Abstract

We discuss the relic density of asymmetric dark matter with long-range interactions in non-standard cosmological scenarios where the extra cosmic energy is introduced. The Hubble expansion rate is modified in non-standard cosmological models, which affects the relic density of dark matter. If the mass of the dark exchanged gauge boson is less than the mass of dark matter particles multiplied by the dark fine-structure constant, the wave function of the incoming particles of dark matter annihilation would be distorted away from the free plane-wave approximation, yielding the significant enhancements to annihilation cross sections, known as Sommerfeld enhancement. Sommerfeld enhancement results the asymmetric dark matter relic density under abundant, while the enhanced cosmic expansion rate increases the relic density of asymmetric dark matter by letting the decoupling from the thermal equilibrium occurs earlier. However, the mixed effect of modified cosmic expansion and the Sommerfeld enhancement on asymmetric dark matter density evolution becomes quite complicated, due to their opposing affects on relic density and contrary strength developments as the temperature fell. We investigated the mixed effects on asymmetric dark matter freeze-out process and current relic abundance, which is significantly different from the standard situation. Further, we calculate the constraint relations of the asymmetric dark matter pertubative annihilation cross section and dark coupling constant with the mass of asymmetric dark matter, the asymmetry factor with the dark coupling constant, when the relic density of asymmetric dark matter falled in the observed region. The upper bounds on the mass of asymmetric dark matter for s-wave and p-wave annihilations are also derived.

1 Introduction

Asymmetric Dark Matter (DM) scenarios have been put forth for explaining why the average density of baryons is comparable to that of DM, $\Omega_{\rm DM} \simeq 5\Omega_b$ [1]. For asymmetric DM, particles and anti-particles are not self-conjugate, and the final DM relic density is determined by the asymmetry between the DM particle and anti-particle. The idea of asymmetric DM provides the possible connection between the baryon asymmetry and postulated DM asymmetry [2–14].

It is natural that DM has new interactions with the standard model particles or among themselves from a theoretical point of view. If these new interactions are taken into account, macroscopic quantities such as DM relic density or DM distributions in galaxies would be different. In the context of DM models, a new light exchanged force-carrying boson, together with the non-perturbative effect it induced, has been studied continuously over the recent two decades [15–33]. According to energy-time uncertainty principle, the range of force of the exchanged boson is approximately inversely proportional to its mass. When the range of mediated force $\propto m_{med}^{-1}$ is larger than the Bohr radius of DM particle pair $\propto (\alpha m)^{-1}$, where α is dark fine-structure constant, this case is called long-ranged potential. The long-ranged effect causes the incoming particle's wave function of annihilation process cannot be considered as free state anymore at the origin. Therefore, the cross section can not be fully calculated in the pertubative methods and the cross section needs to be corrected. This effect is known as Sommerfeld effect. If the mediator is massless, the Sommerfeld effect is naturally present as the condition is fulfilled. Whereas for the massive mediator, the effect depends on the mass ratio between the mediator and particle pairs. In some cases, in order to calculate the cross section, the above process can be decomposed into two separable parts that the high energy (hard) and low energy (soft) momentum transfer process. The cross section of hard annihilation process is calculated with typical perturbative methods. The Sommerfeld correction is described as a re-summation of soft mediator exchanges and solely depend on the potential generated by mediator. Under the assumption that the Sommerfeld factor is separable from the hard matrix element, the annihilation cross section is written as $\sigma_{ann}v_{rel} = \sum_{l=0}^{\infty} \sigma_l v_{rel}^{2l} S_{ann,l}$, where $S_{ann,l}$ is the Sommerfeld factor calculated by utilizing the scattering wave functions of the corresponding Schrödinger equation, l indicates the expansion in partial waves, when $l = 0, 1, S_{ann,0}, S_{ann,1}$ are s-wave and p-wave Sommerfeld factors respectively. As a result, the annihilation rate is enhanced at low velocities. Sommerfeld effect suppresses the couplings needed to achieve the observed DM density through the freeze-out in the early universe. On the contrary, the late-time DM annihilation signals are enhanced due to the Sommerfeld effect.

The relic density of asymmetric DM is determined by the thermal freeze-out mechanism

which assumes the asymmetric DM particles were in thermal equilibrium in the early universe and decoupled from equilibrium when the universe is radiation dominated. The relic density is obtained by solving the Boltzmann equation which describes the evolution of number density of the particles in the expanding universe. In the Boltzmann equation, the Hubble expansion rate plays an extreme significant role, and in the following we would see that the Boltzmann equation in various typical non-standard cosmological models differs only in the rate of cosmic expansion. Standard cosmological scenario assumes the universe is radiation dominated when DM freezes out.

The time when DM began to freeze out was incredibly early, far earlier than 1s after Big Bang, which is far beyond the reach of observations. No one could resist their curiosity and refrain from exploring some different cosmological scenarios. Indeed, in the recent two decades, the affect of non-standard cosmological scenarios on the DM density has been investigated continuously [34–52]. The non-standard scenarios, such as the kination model, the brane world cosmology predict faster expansion rate of the universe. In kination model the kinetic energy of scalar field dominated over the early era, in brane world cosmology, the extra dimension of spacetime changed the Friedmann equation. The modification of the cosmic expansion rate leaves its imprint on the asymmetric DM relic density.

In our previous work [19], we discussed the impact of Sommerfeld enhancement on the relic density of asymmetric DM in the standard cosmological scenarios. In the present work, we investigate the effect of Sommerfeld enhancement with massive gauge boson on the relic density of asymmetric DM in non-standard cosmological scenarios. The Sommerfeld effect lonely would decrease the relic density of DM because of the boosted annihilation cross section. On the other hand, the enhanced expansion rate of universe would increase the relic density of asymmetric DM because of the earlier decoupling point. However, the mixed effect of Sommerfeld enhancement and modification of cosmic expansion rate is quite complicated, in which the mixed effect is not the simply combined operation. The density evolution process is quite different from the standard case. Indeed, as the hypotheses about DM density evolution become increasingly complex, it is difficult to simply yet clearly describe the density evolution with using few phenomenological quantity that have well visual and obvious physical interpretation like the standard case. In our work, we try to find the common parameter space which can fulfill the observed relic density and the coupling strength demanded for cold DM. We would consider two minimal scenarios that the asymmetric DM couples to the light vector mediator or the scalar mediator.

The paper is arranged as following. Boltzmann equation and the cosmic expansion rate in non-standard cosmological models are reviewed in the next section. In the third section, we calculate the relic density of asymmetric DM with Sommerfeld enhancement in non-standard cosmological scenarios. In the fourth section, we present the density evolution of asymmetric DM and analyze the mixed effect of Sommerfeld enhancement and the modification of cosmic expansion on asymmetric DM density evolution. Then we derive the constraint relations of the annihilation cross section and coupling constant with the mass of asymmetric DM, the asymmetry factor with the coupling constant.

2 Boltzmann equation and the cosmic expansion rate in non-standard cosmological models

Following we shortly review the Boltzmann equation and the expansion rate of universe [53–56]. The Boltzmann equation that describes the evolution of DM number density, is

$$L[f] = C[f], \qquad (1)$$

where $f(x^{\mu}, p^{\mu})$ is the phase space distribution function of particle number, C[f] is the collision term which is not generally influenced by cosmology. L[f] is the covariant Liouville operator,

$$L = p^{\mu}\partial_{\mu} - \Gamma^{\mu}{}_{\sigma\nu}p^{\sigma}p^{\nu}\frac{\partial}{\partial p^{\mu}}, \qquad (2)$$

where Γ is Christoffel symbol. Indeed, Eq.(2) can be obtained by expanding $df(x^{\mu}, p^{\mu})/d(\tau/m)$ and substituting it into geodesic equation $d^2x^{\mu}/d\tau^2 + \Gamma^{\mu}{}_{\sigma\nu}(dx^{\sigma}/d\tau)(dx^{\nu}/d\tau) = 0$. For the Robertson-Walker metric $ds^2 = -dt^2 + a^2(t)[dr^2/(1-kr^2) + r^2(d\theta^2 + sin^2\theta d\varphi^2)]$, assuming fis spatially homogeneous and isotropic, the Liouville term becomes

$$L[f(E,t)] = E\frac{\partial f}{\partial t} - H|\vec{p}|^2 \frac{\partial f}{\partial E}.$$
(3)

For non-standard cosmological models, the Liouville term may be changed, such as the Bianchi type I models which assumes the universe is homogeneous but anisotropic before Big Bang Nucleosynthesis (BBN). In this article, the non-standard cosmological models considered is adding an extra energy content into the Friedmann-Robertson-Walker models. Usually, additional energy fields are often introduced to solve certain cosmological problems, such as the dark energy field which is added to solve the cosmic accelerated expansion mechanism, or the scalar field that causes the inflation that is included in order to solve the horizon problem. Without changing the metric of spacetime, adding an extra energy term does not change the abstract form of the Liouville term and the Boltzmann Equation. However, the concrete form of expansion rate of the universe H would be changed due to the additional energy. In other words, the change of H that appeared in the Boltzmann equation, would cause the difference in the evolution of particle number densities.

We introduce the extra energy density ρ_D as

$$\rho_D = \rho_D(T_r) \left(\frac{T}{T_r}\right)^{n_D} , \qquad (4)$$

where n_D is the constant which parametrizes the behavior of the energy density, T_r is reference temperature which we subsequently take the value as $T_r = 4$ GeV. The form of energy in Eq.(4) is consistent with the kination model physically and mathematically when $n_D = 6$, and matches with the brane world model mathematically when $n_D = 8$, but not physically, in that model the extra dimension of space-time changes the Friedmann equation.

Based on the analysis above, we discuss the affect of extra energy density on the cosmic expansion rate and the relic density of DM. The relationship between the expansion rate and energy is described by the Friedmann equation which is the 0 - 0 component of Einstein field equation,

$$H_D^2 = \frac{8\pi G}{3} (\rho_{\rm rad} + \rho_D) \,, \tag{5}$$

where $\rho_{\rm rad}$ is the radiation energy density. Here, we are concerned with the period of the very early universe that the radiation energy is dominated over the matter energy and the term containing the constant k that represents three kinds of space of constant curvature can be neglected. For convenience, we define $\eta \equiv \rho_D(T_r)/\rho_{rad}(T_r)$, then the cosmic expansion rate can be expressed by

$$H_D^2 = \frac{8\pi G}{3} \rho_{\rm rad} \left[1 + \eta \frac{g_*(T_r)}{g_*(T)} \left(\frac{T}{T_r}\right)^{n_D - 4} \right] \,. \tag{6}$$

Integrating Eq.(1), the Boltzmann equation in non-standard cosmological model becomes

$$\frac{\mathrm{d}n_{\chi(\bar{\chi})}}{\mathrm{d}t} + 3H_D n_{\chi(\bar{\chi})} = -\langle \sigma v \rangle (n_{\chi} n_{\bar{\chi}} - n_{\chi,\mathrm{eq}} n_{\bar{\chi},\mathrm{eq}}) , \qquad (7)$$

where $n_{\chi(\bar{\chi})}$ is the number density of DM particle or anti-particle, $\langle \sigma v \rangle$ is the thermal average of annihilation cross section times relative velocity of annihilating asymmetric DM particles and anti-particles.

Simultaneously, in order not to conflict with other theories, the modification of cosmology we considered, are not arbitrary. We considered the BBN constraints which is usually the first significant event that occurs after the DM freeze out. The modification of expansion rate occurs only before BBN and returns to the standard case at the beginning of BBN. The BBN constraint can be taken simply as following

$$\rho_D(1 \text{MeV}) < \rho_{\text{rad}}(1 \text{MeV}) \quad i.e. \quad \eta < \left(\frac{Tr}{1 \text{MeV}}\right)^{n_D - 4}.$$
(8)

Eq.(8) ensures that radiation dominated era returns when the temperature of the universe is 1 MeV. If choosing $n_D>4$ and using Eq.(8), ρ_D (Eq.4) will always be less significant at any time after the BBN.

3 Sommerfeld enhancement and the relic density of asymmetric DM

In this section, we calculate the relic density of asymmetric DM with long-range interactions in non-standard cosmological scenarios. A convenient and useful method of solving the Boltzmann equation (7) is to introduce $Y_{\chi(\bar{\chi})} = n_{\chi(\bar{\chi})}/s$ and x = m/T [56]. Here $s = 2\pi^2 g_{*s}/45 T^3$ is the entropy density, and g_{*s} is the effective number of entropic degrees of freedom. Assuming the entropy is conserved per comoving volume, then Eq.(7) can be expressed as

$$\frac{\mathrm{d}Y_{\chi(\bar{\chi})}}{\mathrm{d}x} = -\frac{H_{\mathrm{std}}}{H_D} \frac{\lambda \langle \sigma v \rangle}{x^2} \left(Y_{\chi} \ Y_{\bar{\chi}} - Y_{\chi,\mathrm{eq}} \ Y_{\bar{\chi},\mathrm{eq}} \right), \tag{9}$$

where $\lambda = 1.32 \, m M_{\rm Pl} \sqrt{g_*}$, $g_* \simeq g_{*s}$ and $dg_{*s}/dx \simeq 0$, and $H_{\rm std}$ is the cosmic expansion rate in the standard cosmology. Here $M_{\rm Pl} = 2.4 \times 10^{18}$ GeV is the reduced Planck mass. By subtracting the Boltzmann equations for χ and $\bar{\chi}$ in Eq.(9), we obtain $Y_{\chi} - Y_{\bar{\chi}} = C$, where Cis a constant. Finally, we rewrite the Boltzmann equation (9) as

$$\frac{\mathrm{d}Y_{\chi(\bar{\chi})}}{\mathrm{d}x} = -\frac{H_{\mathrm{std}}}{H_D} \frac{\lambda \langle \sigma v \rangle_s}{x^2} \left(Y_{\chi(\bar{\chi})}^2 \mp C Y_{\chi(\bar{\chi})} - Y_{\mathrm{eq}}^2 \right). \tag{10}$$

where

$$\frac{H_D}{H_{\rm std}} = \sqrt{1 + \eta \left(\frac{m}{x T_r}\right)^{n_D - 4}}.$$
(11)

Here the annihilation cross section is substituted by $\langle \sigma v \rangle_s$ which is thermally averaged Sommerfeld enhanced annihilation cross section $\langle \sigma v \rangle_s = a \langle S_s \rangle + b \langle v^2 S_p \rangle$. For the massive mediator, the Sommerfeld enhancement factors are [26–29]

$$S_{s} = \frac{2\pi\alpha}{v} \frac{\sinh\left(\frac{6mv}{\pi m_{\phi}}\right)}{\cosh\left(\frac{6mv}{\pi m_{\phi}}\right) - \cos\left(2\pi\sqrt{\frac{6\alpha m}{\pi^{2}m_{\phi}} - \frac{9m^{2}v^{2}}{\pi^{4}m_{\phi}^{2}}}\right)} \qquad s - wave annihilation$$
(12)
$$S_{p} = \frac{\left(\frac{6\alpha m}{\pi^{2}m_{\phi}} - 1\right)^{2} + \frac{36m^{2}v^{2}}{\pi^{4}m_{\phi}^{2}}}{1 + \frac{36m^{2}v^{2}}{\pi^{4}m_{\phi}^{2}}}S_{s} \qquad p - wave annihilation$$
(13)

where v is the relative velocity of the annihilating asymmetric DM particle χ and anti-particle $\bar{\chi}$.

We would consider two minimal cases in which the asymmetric DM couples to a light massive vector or scalar boson. One is $\chi \bar{\chi} \to 2\gamma$, asymmetric DM annihilating into two dark photons. Assuming that DM is Dirac Fermions and couples to the dark photon through local gauged U(1) interaction, formally just as ordinary Dirac particles coupling to photons, but with a dark coupling strength. Then, the Lagrangian is written as $\mathcal{L} = \mathcal{L}_{\text{Dirac}} + \mathcal{L}_{\text{Maxwell}} + \mathcal{L}_{\text{int}} = \bar{\psi}(i\gamma^{\mu}\partial_{\mu} - m_{DM})\psi - F_{D\mu\nu}F_{D}^{\mu\nu}/4 - g_{D}\bar{\psi}\gamma^{\mu}\psi A_{D\mu}$, where subscript *D* represent "dark" quantity. In this case, it is an s-wave process and its Sommerfeld enhanced annihilation cross section times relative velocity is [15, 22–24]

$$(\sigma v)_{\rm s(s-wave)} = \sigma_0 S_s = \frac{\pi \alpha^2}{m^2} S_s , \qquad (14)$$

where the leading order cross section times the relative velocity σ_0 is perturbative value in the non-relativistic regime, $\alpha = g_D^2/(4\pi)$ is dark fine-structure constant. Another case we considered is $\chi \bar{\chi} \to 2\varphi$, asymmetric DM annihilating into two scalars. In this case, DM is assumed to be coupled to scalar particle through Yukawa interaction, and the Lagrangian is $\mathcal{L} = \mathcal{L}_{\text{Dirac}} + \mathcal{L}_{\text{Klein-Gordon}} + \mathcal{L}_{\text{int}} = \bar{\psi}(i\gamma^{\mu}\partial_{\mu} - m_{DM})\psi + \partial_{\mu}\phi\partial^{\mu}\phi/2 - m^2\phi^2/2 - g_D\bar{\psi}\psi\phi$. It is p-wave process and its Sommerfeld enhanced cross section is

$$(\sigma v)_{\rm s(p-wave)} = \sigma_1 v^2 S_p = \frac{3\pi \alpha^2}{8m^2} v^2 S_p ,$$
 (15)

where σ_1 is the tree level cross section.

To confirm the initial value of the Boltzmann equation, we follow the standard picture of DM particle evolution [57]. In the early universe prior to BBN, the asymmetric DM particles and anti-particles were assumed in thermal equilibrium. When the temperature falls, the particle interaction rate drops to less than the cosmic expansion rate, the asymmetric DM decoupled from thermal equilibrium and subsequently formed the DM relic in the current universe. Therefore, the initial value can adopt the Maxwell-Boltzmann thermal equilibrium statistics, i.e. $n_{\chi(\bar{\chi}),eq} = g_{\chi} [mT/(2\pi)]^{3/2} e^{(-m \pm \mu_{\chi})/T}$. The value of chemical potential would be a question. For solving the relic density of asymmetric DM, a useful approach which finely addressed the chemical potential was proposed in Ref. [5]. Closely following the method which is used in Ref. [5], the total final DM relic density is expressed as

$$\Omega_{\rm DM} h^2 = 2.76 \times 10^8 \left[Y_{\chi}(x_{\infty}) + Y_{\bar{\chi}}(x_{\infty}) \right] m, \tag{16}$$

where $\Omega_{\chi} = \rho_{\chi}/\rho_c$ with $\rho_{\chi} = n_{\chi}m = s_0Y_{\chi}$ and $\rho_c = 3H_0^2M_{\rm Pl}^2$, here $s_0 \simeq 2900$ cm⁻³ is the present entropy density, and H_0 is the Hubble constant.

4 Effect of Sommerfeld enhancement and Constraints

In Fig.1, we plot the evolution of asymmetric DM abundances of Y_{χ} and $Y_{\bar{\chi}}$ as a function of inverse-scaled temperature x. Here $\eta = 10^3$, $\alpha = 0.1$ and $n_D = 6$ or $n_D = 8$ correspond to the asymmetric DM abundances Y_{χ} (dashed red line) and $Y_{\bar{\chi}}$ (long dashed red line) in the non-standard cosmological scenarios with Sommerfeld effect, respectively. $\eta = 0$ and $\alpha = 0.1$

Figure 1: Asymmetric DM abundances Y_{χ} and $Y_{\bar{\chi}}$ as a function of x. Here m = 500 GeV, $m_{\phi} = 0.25$ GeV, $g_{\chi} = 2, g_* = 90$.

(dotted blue line and double dot-dashed blue line) are for the standard cosmological scenarios including Sommerfeld enhancement while $\eta = 0$ and $\alpha = 0$ (solid black line and dot-dashed black line) returns to the situation when there is no Sommerfeld enhancement. We noted that both the asymmetric DM particle abundance Y_{χ} and anti-particle abundance $Y_{\bar{\chi}}$ are affected by Sommerfeld enhancement. The effect on anti-particle's abundance is more visible. Compared the dot-dashed black line $Y_{\bar{\chi}}(\eta = 0, \alpha = 0)$ with the double dot-dashed blue line $Y_{\bar{\chi}}(\eta = 0, \alpha = 0.1)$ in panel (a), we can see the relic abundance of anti-particle is decreased from 7.51×10^{-14} to 6.13×10^{-17} in the standard cosmological scenario, which is three orders of magnitude. Making an analogy between the dot-dashed black line with the double dotdashed blue line, we find the double dot-dashed blue line does not flatten quickly. Morever, it continues to decrease slowly. That is because of the enhanced annihilation cross section due to the Sommerfeld effect as the temperature drops. The Sommerfeld factor is increased following the decrease of temperature, for example, $\langle S_s \rangle (x = 10) = 1.70$, $\langle S_s \rangle (x = 10^2) = 3.73$, $\langle S_s \rangle (x = 10^3) = 11.22$, $\langle S_s \rangle (x = 10^4) = 35.48$, $\langle S_s \rangle (x = 10^5) = 113.17$ in Fig.1. We can see that, around the typical decoupling temperature $(x \sim 20)$, the effect of Sommerfeld enhancement is not significant, which accounts for the point that double-dot dashed blue line deviates from $Y_{\bar{\chi},eq}$ is nearly the same as the point that dot-dashed black line deviates from $Y_{\bar{\chi},eq}$.

On the other hand, for the non-standard cosmological scenarios with Sommerfeld effect, Y_{χ} and $Y_{\bar{\chi}}$ are both increased, i.e, in panel (a) of Fig.1, the abundance of anti-particle $Y_{\bar{\chi}}(\eta =$ $10^3, \alpha = 0.1$ (long dashed red line) is rather sensitive to the enhanced expansion rate. The long dashed red line is evidently higher than the double dot-dashed blue line $Y_{\bar{\chi}}(\eta = 0, \alpha = 0.1)$. For example in panel (a), the abundance of anti-particle $Y_{\bar{\chi}}(\eta = 10^3, \alpha = 0.1)$ is increased from 6.13×10^{-17} to 4.51×10^{-13} , which is caused by the enhanced cosmic expansion rate. We can see, the point at $Y_{\bar{\chi}}(\eta = 10^3, \alpha = 0.1)$ deviates from $Y_{\bar{\chi},eq}$ is earlier than the point that dotdashed black or double dot-dashed blue lines. The reason is following, the enhancement factor of cosmic expansion rate $H_D/H_{\rm std}$ is quite large around $x \sim 10$ as $H_D(x = 10)/H_{\rm std}(x =$ 10) = 395.29 in panel (a), while the enhancement factor of Sommerfeld effect $\langle S_s \rangle$ is not visible as $\langle S_s \rangle (x = 10) = 1.70$. The additional energy term enhanced the expansion rate of the universe, and then the cosmic expansion rate at an earlier moment already exceeds the Sommerfeld enhanced particle interaction rate. That also caused, for a not-long period of time, the dashed red line and long dashed red lines around the decoupling temperature are remarkably higher than the solid black and dotted blue lines. As temperature falls, the cosmic expansion enhancement factor is continuously decreased to less than 1 before BBN era $(\rho_D(T = 1 \text{MeV}) / \rho_{\text{rad}}(T = 1 \text{MeV}) < 1)$. In contrast, Sommerfeld enhancement factor is continuously increased. As a result, the previous comparative condition is unable to persist. Therefore, over relatively long period of time, the dashed red line gradually approaches the black solid line and in the end the difference between them becomes very small. In Fig.1, we can see that, in the presence of the Sommerfeld effect, the current relic density of DM particles Y_{χ} in non-standard cosmology where the cosmic expansion rate is enhanced, is close to that in standard cosmology in panels (a) and (c), while this is not the case in panel (b) and (d). That is to say, if the enhancement factor of cosmic expansion is not sufficiently large, then even though the point of decoupling from thermal equilibrium value is advanced, the final relic abundance of DM particles $Y_{\chi}(\eta = 10^3, \alpha = 0.1)$, due to the gradually increased Sommerfeld factor as the temperature fell, becomes close to that of standard cosmology $Y_{\chi}(\eta = 0, \alpha = 0.1)$. On the contrary, if the enhancement of cosmic expansion is taken much larger or the enhancement of Sommerfeld effect is taken much smaller, then the difference between $Y_{\chi}(\eta, \alpha)$ and $Y_{\chi}(\eta = 0, \alpha)$ will be considerable.

In Fig.2, we show the relations of the perturbative annihilation cross section parameters $\sigma_0(\sigma_1)$ and the dark fine-structure constant α with mass m for the observed value of DM

Figure 2: Contour plots of the perturbative annihilation cross section σ_0 (σ_1) and the coupling constant α with mass m, when $\Omega_{DM}h^2 = 0.120$. Here $m_{\phi} = 0.25$ GeV, $g_{\chi} = 2$, $g_* = 90$.

abundance $\Omega_{DM}h^2 = 0.120$. From panels (a) and (b), we can see that, for a certain mass $m, \sigma_0(\sigma_1)$ is increased in the non-standard cosmological scenarios where the expansion rate is enhanced. The lines corresponded to $n_D = 6$ is higher than the lines with $n_D = 8$. If the point that asymmetric DM decoupled from equilibrium $Y_{\bar{\chi},eq}$ is later than T_r , which is indeed typical assumption, then for the same value of η , the smaller n_D corresponds to the larger values of $\sigma_0(\sigma_1)$. If the decoupling point is earlier than T_r , the case would be inverse. We also see the enhanced cosmic expansion rate does not change the maximum value of asymmetric DM mass m. As η is gradually decreased to 0, the situation would return to the standard case. The broadened range of parameter spaces of DM annihilation cross sections comes at the cost of modifying the situation of the universe prior to BBN. For example, in panel (a), when m = 100 GeV, σ_0 is increased from 4.91×10^{-26} which corresponded to the standard expansion rate to 1.70×10^{-25} for $n_D = 8$ and to 3.85×10^{-25} for $n_D = 6$, respectively. If fixing n_D , the maximum value of $\sigma_0(\sigma_1)$ examined by a certain aspect of the cosmological perspective is determined by η_{max} which corresponded to the weakest-limit-value of BBN limit

range, here $\eta_{\text{max}} = (Tr/1\text{MeV})^{n_D-4}$. The increase of perturbative annihilation cross section is quite sizable, that the extent of the enhancement could even exceeded to three or four orders of magnitude in the case which we discussed. Panels (c) and (d) are compatible with (a) and (b) through $\sigma_0 = \pi \alpha^2/m^2$ and $\sigma_1 = 3\pi \alpha^2/(8m^2)$. Here the solid red lines are for $n_D = 6$, the dashed blue lines are for $n_D = 8$ and the dotted red lines are for the standard cosmology. The maximum values of the mass for the fixed asymmetry factor are the same for various cases. For the same mass bound, stronger coupling is needed for smaller n_D . We find the reason from Fig.1. The final abundance for $n_D = 6$ is greater than the case of $n_D = 8$. In order to satisfy the observed value of DM abundance, one needs stronger coupling constant α . On the other hand, larger asymmetry factor leads the lower mass bound. Compared to s-wave case, the p-wave annihilation cross section requires stronger coupling as shown in panel (d) in Fig.2.

Figure 3: Contour plot of asymmetry factor C with the coupling strength α for s-wave (p-wave) annihilation cross section when $\Omega_{\rm DM}h^2 = 0.120$. Here m = 130 GeV for, $m_{\phi} = 0.25$ GeV, $g_{\chi} = 2$, $g_* = 90$.

The contour plots of asymmetry factor C and the coupling strength α are shown in Fig.3. We can see that when α is much larger, the asymmetry factor C required by the observed DM relic density does not depend on the expansion rate, as shown in the Fig.3 where the three lines corresponded to different cosmic expansion rates eventually converge into one. For fixed C, the observed data requires the stronger coupling α when the expansion rate of the universe is enhanced.

5 Summary

In this article, we investigated the relic abundance of asymmetric DM with Sommerfeld enhancement in non-standard cosmological scenarios. We first discussed the affect of the cosmology on the Boltzmann equation and subsequently introduced the additional energy density as the non-standard cosmological scenarios. Analyzing the construction of relativistic and covariant Liouville operators, we find that the final form of the Boltzmann equation in non-standard cosmology differs from the form of that in standard cosmology only in the specific expression of cosmic expansion rate.

In DM particle-anti-particle annihilation process, if the interaction length of the process is much larger than the Bohr radius, the incoming particle's wave functions can not be considered as free state at the origin, causing the Sommerfeld effect. Then, we discussed the effect of Sommerfeld enhancement on the density evolution of asymmetric DM when the expansion rate of universe is enhanced. The mixed impact of non-standard cosmology and Sommerfeld effect lies in the decoupling point from thermal equilibrium value and the freeze-out process of relic density, as well as in the difference between DM particle and anti-particle. At the early time of the evolution of asymmetric DM density, the impact of Sommerfeld enhancement is not significant. However, the enhancement of the expansion rate of the universe can be quite large. Taking both effects into account, the asymmetric DM decoupling point from the equilibrium is still advanced compared to the standard cosmology. Following the decrease of the temperature, the enhancement factor of the cosmic expansion rate is continuously decreased, while the Sommerfeld factor is continuously increased. As a result, the freeze-out process of relic density would last for a long time, which also affect the final relic abundance. The two opposing effect on relic density and contrary trend of the strength development, results a significantly different and interesting asymmetric DM density evolution process, as shown in Fig.1.

Finally, we calculated the constraints on the parameter spaces, such as perturbation annihilation cross section, the coupling strength, asymmetric DM mass and the asymmetry factor, to obtain the observed relic density of DM. Due to the introduction of additional energy fields, the expansion rate of the universe is enhanced. These non-standard cosmological models would predict the more larger dark coupling strength and perturbative annihilation cross section, through the observed DM relic abundance in the current universe. The parameter spaces of DM particle would be broadened. For the non-standard cosmological models where the cosmic expansion rate is reduced, the result is inverse. In the cases which we discussed, the broadening of the allowable range of the parameters of DM annihilation processes would give a wider region for DM detections and researchs. As a trade-off, the history of universe prior to BBN is changed. These findings demonstrate the implications of cosmological models on the interaction properties of DM particles.
