the source is made of neutron or fermionic dark matter. In particular, the orange solid and dashed-dotted curves refer to FDM, while the light-blue solid and dashed-dotted ones to NS matter. From the results of this plot (Fig. 15) we observe that an *f*-mode observation of decent accuracy should allow to distinguish between nuclear and dark matter. In the case of dark matter, these equations, however, do not allow to distinguish between fermionic and bosonic matter in particular; other observations or relations would be necessary to decide this.

Since all the universal relations considered hold only approximately, the inferred values of M, R and I are expected to deviate from the exact values by δM , δR and δI , respectively. To validate the inversion schemes outlined above and test their accuracy, we assume to have

FIG. 15. An illustration of how accurately the radius and the mass of a bosonic dark matter star can be inferred from detected f-mode data and universal relations of Eq. (8) (green curve) and (13) (green dashed-dotted curve). The true values of the BDM model considered are represented with a black point. For comparison, we also include the universal relations for FDM given by Eq. (9) (orange curve) and (14) (orange dashed-dotted curve), as well as those for NS matter given by Eq. (6) (light-blue curve) and (11) (light-blue dashed-dotted curve).

measured the f-mode frequency f and damping time τ of several bosonic and fermionic dark matter stellar models and we try to numerically estimate their mass M, radius R and moment of inertia I by making use of the universal relations associated to the specific type of matter. Table IV shows the EoS defining the stellar models, the true values of their mass M, radius R, as well as f-mode frequency f and damping time τ ; further, the relative errors of the estimated mass, radius and moment of inertia obtained from the universal relations are listed in the last four columns. More precisely, columns six and seven refer to results of the inversion scheme based on universal relations of Andersson and Kokkotas [45], while the last two columns refer to the scheme based on the universal relations from Lau et al. [46]. In general, the inversion scheme works very well for both bosonic and fermion dark matter EoSs. The relative error in the estimates of mass and radius are of the order of few percent or better, while the estimate of the moment of inertia is less accurate, with a relative error of the order of 10%.

TABLE III. Coefficients to be used in the proposed inversion scheme based on the universal relations of Ref. [45] in case of neutron matter, bosonic or fermionic dark matter.

V. CONCLUSIONS

In this paper we have investigated compact stars modeled with fermionic and bosonic DM EoSs, as viable candidates to be tested with future GW observations. By solving the stellar structure for static, sphericallysymmetric bodies, we have derived some basic bulk properties of such dark stars, namely their mass and radius. We have compared these results with some well known nuclear EoSs, showing that dark objects may cover large portions of the parameter space close to standard NSs.

We have also tested the validity of some universal relations connecting the *f*-mode oscillation frequency and damping time to the mass, radius, moment of inertia and tidal deformability of compact objects. These relations hold true for a large variety of NS EoSs, but in most cases dark stellar models deviate to some extent from them. Consequently, we propose alternative forms of those relations, which best fit the dark sector. More precisely, we establish a pair of empirical equations, namely Eqs. (8)and (13), which can predict the frequency and the damping time of f-modes from M and R with good accuracy for BDM. An analogous approach is followed for determining those quantities with FDM, leading to Eqs. (9)and (14). Additionally, we study the universality embedded in the moment of inertia of dark objects, finding Eq. (16) for bosonic dark matter, and the corresponding Eq. (17) for fermionic dark matter. The universality

encoded by the aforementioned relations leads to an accurate inversion scheme.

Finally, we take into account the tidal deformability characterizing the dark objects if they existed in binary systems, and we explore the validity of some universal relations previously established for NSs. We find that the universal relation for the mass-scaled f-mode frequency holds for all types of stars, while the radius-scaled fmode frequency acquires different universal relations for the different types of matter; we encode those in Eqs. (22) and (21) for bosonic and fermionic dark matter, respectively.

As an application, we present a simple inversion scheme to demonstrate how the competing universal relations for the different types of matter can be inverted, given some potential observations; distinguishing between different types of matter is, in principle, possible, however, sufficiently accurate observations are necessary. A more thorough exploration of the parameter space of dark stars could be conducted by employing Bayesian inference which, however, is beyond the scope of the present paper and we keep this extension for future work.

Appendix A: Equilibrium stellar model near r = R

To calculate the pulsation of a stellar model, one must first numerically determine the equilibrium stellar model. The general static spherical metric, which describes the geometry of an equilibrium stellar model, can be expressed as follows:

$$ds^{2} = -e^{\nu} dt^{2} + e^{\lambda} dr^{2} + r^{2} (d\theta^{2} + \sin^{2}\theta d\phi^{2}), \quad (A1)$$

where the metric potentials ν and λ are functions of r. It might be useful to define the function M(r) as follows:

$$M(r) = \frac{1}{2}r(1 - e^{-\lambda}).$$
 (A2)

Given this metric, Einstein's equations correspond to the very well known Tolman-Oppenheimer-Volkoff equations, namely

$$\frac{dM}{dr} = 4\pi r^2 \epsilon$$

$$\frac{d\nu}{dr} = 2\frac{M + 4\pi r^3 P}{r(r - 2M)}$$

$$\frac{dP}{dr} = -\frac{1}{2}(\epsilon + P)\frac{d\nu}{dr}.$$
(A3)

where ϵ and P are the energy density and the pressure of the fluid in the star, respectively. The pressure and the density are related by an equation of state $\epsilon = \epsilon(P)$. These equations are numerically integrated as an initial value problem starting from the center of the star, r = 0. At the center, the mass function must be zero, M(0) = 0, while the values of P and ν can be freely specified. The integration continues up until the radius r at which the pressure vanishes, P(r) = 0. We denote this radius by Rand it represents the surface of the star. The total mass of the star is given by M(R), and the arbitrary constant in the function ν is determined by normalizing the time coordinate at spatial infinity:

$$e^{\nu(R)} = 1 - \frac{2M(R)}{R}.$$
 (A4)

Approaching the star's surface, pressure values approach zero. Considering the fermionic dark matter EoS, cf. Eqs. (2) and (3), we point out that, for small values of P and, consequently, of x, the two relations suffer

from numerical cancellation. Consequently, a power series expansion of both $\epsilon(x)$ and P(x) around x = 0 is required. More precisely, the relevant quantities to be Taylor expanded are the functions $\xi(x)$ and $\chi(x)$, which are contained in the definition of $\epsilon(x)$ and P(x). Starting from $\xi(x)$, the following Taylor expansion should be considered for $x \leq 0.19$:

$$\xi(x) \approx \frac{8}{3}x^3 + \frac{4}{5}x^5 - \frac{1}{7}x^7 + \frac{1}{18}x^9 - \frac{5}{176}x^{11} + \frac{7}{416}x^{13} - \frac{7}{640}x^{15} + \frac{33}{4352}x^{17} - \frac{429}{77824}x^{19}.$$
 (A5)

The threshold $x \simeq 0.19$ has been computed equating the smallest contribution given by the Taylor expansion to machine precision, assuming the latter to be EPS $\approx 10^{-16}$, namely

EPS
$$\approx \frac{429}{77824} x^{19}.$$
 (A6)

As regards $\chi(x)$, we find that the following power series expansion holds for $x \leq 0.27$:

$$\begin{split} \chi(x) \approx &\frac{8}{15}x^5 - \frac{4}{21}x^7 + \frac{1}{9}x^9 \\ &- \frac{5}{66}x^{11} + \frac{35}{624}x^{13} - \frac{7}{160}x^{15} \\ &+ \frac{77}{2176}x^{17} - \frac{143}{4864}x^{19} + \frac{715}{28672}x^{21} \\ &- \frac{12155}{565248}x^{23} + \frac{46189}{2457600}x^{25}. \end{split}$$
(A7)

Similarly to what is done for $\xi(x)$, also in this case the threshold for x has been computed relating the magnitude of the smallest contribution of the series to machine precision.

Let us now consider the EoS for bosonic dark matter given by Eq. (4). By defining the quantity $\epsilon_0 \equiv m_{\rm X}^4 c^3/(4\pi\beta\hbar^3)$ and setting $x \equiv \epsilon/\epsilon_0$, the EoS can be rewritten as

$$P = \frac{1}{9}\epsilon_0 \left(\sqrt{4+3x} - 2\right)^2. \tag{A8}$$

Let us assign the content of the parenthesis to an auxiliary variable $F \equiv \sqrt{4+3x} - 2$. At low energy densities, the calculation of F is numerically unstable. Consequently, for small x, a Taylor expansion should be used. While the numerical cancellation in the expression for the pressure can be avoided by multiplying out F^2 , the variable F itself appears in other expressions, making a Taylor expansion indeed useful. More precisely, we find that, for $x \leq 10^{-4}$, it holds

$$F \approx \frac{3}{4}x - \frac{9}{64}x^2 + \frac{27}{512}x^3 - \frac{405}{16384}x^4 + \frac{1701}{131072}x^5.$$
 (A9)

The presented Taylor expansions allow not only a more accurate determination of the stellar models in the crustal part, but due to the higher accuracy that is achieved, the Runge-Kutta integrator is allowed to make larger steps which considerably speeds up the calculation.

Appendix B: Self-similarity of the bosonic DM EoS

In this appendix we present the features of the EoS which lead to self-similarity of the bosonic dark matter EoS, i.e. the shape of the mass-radius relation is independent of EoS parameters such as the mass of the dark particle $m_{\rm X}$ and the coupling constant β .

The following derivation is closely based on, and some parts are directly reproduced from, the mathematical proof given in Ref. [32]. To begin, we define the following quantities corresponding to a dimensionless mass and radius:

$$M_* = \frac{GM}{c^2l} \quad \text{and} \quad r_* = \frac{r}{l}, \tag{B1}$$

where l is a length scale. Moreover, we use this scaling l to define a dimensionless density ϵ_* and pressure P_*

$$\epsilon_* = \frac{l^2 G}{c^2} \epsilon$$
 and $P_* = \frac{l^2 G}{c^4} P.$ (B2)

Using these variables, the TOV equations can be cast in the following dimensionless form

$$\frac{dP_*}{dr_*} = -\frac{M_*\epsilon_*}{r_*^2} \left(1 + \frac{P_*}{\epsilon_*}\right) \left(1 + \frac{4\pi r_*^3 P_*}{M_*}\right) \left(1 - \frac{2M_*}{r_*}\right)^{-1} \frac{dM_*}{dr_*} = 4\pi r_*^2 \epsilon_*.$$
(B3)

Given an EoS, the mass-radius relation follows by varying the central energy density $\epsilon_*(0)$. Parameters of the model such as the dark particle mass m_X and the coupling constant β can affect the TOV equations only if they are contained in the EoS. However, it is possible to choose the scaling parameter l such that the EoS written in dimensionless variables is independent of the model parameters. This happens when the scaling factor is defined as

$$l = \sqrt{\frac{3\hbar^3\beta}{Gc}} \frac{1}{m_{\rm X}^2},\tag{B4}$$

and the EoS is given by

$$P_* = \frac{1}{3}(\sqrt{1+\epsilon_*} - 1)^2.$$
 (B5)

We have repeated the self-similarity of the bosonic DM EoS here because it provides a simple argument that we expect certain universal relations based on bosonic EoS to be linear functions. These are the relations concerning the f-mode frequency or damping time as a function of compactness or effective compactness.

Appendix C: Results for various equations of state

This appendix provides the numerical data for mode frequencies of all the EoSs considered in the present study. These data were used to infer the empirical relations discussed in the main body of the paper. We provide the data in the form of one table for each type of matter, namely neutron matter (c.f., Table V), bosonic dark matter (c.f., Table VI) and fermionic dark matter (c.f., Table VII). In each table we list the EoS, the central energy density, the mass and the radius of the stellar model, the frequency and damping time of the *f*-mode, the moment of inertia and the tidal deformability of the compact object.

TABLE V. Data for EoSs of neutron matter. The columns are the identifier of the EoS, the energy density ϵ_c , the mass M, the radius R, the f-mode's frequency f and damping time τ , the stars's moment of inertia I and its tidal deformability Λ , respectively.
