Abstract

Assessing treatment effect heterogeneity (TEH) in clinical trials is crucial, as it provides insights into the variability of treatment responses among patients, influencing important decisions related to drug development. Furthermore, it can lead to personalized medicine by tailoring treatments to individual patient characteristics. This paper introduces novel methodologies for assessing treatment effects using the individual treatment effect as a basis. To estimate this effect, we use a Double Robust (DR) learner to infer a pseudo-outcome that reflects the causal contrast. This pseudo-outcome is then used to perform three objectives: (1) a global test for heterogeneity, (2) ranking covariates based on their influence on effect modification, and (3) providing estimates of the individualized treatment effect. We compare our DR-learner with various alternatives and competing methods in a simulation study, and also use it to assess heterogeneity in a pooled analysis of five Phase III trials in psoriatic arthritis. By integrating these methods with the recently proposed WATCH workflow (Workflow to Assess Treatment Effect Heterogeneity in Drug Development for Clinical Trial Sponsors), we provide a robust framework for analyzing TEH, offering insights that enable more informed decision-making in this challenging area.

Keywords: Heterogeneous Treatment Effect, Conditional Average Treatment Effect, Meta-learners, Machine Learning, Subgroup Analysis.

1 Introduction

The assessment of treatment effect heterogeneity (TEH) is crucial for advancing drug development and personalized healthcare.[1] TEH facilitates subgroup identification based on baseline covariates, allowing scientists to pinpoint variations in treatment efficacy and safety, which is invaluable for optimizing clinical trial design and stratifying patient groups.[2] Additionally, TEH enables healthcare providers to tailor medical interventions to an individual's unique biological makeup, lifestyle, and environmental factors, ensuring the most effective and safest treatment.[3] This personalized approach represents a shift from the traditional 'one-size-fits-all' model to a more nuanced, patient-centric model, promising improved health outcomes and a higher standard of care.[4]

Assessing TEH using clinical trial data is challenging due to several factors. Firstly, sample size limitations in clinical trials often prevent definitive statements about testing interactions or estimating treatment effects in subgroups, as the trials are typically designed to demonstrate effects in the overall population.[5, Chapter 16]

Secondly, multiplicity issues arise when assessing treatment effects across various subgroups, leading to selection bias, and findings that cannot be replicated in subsequent studies.[6] Despite these challenges, understanding and accurately interpreting the observed TEH is crucial, as it can influence drug development decisions and future trial designs.

In an attempt to tackle the main challenges around assessing TEH, Sechidis et al.[7] introduced a Workflow for Assessing Treatment effect Heterogeneity (WATCH) designed for clinical trial sponsors. The main goal of WATCH is to provide a systematic approach for sponsors to make informed decisions based on treatment effect heterogeneity, considering external evidence and scientific understanding. It consists of four main steps: Analysis Planning, Initial Data Analysis and Analysis Dataset Creation, TEH Exploration, and Multidisciplinary Assessment (Figure 1). The TEH exploration is the core analytical part of the workflow, and it is focusing on addressing three key objectives:

Figure 1: Overview of WATCH workflow and the four main steps: (1) Analysis Planning, (2) Initial Data Analysis and Analysis Dataset Creation, (3) TEH Exploration, and (4) Multidisciplinary Assessment.

- Objective 1: perform a global test to assess the evidence against homogeneity,
- Objective 2: derive a ranking of the baseline covariates that captures their strength in the effect modification,
- Objective 3: explore how the treatment effect varies with the most promising effect modifiers.

WATCH is a generic workflow, and it can be used with any method that can address the three objectives above. In this paper we will explore implementations building upon causal inference, and more specifically on the potential outcomes framework. This framework provides a powerful tool to conduct individual-level analysis to assess TEH and understand the differential impacts of treatments across diverse patient characteristics.[8] Over the last few years, a plethora of methods have been suggested to estimate individual effects, such as the Conditional Average Treatment Effect (CATE), using various types of models, ranging from traditional regression techniques to more advanced machine learning (ML) algorithms.[9] Among these advanced approaches, meta-learners have emerged as a powerful framework for estimating CATE, leveraging the strengths of multiple models to improve predictive accuracy and robustness in treatment effect estimation.[10, 11, 12]

In this paper, we will focus on a specific type of meta-learner, known as Doubly Robust (DR) learner,[13] which combines the strengths of both outcome modeling and propensity score modeling to achieve more accurate estimates of CATE. DR-learner is particularly advantageous because it remains consistent if either the outcome model or the propensity score model is correctly specified, offering some safeguards against model misspecification.

While it was originally introduced to estimate CATE (Objective 3), we will illustrate ways in which it can also be used to perform a global test against homogeneity (Objective 1) and to identify effect modifiers (Objective 2). By employing the DR-learner within the WATCH workflow, we aim to provide a nonparametric solution for assessing heterogeneity, suitable for both continuous and binary endpoints.

The remainder of the article is structured as follows: In Section 2.1, we provide a brief review of methods for estimating treatment effects. The core of our novelty lies in Section 2.2, where we implement the DR-learner and demonstrate how it can be used to assess heterogeneity under the three objectives of the WATCH framework. Section 3 presents a comprehensive study evaluating the performance of our methods against other approaches in various simulated scenarios. Section 4 showcases a real clinical case scenario, where we apply our methods to assess heterogeneity and identify effect modifiers in psoriatic arthritis trials. Finally, Section 5 concludes the article with a discussion and future directions.

2 Methods

2.1 Background on estimating treatment effect

We assume access to an i.i.d. sample of observations of Z = (X, A, Y), where $X \in \mathbb{R}^p$ are covariates, $A \in \{0, 1\}$ is a binary treatment or exposure, and $Y \in \mathbb{R}$ is an outcome of interest. Our work is applicable to randomized clinical trials (RCTs), where patients are randomly assigned to treatments, but also to observational data under standard assumptions, where the treatment is assigned based on observed characteristics. We denote the *n* realizations of these observations as $\{(\mathbf{x}_i, a_i, y_i)\}_{i=1}^n$. Furthermore, it is useful to define the following nuisance functions: $\mu_a(\mathbf{x}) = \mathbb{E}(Y|X = \mathbf{x}, A = a)$, and $\pi(\mathbf{x}) = \mathbb{P}(A = 1|X = \mathbf{x})$.

In this work, we will follow the potential outcome (or counterfactual) framework, a common approach for formalising causal inference introduced by J. Neyman[14] in the context of RCT. It is also known as the "Rubin causal model", since Rubin[15] extended the potential outcome framework to perform causal inference in both observational and experimental studies (for the curious reader, Rubin[16] provides a review on the history of causal inference). Under this framework, we denote as Y(1) the potential outcome that it would have been observed if the patient was receiving the treatment A = 1, while as Y(0) if the patient was receiving the treatment A = 0. The individual treatment effect is defined by the difference: Y(1) - Y(0). The fundamental difficulty of causal inference is that we observe only one of the potential outcomes for each patient, denoted by Y, since each patient received either treatment A = 1 or control A = 0, and as a result the individual treatment effects are not observed.

2.1.1 Average Treatment Effect

The Average Treatment Effect (ATE) is a key concept in understanding the impact of a treatment.[17] It measures the difference in outcomes between those who receive the treatment and those who do not. Formally, it is defined as $ATE := \mathbb{E}[Y(1) - Y(0)]$, and there are three main methods to estimate it:[18, 19]

$$\widehat{\text{ATE}}_{\text{G-comp}} = \frac{1}{n} \sum_{i=1}^{n} \left\{ \widehat{\mu}_1(\mathbf{x}_i) - \widehat{\mu}_0(\mathbf{x}_i) \right\},\tag{1}$$

$$\widehat{\text{ATE}}_{\text{IPW}} = \frac{1}{n} \sum_{i=1}^{n} \left\{ \left(\frac{a_i}{\widehat{\pi}(\mathbf{x}_i)} - \frac{(1-a_i)}{1-\widehat{\pi}(\mathbf{x}_i)} \right) y_i \right\} = \frac{1}{n} \sum_{i=1}^{n} \left\{ \frac{a_i - \widehat{\pi}(\mathbf{x}_i)}{\widehat{\pi}(\mathbf{x}_i) \left(1 - \widehat{\pi}(\mathbf{x}_i)\right)} y_i \right\},\tag{2}$$

$$\widehat{\text{ATE}}_{\text{AIPW}} = \frac{1}{n} \sum_{i=1}^{n} \left\{ \frac{a_i - \widehat{\pi}(\mathbf{x}_i)}{\widehat{\pi}(\mathbf{x}_i) \left(1 - \widehat{\pi}(\mathbf{x}_i)\right)} y_i + \left(\left(1 - \frac{a_i}{\widehat{\pi}(\mathbf{x}_i)}\right) \widehat{\mu}_1(\mathbf{x}_i) - \left(1 - \frac{1 - a_i}{1 - \widehat{\pi}(\mathbf{x}_i)}\right) \widehat{\mu}_0(\mathbf{x}_i) \right) \right\}, \quad (3)$$

where $\hat{\mu}_1(\mathbf{x}_i)$ is the estimated conditional expectation of the outcome given \mathbf{x}_i within the treated group, i.e. $\hat{\mathbb{E}}(Y|X = \mathbf{x}_i, A = 1)$ and $\hat{\mu}_0(\mathbf{x}_i)$ defined analogously for the control group. Furthermore, $\hat{\pi}(\mathbf{x}_i)$ is the estimated propensity score, that is the estimated conditional probability of treatment given \mathbf{x}_i , i.e. $\hat{\mathbb{E}}(A|X = \mathbf{x}_i)$.

G-computation, Equation (1), allows for a flexible modeling of the outcome based on covariates and treatment, which can lead to accurate estimates if the model for the outcome is specified correctly. However, G-computation is sensitive to model misspecification; if the model for the outcome is incorrectly specified, the estimates can be biased. Inverse Probability Weighting (IPW), Equation (2), adjusts for confounding by reweighting the observed outcomes, creating a pseudo-population where the treatment assignment is effectively randomized. It relies on the propensity score model, which may be simpler to specify and estimate compared to the outcome model in G-computation. However, IPW can be highly sensitive to extreme propensity score estimates, leading to high variance and instability in the ATE estimates.

The Augmented Inverse Probability Weighting (AIPW) is a Doubly Robust (DR) way of estimating ATE that combines outcome modeling and IPW, providing an additional layer of robustness. AIPW estimator remains consistent for the ATE if either the propensity score model or the outcome regression is misspecified but the other is properly specified. The expression presented in Equation (3) can be interpreted as an adjustment of the IPW estimator, since it corrects it by incorporating the outcome models $\hat{\mu}_{a_i}(\mathbf{x}_i)$, ensuring robustness against misspecification of either the outcome models or the propensity score model $\hat{\pi}(\mathbf{x}_i)$. AIPW often results in more efficient and less biased estimates compared to either G-computation or IPW alone.[18] However, implementation of AIPW methods can be more complex, requiring careful specification and estimation of both the outcome model and the propensity score model.

In summary, within the context of randomized controlled trials (RCTs) where the propensity score is predetermined (such as 0.50 in a balanced 1:1 trial), the AIPW estimator remains consistent even if the outcome models are misspecified. Furthermore, when the outcome models are reasonably well estimated, the AIPW estimator can offer enhanced efficiency compared to the IPW estimator.

2.1.2 Conditional Average Treatment Effect and Meta-learners

Another important estimand is the conditional average treatment effect (CATE), which represents the expected difference in outcomes when subjected to a treatment versus no treatment, given specific covariate values (\mathbf{x}_i) . Formally, CATE is defined as:

$$\tau(\mathbf{x}_i) = \mathbb{E}[Y_i(1) - Y_i(0) \mid X_i = \mathbf{x}_i].$$
(4)

Here, \mathbf{x}_i represents the covariates for individual *i*, and \mathbb{E} denotes the expectation operator. While ATE provides a general measure of the treatment effect averaged over the entire population, the CATE is important because it allows us to understand the effect of a treatment on a more personal level, taking into account specific characteristics or conditions of each individual.

Estimating CATE is a complex task, especially in the presence of high-dimensional data and potential confounders. To tackle this challenge, a range of approaches known as *meta-learners* have been developed.[10, 11, 12, 13] Meta-learners provide flexible and robust frameworks for CATE estimation by leveraging machine learning models and combining them in different ways. The key idea behind meta-learners is to transform the problem into more manageable steps, often allowing the use of existing predictive models to estimate the treatment effects. In the literature, numerous meta-learners have been proposed; here, we focus on a representative set of them, that they have a direct correspondence/relationship with the ATE estimators we presented in the previous section.

The first meta-learners that have been suggested in the literature, where the S and T-learner. **S-learner**[10] uses a single model to predict the outcome by including both the treatment indicator and the covariates as inputs.

This method leverages a single predictive model that accounts for the treatment effect implicitly:

$$\widehat{\tau}_{\mathrm{S}}(\mathbf{x}_i) = \widehat{\mu}(\mathbf{x}_i, 1) - \widehat{\mu}(\mathbf{x}_i, 0),$$

where $\hat{\mu}(\mathbf{x}, a)$ represents the predictive model that is trained with inputs from the combined space of covariates and the treatment indicator. This learner, used to estimate CATE, can be seen as the corresponding method for G-computation to estimate ATE, Equation (1). Another approach, similar to the S-learner, is the **T-learner**.[10] In contrast to using a single model that incorporates both the covariates and the treatment, the T-learner builds two separate models. One model is trained the data from the treated group (where a = 1), and the other model from the control group (where a = 0):

$$\widehat{\tau}_{\mathrm{T}}(\mathbf{x}_i) = \widehat{\mu}_1(\mathbf{x}_i) - \widehat{\mu}_0(\mathbf{x}_i),$$

where $\hat{\mu}_1(\mathbf{x})$ represents the model trained using only treated data, while $\hat{\mu}_0(\mathbf{x})$ using control data. In the pharmaceutical statistics literature, the S- and T-learners were introduced under the name "Virtual Twins" in the seminal work of Foster et al. [20]

After these relatively simple approaches, a plethora of meta-learners have been proposed in the literature. These meta-learners use machine learning models to estimate nuisance parameters (i.e., outcome models and propensity scores) and provide more accurate and robust estimates of the CATE. A special class of these metalearners splits the process into two parts, and to present them we will use the notation of Jacob[11]: in the first step, a pseudo-outcome, defined as ψ , is derived, while in the second step, the pseudo-outcomes are regressed on the covariates to obtain the final estimate of the CATE. In our work, we will focus on the following two meta-learners:

• F-learner or IPW-learner: F-learner[10] or Inverse Probability Weighting (IPW)-learner[12] focuses on reweighting the observed outcomes to create a pseudo-population where the treatment assignment is effectively randomized. The idea is to generate a pseudo-outcome using the estimated nuisance function for the propensity score:

$$\widehat{\psi}_{\text{IPW}}(\mathbf{x}_i) = \frac{a_i - \widehat{\pi}(\mathbf{x}_i)}{\widehat{\pi}(\mathbf{x}_i) \left(1 - \widehat{\pi}(\mathbf{x}_i)\right)} y_i$$

To get CATE, the pseudo-outcome is regressed on the covariates, i.e. $\hat{\tau}_{\text{IPW}}(\mathbf{x}_i) = E[\hat{\psi}_{\text{IPW}}(\mathbf{x}_i)|X = \mathbf{x}_i]$. This learner, used to estimate CATE, can be seen as the corresponding method for IPW to estimate ATE, Equation (2).

• DR-learner: Doubly Robust (DR)-learner[13] combines both the outcome model and the inverse probability weighting approaches, and it achieves doubly robust property, meaning it can provide consistent estimates if either the outcome model or the propensity score model is correctly specified. Kennedy[13] and Curth and Van der Schaar[12] have suggested two equivalent expressions of the pseudo-outcome DR-learner:

$$\widehat{\psi}_{\text{DR:1}}(\mathbf{x}_i) = \frac{a_i - \widehat{\pi}(\mathbf{x}_i)}{\widehat{\pi}(\mathbf{x}_i) \left(1 - \widehat{\pi}(\mathbf{x}_i)\right)} \left(y_i - \widehat{\mu}_{a_i}(\mathbf{x}_i)\right) + \widehat{\mu}_1(\mathbf{x}_i) - \widehat{\mu}_0(\mathbf{x}_i), \text{ and}$$
(5)

$$\widehat{\psi}_{\text{DR:2}}(\mathbf{x}_i) = \frac{a_i - \widehat{\pi}(\mathbf{x}_i)}{\widehat{\pi}(\mathbf{x}_i) \left(1 - \widehat{\pi}(\mathbf{x}_i)\right)} y_i + \left(1 - \frac{a_i}{\widehat{\pi}(\mathbf{x}_i)}\right) \widehat{\mu}_1(\mathbf{x}_i) - \left(1 - \frac{1 - a_i}{1 - \widehat{\pi}(\mathbf{x}_i)}\right) \widehat{\mu}_0(\mathbf{x}_i).$$
(6)

The expression in Equation (5) can be seen as providing correction to a simple outcome-model estimator, i.e. $\hat{\mu}_1(\mathbf{x}_i) - \hat{\mu}_0(\mathbf{x}_i)$. The corresponding correction is an IPW applied to the residuals of the outcome-model estimate.[21] On the other side, Equation (6) can be seen as providing correction to the IPW estimator, i.e. $\frac{a_i - \hat{\pi}(\mathbf{x}_i)}{\hat{\pi}(\mathbf{x}_i)(1 - \hat{\pi}(\mathbf{x}_i))}y_i$. The correction this time corresponds to an outcome model reweighted by the residual treatment probabilities.[21] In Appendix A we provide a detailed proof over the equivalence of these two expressions. The pseudo-outcome is regressed on the covariates to get the final estimate of $\hat{\tau}_{DR}(\mathbf{x}_i) =$ $E[\hat{\psi}_{DR}(\mathbf{x}_i)|X = \mathbf{x}_i]$. This learner, used to estimate CATE, can be seen as the corresponding method for AIPW to estimate ATE, equation (3).

To sum up, these meta-learners employ diverse methodologies for estimating CATE, utilizing both outcome modeling and propensity score techniques to produce results that are both robust and flexible. One way to conceptualize these meta-learners for estimating CATE is to view them as a means of estimating the individual contributions (summands) that sum up to the overall estimation of ATE. These individual contributions can be seen as causal contrasts, Y(1) - Y(0), in expectation.

2.2 Using DR-learner to assess TEH within the WATCH framework

In the following sections, we will illustrate how the DR-learner procedure can be used to address the three objectives we aim to answer in WATCH to assess heterogeneity. However, before that, we will demonstrate how we implemented the DR-learner.

2.2.1 Implementing DR-learner Using Stacking Machine Learning

Kennedy [13] introduced the approach for constructing the DR-learner building upon the idea of estimating "pseudo-outcomes" as an intermediate step. Apart from providing a clear expression for the estimator (Equation (5)), Kennedy also introduced an algorithm (Algorithm 1) that leverages cross-fitting techniques. Cross-fitting[22] helps to mitigate overfitting and improve the estimator's performance by partitioning the data into folds. The propensity score model $\hat{\pi}(x)$ and the outcome models $\hat{\mu}_1(x)$ and $\hat{\mu}_0(x)$ are estimated using training data, then the pseudo-outcomes are computed based on the estimated models. Finally, these pseudo-outcomes are used to estimate the CATE in the test data. At the end, the results from all folds are aggregated to produce the final doubly robust estimate of CATE. Kennedy's approach provides desirable guarantees, including consistency and asymptotic normality of the estimator. These guarantees enhance the reliability of the DR-learner in practical applications, ensuring that it delivers robust and accurate estimates even in the presence of complex data structures and potential model misspecifications.

Algorithm 1 DR-learner

Input: $Z = \{y_i, a_i, \mathbf{x}_i\}_{i=1}^n$

- 1: Split sample Z into K random subsets (folds)
- 2: for $k \in \{1, ..., K\}$ do
- 3: assign samples two train/test set: $S_{train} = Z \setminus S_k$ and $S_{test} = S_k$
- 4: Step 1: Nuisance training
- 5: learn nuisance functions: $\hat{\pi}, \hat{\mu}_0$ and $\hat{\mu}_1$ in S_{train}

6: Step 2: Pseudo-outcome regression

7: estimate pseudo-outcomes: $\widehat{\psi}_{\text{DR},k}(\mathbf{x}_i) = \frac{a_i - \widehat{\pi}(\mathbf{x}_i)}{\widehat{\pi}(\mathbf{x}_i)(1 - \widehat{\pi}(\mathbf{x}_i))} \left(y_i - \widehat{\mu}_{a_i}(\mathbf{x}_i)\right) + \widehat{\mu}_1(\mathbf{x}_i) - \widehat{\mu}_0(\mathbf{x}_i) \text{ in } i \in S_{test}$

- 8: train final CATE model: $\hat{\tau}_{DR,k}$ in S_{test}
- 9: estimate CATE: $\hat{\tau}_k(\mathbf{x}_i) = \hat{\tau}_{DR,k}(\mathbf{x}_i)$ for $\mathbf{x}_i \in Z$
- 10: end for(Step 3: Cross-fitting by repeating the process with different folds)

11: generate vector of pseudo-outcomes: $\hat{\psi}_{\text{DR}} = \{\hat{\psi}_{\text{DR},1}, \hat{\psi}_{\text{DR},2}, \dots, \hat{\psi}_{\text{DR},K}\}$

12: generate vector of CATE estimates: $\hat{\tau}_{DR}(\mathbf{x}_i) = \frac{\sum_{k=1}^{K} \hat{\tau}_k(\mathbf{x}_i)}{K}$ for $\mathbf{x}_i \in Z$

because they represent the estimated effect of the treatment on the outcome for each individual, adjusting for covariates. This creates a pseudo-observation that reflects the causal effect of the treatment at the individual level, i.e. ITE, which is the difference between the potential outcomes Y(1) - Y(0) for that individual.

As we see in Algorithm 1, to construct the DR-learner we need to estimate in each fold three nuisance functions $(\hat{\pi}, \hat{\mu}_0, \hat{\mu}_1)$ and CATE $(\hat{\tau}_{DR})$. To this end we can utilize flexible regression models using machine learning. In our work we implement an ensemble of models using the **SuperLearner** R package, an algorithm that uses cross-validation to estimate the performance of multiple models, and it then creates an optimal weighted average of those models (stacking) using the test data performance.[23] In this ensemble we included two diverse models: LASSO regression model using the **glmnet** R package[24] and random forest of conditional inference trees (cforest) implemented in **party** R package [25]. The Super-Learner is used for estimating the outcome models for the control and treatment group, $\hat{\mu}_0$, $\hat{\mu}_1$ respectively, the propensity $\hat{\pi}$ and CATE $\hat{\tau}_{DR}$. The cross-validation of the **SuperLearner** is nested within the cross-fitting, and we use 10 folds (the default parameter) for the cross-validation, while for the cross fitting we use 5 folds.

Related works: Apart from the meta-learners we have discussed so far to derive pseudo-outcomes, there is a plethora of methods that have been suggested in the literature. Some other examples include the X-learner[10], which is an extension of the T-learner, specifically designed to handle scenarios with strong imbalances between treatment arms, while it is also adapt to handle situations with confounding variables. R-learner[26] is a two-stage procedure where in the first stage the nuisance parameters are estimated, such as the propensity score and the outcome model. Residuals are then computed by subtracting the predicted values from the observed data and in the second stage, these residuals are used to construct a "pseudo-outcome", which is then modeled in order to estimate the causal parameter of interest. This two-step process enables the R-learner to accurately estimate the treatment effect by controlling for confounding variables. More recently, the Efficient Plug-in (EP)-learner[27] was introduced, which is based on a novel, efficient plug-in estimator for the class of population risk functions under consideration, addressing challenges such as the instability associated with inverse probability weighting and the violation of bounds in pseudo-outcomes.

2.2.2 Using DR-learner to assess the evidence against treatment effect heterogeneity (Objective 1)

In this section we will show how to use pseudo-outcomes to perform an overall test against homogeneity. We will utilize the conditional inference procedures leveraging a permutation test framework.[28] Our main aim is to test independence between the pseudo-outcomes $\hat{\psi}_{\text{DR}}$ and the high-dimensional set of covariates $X = (X_1, X_2, \ldots, X_p)$. Formally, we test the null hypothesis $H_0: P(\hat{\psi}_{\text{DR}} \mid X) = P(\hat{\psi}_{\text{DR}})$ against arbitrary alternatives, where P denotes the probability measure.[†]

Permutation tests are one option for performing this test, and in our work we will consider the conditional inference framework reviewed in [28] and implemented in the **coin** R package[30]. The default implementation uses linear statistics of the form

$$\mathbf{\Gamma} = \sum_{i=1}^{N} g(\mathbf{x}_i) \widehat{\psi}_{\mathrm{DR}}(\mathbf{x}_i) \in \mathbb{R}^p,\tag{7}$$

[†]Please note that in a formal mathematical perspective, rejecting this null does not prove that there is treatment effect heterogeneity. Indeed, treatment effects are heterogeneous precisely when the mean of $\hat{\psi}_{\text{DR}}$ depends on X, but technically, it is possible that (e.g.) the variance of $\hat{\psi}_{\text{DR}}$ depends on X but not the mean, in which case the null would be false while the treatment effect is homogeneous. However, our test statistics should only have power when $\mathbb{E}[\hat{\psi}_{\text{DR}} | X]$ depends on X, so in practice this should not be an issue. Indeed, previous literature shows that permutation tests can often be robust to this sort of issue (see, e.g., Chung and Romano[29]). Overall, our simulations show that our method effectively controls type I error while having high power.

where g is a transformation of the covariates (this transformation is important when we have categorical variables), and $\hat{\psi}_{DR}(\mathbf{x}_i)$ is the pseudo-outcome derived by the DR-learner for the example \mathbf{x}_i .

By (jointly) permuting the covariates \mathbf{x}_i against the outcome $\widehat{\psi}_{DR}(\mathbf{x}_i)$, the null distribution of \mathbf{T} can be derived. The mean and covariance matrix under the null are then calculated to create a standardized version of \mathbf{T} . The test statistic \mathbf{T} is a *p*-dimensional vector, i.e. $\mathbf{T} = \{T_1, ..., T_p\}$, and to reduce it to a univariate statistic (and thus perform a global test), Hothorn et al.[30] suggest the maximum or the quadratic form of the standardized versions of \mathbf{T} as the final test statistic.

- Max-type statistic takes the maximum of the absolute values of the standardized test statistics, i.e. $T_{\max} = \max_{j=1,\dots,p} |T_j|$. This approach is useful for detecting the largest effect among multiple comparisons.
- Quadratic-type statistic takes a quadratic form of the test statistics, $T_{quad} = \sum_{j=1}^{p} T_{j}^{2}$. This approach offers a collective deviation of the observed data from the null hypothesis by summing the squared standardized deviations of all comparisons.

The choice between the maximum and quadratic statistics depends on the specific hypothesis and the nature of the expected associations in the data. The maximum statistic is ideal for scenarios where a single predictor is expected to have a large impact, while the quadratic statistic is suited for detecting distributed moderate effects across multiple predictors.

Given that X may be a mixture of continuous and categorical variables, the transformation process defined by g becomes crucial. Continuous variables generally undergo rank transformation to make the test robust against outliers and non-normality. Each continuous variable X_j is transformed into its rank among all observations. For categorical variables, contrast coding is typically applied, converting categorical variables into a set of binary variables representing the different levels.

In conclusion, the independence test using the permutation-based approach with max-type or quadratic-type statistics provides a robust framework for assessing the relationship between a scalar outcome and high-dimensional input variables, even when the data include a mixture of continuous and categorical variables. Furthermore, the **coin** package [30] provides the option to use an asymptotic approximation of the conditional null distribution of the test statistics, allowing for the efficient computation of p-values. This enhances the practicality of the method, particularly for large datasets. In Section 3.3.1, we compare these two approaches (max-type and quadratic-type), and the best method is then compared against other methods suggested in the literature in Section 3.4.

Related works: In their tutorial, Lipkovich et al. [31, Section 6.1] provide a comprehensive review of various strategies for assessing heterogeneity. Chernozhukov et al. [32] introduced the concept of the best linear projection (BLP) of a ML proxy for the CATE, denoted as $\widehat{\Delta}(X_i)$. The BLP is formulated through the following equation:

$$Y_i - \widehat{m}^{-i}(X_i) = \alpha \overline{\Delta} \left(A_i - \widehat{\pi}^{-i}(X_i) \right) + \beta \left(A_i - \widehat{\pi}^{-i}(X_i) \right) \left(\widehat{\Delta}^{-i}(X_i) - \overline{\Delta} \right)$$

In this equation, $\hat{m}^{-i}(X_i)$ and $\hat{\pi}^{-i}(X_i)$ represent the use of leave-one-out cross-validation (i.e. the predictions for the outcome and for the propensity score model are generated by excluding the *i*-th observation from the dataset when fitting the models), and $\overline{\Delta}$ is the average treatment effect. This technique is commonly employed to reduce bias and improve estimation accuracy. A coefficient $\beta > 0$ signifies the presence of heterogeneity in the treatment effect. The BLP framework allows for the incorporation of ML estimators of CATE into a linear regression model, providing a method for testing hypotheses regarding treatment effect heterogeneity. The **grf** R package for Causal Forest[33] offers an omnibus test to identify heterogeneity in treatment effects, based on the best linear fit of the target estimand. This test utilizes predictions made on held-out data and is grounded in the previously discussed equation, and we compare against this method in our simulations. Finally, the concept of Group Average Treatment Effect (GATE) testing, introduced by Chernozhukov et al.[32] and further developed by Imai and Li[34], plays a pivotal role in assessing heterogeneity in treatment effects across different subpopulations. The null hypothesis for GATE testing asserts that $E(\Delta(X)|G_1) = \cdots = E(\Delta(X)|G_K)$, where the groups G_K are defined using a general ML technique for estimating CATE. Imai and Li's[34] significant contribution is their development of a cross-validation or cross-fitting framework, which enhances the robustness of testing for treatment effect heterogeneity. This framework is versatile and can be applied regardless of the specific ML algorithm used for estimating CATE. Additionally, they derived the asymptotic variance for the test statistics within this cross-fitting framework, providing a solid foundation for evaluating the homogeneity of treatment effects. Finally, in a recent work Ji et al. [35] introduced dual bound method to estimate and perform inference on a class of partially identified causal parameters. Interestingly, when these bounds can be applied to the variance of the CATE to test for heterogeneity. While the primary focus of this work is on estimation rather than testing, the derived bounds offer a valuable byproduct for testing purposes.

2.2.3 Using DR-learner to identify effect modifiers (Objective 2)

To determine which covariates influence the treatment effect, we will derive importance scores from the pseudooutcomes and rank the variables based on their impact on the treatment effect. To accomplish this in a multivariate fashion, we will use the data $(X, \hat{\psi}_{DR})$, where X represents the set of covariates and $\hat{\psi}_{DR}$ represents the pseudo-outcomes derived in Line 11 of Algorithm 1, to build a regression model. Then, to rank the different covariates based on their variable importance scores, we will employ a method that ensures unbiased selection,[36] given that our clinical variables include a mix of continuous and categorical data types. It is crucial to avoid any selection bias towards covariates with many potential splits, such as continuous variables or categorical variables with many categories, as this can distort the true importance of the variables. This bias arises because such variables tend to create more opportunities for splits that decrease impurity.

For that reason, we use conditional inference trees, an unbiased recursive partitioning method specifically designed to handle such biases.[37] Conditional inference trees are a type of decision tree algorithm that addresses the selection bias inherent in traditional decision trees by using statistical tests to select splits, rather than choosing splits based solely on impurity reduction measures. This approach leads to more unbiased variable selection and often more reliable importance scores, particularly when dealing with variables of differing types. More specifically, we will utilize the **party** R package [25] to construct conditional random forests (CRF). CRF are ensemble methods that build multiple conditional inference trees as base learners, thereby improving the stability and accuracy of the model. Each tree in the forest is built with a different bootstrap sample of the data, and the final model aggregates the predictions from these trees, leading to robust estimates of variable importance.

The main way to derive variable importance scores in the context of CRF is the permutation importance. This approach involves shuffling the values of a predictor variable and then measuring the subsequent decrease in model accuracy. The underlying intuition is straightforward: if a variable is crucial to the model's predictive power, randomly permuting its values will significantly disrupt the model's performance, leading to a notable decline in the performance. It reflects the contribution of each variable to the model's predictive power, and it is useful when the goal is to identify which variables have the largest direct impact on model performance. To derive these importance scores, we will then use the **permimp** R package [38]. In our case this importance score is an interpretable metric that capture how "important" each covariate is in predicting the pseudo-outcomes. Covariates with higher importance scores are more influential in determining the treatment effect and are thus identified as potential effect modifiers. The top-ranking covariates are chosen for further exploration in subsequent

analyses.

The approach we followed in this section, which involves deriving pseudo-outcomes and then using a method to obtain variable importance scores by regressing X on these pseudo-outcomes, is highly versatile. For example, this approach can be applied with any other method for deriving importance scores from pseudo-outcomes, such as those discussed by Hooker et al.[39] In the simulations (Section 3.3.2), we compare against SHAP (SHapley Additive exPlanations) values, which is another state-of-the-art method to derive variable importance scores.[40] **Related works:** Importance scores that capture how strongly a variable modifies treatment effects can also be derived from Causal forest,[33] and in our simulation study, in the simulations we compare against this method in Section 3.4. Other works have developed methods to formally test which covariates modify treatment effects,[41, 42, 43] but this alternative objective is beyond the scope of this work—we instead focus on Objective 2, getting a good (unbiased) ranking of which covariates modify the treatment.

2.2.4 Using DR-learner to estimate individual treatment effects (Objective 3)

DR-learner by design is tailored in estimating CATE (this outcome is provided in Line 12 of Algorithm 1).[13] One of the key features of the DR-learner is its use of cross-fitting, a technique that plays a critical role in reducing bias and improving the precision of causal estimates. While Kennedy[13] suggested one way of performing cross-fitting in DR-learner, various other alternatives can be performed. For example, Jacob[11, Algorithm 2] uses an alternative implementation, which firstly derives the pseudo-outcomes for all the examples using cross-validation, and in a second layer of cross-fitting CATE is estimated through an out-of-bag procedure. Another implementation of cross-fitting is suggested by Jacob[44, Algorithm 1], which can be seen as the bootstrapped version of the original algorithm suggested by Kennedy[13]. In our work, we will explore two different variations of the cross-fitting:

- CATE from DR-learner: In this approach we are using CATE estimates returned by the original methodology, in other words we are using the $\hat{\tau}_{DR}$ estimates from Line 12 of Algorithm 1.
- CATE from OOB estimates of cforest: In this approach we utilise the conditional random forest model that we build using (X, \$\hat{\psi}_{DR}\$) to derive the effect modifiers for Objective 2 (Section 2.2.3), where \$\hat{\psi}_{DR}\$ represents the pseudo-outcomes derived in Line 11 of Algorithm 1. While we build this model to derive variable importance scores, we can use it also to predict CATE using the out-of-bag prediction capabilities that it offers. This approach shares similarities with the cross-fitting for DR-learner suggested by Jacob[11, Algorithm 2].

In Section 3.3.3, we compare these two approaches and the best method is then compared against other methods suggested in the literature in Section 3.4.

3 Simulations study

In this section, we will perform a simulation study to compare all the different flavors of the DR-learner we described in Section 2. To generate scenarios that mimic clinical trial data, we will use the **benchtm** R package. Section 3.1 provides a brief description of how the scenarios were simulated, while Sun et al. [45] provide more detailed information on these scenarios. Section 3.2 discusses the performance measures for assessing TEH under the three objectives of the WATCH framework. Sections 3.3.1, 3.3.2, and 3.3.3 present our results on using different flavors of the DR-learner for Objectives 1, 2, and 3, respectively. Finally, Section 3.4 compares our DR-learner against various competing methods.

Table 1: Simulation models. Here $a \lor b$ is a logical statement representing "a or b", $a \land b$ a logical statement representing "a and b", I(.) is the indicator function, $\Phi(.)$ is the cumulative distribution function (cdf) of standard normal distribution, and s is a scaling factor that is chosen depending on the simulation scenario to achieve a specific R^2 on the control group (A = 0). Each of the four scenarios is run for 5 settings (corresponding to $\beta_1 = 0, 0.5\beta_1^*, \beta_1^*, 1.5\beta_1^*, 2\beta_1^*$).

No.	Models for covariates from mimic real data
Scenario 1	$f(\mathbf{X}, A) = s \times (0.5I(X_1 = \mathbf{Y}) + X_{11}) + A(\beta_0 + \beta_1 \Phi(20(X_{11} - 0.5)))$
Scenario 2	$f(\mathbf{X}, A) = s \times (X_{14} - I(X_8 = N)) + A(\beta_0 + \beta_1 X_{14})$
Scenario 3	$f(\mathbf{X}, A) = s \times (I(X_1 = \mathbf{N}) - 0.5X_{17}) + A(\beta_0 + \beta_1 I((X_{14} > 0.25) \land (X_1 = \mathbf{N})))$
Scenario 4	$f(\mathbf{X}, A) = s \times (X_{11} - X_{14}) + A(\beta_0 + \beta_1 I((X_{14} > 0.3) \lor (X_4 = \mathbf{Y})))$

3.1 Data generation scenarios

Let Y represent a clinical endpoint, $\mathbf{X} = (X_1, X_2, \dots, X_p)$ denote the vector of p baseline covariates, and $A \in \{0, 1\}$ the binary treatment indicator. We set $P(A = 1|X = \mathbf{X}) = P(A = 0|X = \mathbf{X}) = 0.5$. The response is generated from

$$f(\mathbf{X}, A) = f_{\text{prog.}}(\mathbf{X}) + A(\beta_0 + \beta_1 f_{\text{pred.}}(\mathbf{X})),$$
(8)

where $f_{\text{prog.}}(\mathbf{X})$ represents the prognostic function and $f_{\text{pred.}}(\mathbf{X})$ represents the predictive function. In our simulation study, we focus on continuous response variables, $Y = f(\mathbf{X}, A) + \epsilon$, where $\epsilon \sim N(0, 1)$, although our methods also apply to binary responses and the real case study in Section 4 focuses on this endpoint type. We use p = 30 baseline covariates, which typically include demographic, disease severity or subtype covariates, and drug mechanism-related biomarkers. This number is realistic based on our experience with clinical studies. Four scenarios for $f_{\text{prog.}}(\mathbf{X})$ and $f_{\text{pred.}}(\mathbf{X})$ are shown in Table 1.

The parameters β_0 and β_1 together determine the overall treatment effect. They are selected to achieve a power of 0.5 for an unadjusted Gauss test of the overall treatment effect. This realistically mimics Phase III study settings where the overall treatment effect is slightly smaller than anticipated during the design stage. Investigating covariates that modify the treatment effect and identifying subgroups with enhanced treatment effects is particularly relevant in this context. The parameter β_1 determines the extent of treatment effect heterogeneity: a value close to zero indicates similar treatment effects across patients, while a large positive or negative value suggests that treatment effects vary according to $f_{\text{pred.}}(\mathbf{X})$. Values β_1^* are calculated to achieve a power of 0.8 for testing $H_0: \beta_1 = 0$ versus $H_1: \beta_1 \neq 0$ given the data-generating model in (8), with a Type I error rate of 0.1. Scenarios $0, 0.5\beta_1^*, \beta_1^*, 1.5\beta_1^*, 2\beta_1^*$ are considered for β_1 . For scenarios where $\beta_1 \geq \beta_1^*$, treatment effect modification is realistically detectable, assuming known $f_{\text{prog.}}(\mathbf{X})$ and $f_{\text{pred.}}(\mathbf{X})$. The value β_0 is chosen to achieve an overall treatment effect power of 0.5 in each scenario. Refer to Sun et al. for details on the analytical power calculation.

Our simulation study also generates covariates to emulate the joint distribution of predictors from Phase III pharmaceutical trials for an inflammatory disease. This approach approximates both marginal distributions and predictor dependencies. We use 30 baseline covariates (8 categorical, 22 numerical), including demographic and disease-related variables. We utilize the **synthpop** R package with default settings to generate synthetic data.[46] For confidentiality, covariates are labeled X_1, X_2, \ldots, X_{30} , with categorical variable levels ciphered and numeric variables scaled to [0, 1]. Using this generated synthetic data set as input, the **synthpop** function generates data sets of n = 500 for each simulation.

The treatment effect varies as a step-like (Scenario 1) or linear (Scenario 2) function of a single continuous

covariate. Although step and linear functions might seem unrealistic, they lie at the extremes of a plausible range of smooth monotonic functions. Scenarios 3 and 4 involve step functions defined by two covariates, with "and" or "or" structures, respectively. Each scenario includes a covariate that is prognostic but not predictive, alongside one that is both prognostic and predictive. To account for the magnitude of prognostic effects on outcomes, we select the scaling factor s in Table 1 to achieve realistic R^2 values on how well covariates predict outcomes in the control arm in the original data. LASSO regression on real data models the outcome based on covariates for the control group, leading to R^2 value of $R^2 = 0.32$. This value then guided the selection of s in Table 1, ensuring it is replicated in the control arm across scenarios. More details on the simulation process can be found in Sun et al.[45]

3.2 Performance measures

We will compare the methods with respect to their performance on the following measures:

- *Objective 1:* The treatment effect heterogeneity assessment is conducted, and each method provides a corresponding p-value. These p-values should have two desirable properties:
 - (i) when data are simulated with no treatment effect heterogeneity, i.e. $\beta_1 = 0$, the p-values should follow a uniform distribution in [0, 1],
 - (ii) when data are simulated with treatment effect heterogeneity, i.e., $\beta_1 > 0$, smaller p-values indicate a more powerful method.
- Objective 2: To identify effect modifiers, we consider the most predictive biomarker reported from each method. Again, there are two desirable properties:
 - (i) when data are simulated with no treatment effect heterogeneity, i.e. $\beta_1 = 0$, an unbiased method should select each biomarker as the most predictive one with equal probability. In this case, we reported the probability that each biomarker is selected as the most important predictive biomarker.
 - (ii) when data are simulated with treatment effect heterogeneity, i.e., $\beta_1 > 0$, the true predictive biomarkers should have higher probability to be selected. In this case, we reported the probability that the top selected biomarker is truly predictive.
- Objective 3: each method returns an estimate of the individualized treatment effect, i.e. estimate of CATE, and we calculate the Mean Squared Error (MSE) between the estimated value and the actual individual treatment effect. Lower MSE values indicate more accurate estimations of the individual treatment effects.

3.3 Evaluating approaches within the DR-learner framework

As presented in Section 2.2, our DR-learner framework for assessing heterogeneity is quite versatile, allowing for various approaches to address the three objectives. In this simulation study, we will empirically identify the best approach for each objective. In Section 3.4, we will compare the top-performing DR-learner with various other competing methods from the literature.

3.3.1 Evaluation with respect to overall test against homogeneity (Objective 1)

In this section we will compare the two tests of our DR-learner approach we presented in Section 2.2.2 with two more tests we reviewed in the same section. The four methods we compare are the following.

• *DR-Maximum Statistic:* Utilize the coin R package to conduct an independence test between the multivariate covariate space and the pseudo-outcome, employing the maximum statistic and derive the p-values.

• *DR-Quadratic Statistic:* Utilize the **coin** R package to conduct an independence test between the multivariate covariate space and the pseudo-outcome, employing the quadratic statistic and derive the p-values.

In Figure 2, we present the boxplots of the p-values over 500 runs. Ideally, these values should be uniformly distributed under the no treatment effect heterogeneity setting. Interestingly, this uniform distribution is observed for our two suggested methods.

Figure 2: Comparison of the two methods for testing heterogeneity presented in Section 2.2.2 with respect to Objective 1(i). Data are simulated under the condition of no treatment effect heterogeneity (i.e., $\beta_1 = 0$). We report the boxplot of the p-values across 500 runs, and we are expected to be uniformly distributed between 0 and 1.

In Figure 3, we present the averages of the p-values over 500 runs in scenarios with various degrees of treatment effect heterogeneity (TEH). The lower the p-value, the more powerful the method, so the DR-learner approaches outperform the other methods. Overall, the maximum statistic outperforms the quadratic statistic, and this trend is more pronounced when there is only one biomarker contributing to the TEH (for example Scenarios 1 and 2). The quadratic statistic may be more suitable for scenarios where many covariates interact to generate the TEH (for example Scenarios 3 and 4), as it focuses on the overall strength. In contrast, the maximum statistic may be more suitable when the effect modifiers do not interact to create the TEH.

Figure 3: Comparison of the two methods for testing heterogeneity presented in Section 2.2.2 with respect to Objective 1(ii). Data are simulated under various degrees of treatment effect heterogeneity (x-axis). We report the average p-values (across 500 runs) and when there is treatment effect heterogeneity (i.e., $\beta_1 > 0$), the lower the p-value, the more powerful the method.

3.3.2 Evaluation with respect to identification of effect modifiers (Objective 2)

In this section, we compare two methods for deriving effect modifiers using the pseudo-outcomes from the DRlearner, as presented in Section 2.2.3. The methods we compare are the following.

- *DR-Perm(cforest)*: Utilize the **party** R package to build a cforest (i.e. a forest of conditional inference trees) on the covariate space to predict pseudo-outcomes generated by the DR-learner. Then, use the **permimp** R package to derive permutation importance scores.
- DR-SHAP(rf): Utilize the ranger R package to build a random forest on the covariate space to predict pseudooutcomes generated by the DR-learner. Then, use the treeshap R package to derive TreeSHAP explanations and importance scores.

In Figure 4 we simulate scenarios without treatment effect heterogeneity, and we present how often each biomarker is selected as the most important. Under this scenario, a method without selection preference will have probability of selecting each biomarker close to $1/30 \approx 0.033$. The SHAP(rf) method is biased toward continuous biomarkers, since there are continuous biomarkers that have selection probability around 15%, while all the categorical biomarkers have the smallest probabilities to be selected. The bias of SHAP towards high entropy biomarkers is also reported in the literature, e.g. Baudeu et al.[47]

Figure 4: Comparison of two methods for deriving effect modifiers (presented in Sec. 2.2.3) with respect to Objective 2(i). Data are simulated under the condition of no treatment effect heterogeneity (i.e., $\beta_1 = 0$). We report the average probability (across 500 runs) that each biomarker is selected as the most important predictive biomarker. Since there is no treatment effect heterogeneity, for a method to be unbiased all biomarkers should have probability equal to $1/30 \approx 0.03$, dashed vertical line.

In Figure 5, we present the probability that the top biomarker returned by each method to be an actual effect modifier across 500 runs in scenarios with various degrees of TEH. Both methods perform similarly, but we should mention that when biomarker interact to create TEH (Scenarios 3 and 4) the permutation approach outperforms SHAP in all settings.

3.3.3 Evaluation with respect to estimation of individual treatment effects (Objective 3)

In this section we will compare the performance of various methods we discussed for estimating CATE. Firstly, we will compare the two different cross-fitting approaches presented in Section 2.2.4.

- CATE from DR-learner: Using the estimates of CATE returned by the original approach[13], i.e. Algorithm 1.
- CATE from OOB(cforest): Using the out-of-bag predictions from the cforest we used for answering Objective 2, i.e. identify effect modifiers by building a cforest to predict the pseudo-outcomes. As we already mentioned,

Figure 5: Comparison of two methods for deriving effect modifiers (presented in Sec. 2.2.3) with respect to Objective 2(ii). Data are simulated under various degrees of treatment effect heterogeneity (x-axis). We report the average (across 500 runs) probability that the top selected biomarker is truly predictive, and the higher this probability are the better the performance.

this approach can be seen similar to the one presented by Jacob[11, Algorithm 2].

Figure 6 compares the two methods in terms of the MSE, and as we see the original cross-fitting performs the best. This phenomenon can be attributed to the way CATE from OOB(cforest) is structured. In this method, pseudo-outcomes are initially estimated using all available data, and then the cforest is constructed based on this same dataset. Effectively, this equates to each data point being used twice; a practice which can introduce a risk of over-fitting.

Figure 6: Comparison of two different cross-fitting strategies (presented in Sec. 2.2.4) with respect to Objective 3. Data are simulated under various degrees of treatment effect heterogeneity (x-axis). We report the MSE (across 500 runs) for estimating CATE, and the lower this error is the better the performance of the cross-fitting strategy.

Another insightful comparison is to evaluate the performance of the DR-learner against its "main components", the IPW and T-learner. Details about these learners can be found in Section 2.1.2. To keep the comparison fair, we will use the same nuisance models and cross-fitting procedure for all the learners as described in Algorithm 1. As we see in Figure 7, the DR-learner outperforms the other two methods, since it achieved lower MSE almost in all settings.

Figure 7: Comparison of three learners for estimating individual treatment effect (presented in Sec. 2.1.2) with respect to Objective 3. Data are simulated under various degrees of treatment effect heterogeneity (x-axis). We report the MSE (across 500 runs) for estimating CATE, and the lower this error is the better the performance of the learner.

3.4 Comparing our DR-learner proposal with various other competing methods

In this section, we will compare our DR-learner based methodology for assessing heterogeneity against various competing methods. These methods have demonstrated competitive performance in a neutral comparison study conducted by Sun et al.[45] Below is a brief description of the approaches we will compare:

- *DR-learner:* Building on our results of Section 3.3, we will use the DR-learner with the best performing approach for each objective:
 - *Objective 1:* Utilize the **coin** R package to conduct an independence test between the multivariate covariate space and the pseudo-outcome, employing the maximum statistic and derive the p-values.
 - Objective 2: Utilize the **party** R package to build a cforest (i.e. a forest of conditional inference trees) on the covariate space to predict pseudo-outcomes generated by the DR-learner. Then, use the **permimp** R package to derive permutation importance scores.
 - Objective 3: Using the estimates of CATE returned by the original approach[13], i.e. Algorithm 1.
- Univariate: A linear model is used, and a likelihood ratio test is performed for each biomarker X_j (j = 1, 2, ..., 30). This test compares the interaction model $f(X_j, A) = \alpha_1 X_j + \beta_0 A + \beta_1 A X_j$ with the main effect model $f(X_j, A) = \alpha_1 X_j + \beta_0 A$. The p-value p_j for each biomarker X_j is recorded.
 - Objective 1: We use $\min(p_j) \times 30$ (Bonferroni adjustment) as the p-value for the treatment effect heterogeneity test.
 - Objective 2: The biomarker X_i^* with the smallest p-value is selected as the top predictive biomarker.
 - Objective 3: The model $f(X_j, A) = \alpha_1 X_j^* + \beta_0 A + \beta_1 A X_j^*$, where X_j^* is the top predictive biomarker, is used to predict the treatment effect τ for each individual.
- Multivariate: A linear model is used, and a likelihood ratio test is conducted to compare the interaction model $f(\mathbf{X}), A) = \sum_{j=1}^{30} \alpha_j X_j + \beta_0 A + \sum_{j=1}^{30} \beta_j A X_j$ to the main effect model $f(\mathbf{X}), A) = \sum_{j=1}^{30} \alpha_j X_j + \beta_0 A$.
 - Objective 1: The corresponding p-value is recorded and used.
 - Objective 2: The p-values from the interaction model for each interaction X_jA are compared, and the X_j^* with the smallest interaction p-value is selected as the top predictive biomarker.

- Objective 3: The interaction model $f(\mathbf{X}), A) = \sum_{j=1}^{30} \alpha_j X_j + \beta_0 A + \sum_{j=1}^{30} \beta_j A X_j$ is used to predict individual treatment effects.
- MOB-L: We use the R package partykit to implement the MOB method, utilizing the glmtree function for continuous outcomes. A variant of the MOB procedure is applied, where MOB is restricted to split only based on parameter instability for the treatment effect parameter in the model. This is achieved using the parm option (as described in the literature[48, 49]). Although this approach seems intuitive, Seibold et al.[50] demonstrate that, in purely prognostic scenarios, it may lead to prognostic biomarkers being misidentified as predictive. This issue is also evident in the simulation results of Loh and Cao[48] and Thomas et al.[49] To address this, LASSO is first used to select prognostic biomarkers. This involves fitting LASSO regression models (glmnet package with the penalty parameter chosen by cross-validation and the lambda.1se option) f(X)) = ∑_{j=1}³⁰ α_jX_j to each of the two treatment groups separately and selecting the union of the two sets of selected biomarkers X₁^{*}, X₂^{*}, ..., X_k^{*}. The model fitted in each node in MOB is f(X)) = β₀A + ∑_{j=1}^k α_jX_j^{*} where all biomarkers are used for node splitting selection. To build each tree, the model uses Bonferroni adjustment with alpha = 0.10 and minsize = 0.2 x 500 = 100.
 - *Objective 1:* The Bonferroni adjusted p-value for each biomarker when testing the root node is extracted, and the smallest p-value is used.
 - *Objective 2:* The biomarker with the smallest p-value is selected as the top predictive biomarker, regardless of its significance.
 - *Objective 3:* Individualized treatment effects are predicted on a linear scale based on the model tree. Since a linear model with prognostic biomarkers is considered for each node, the MOB model is abbreviated as MOB-L.
- Causal Forest (CF): To build the causal forest, we use 2000 trees (default parameter), and all tunable parameters are tuned by cross-validation using the **grf** package.
 - Objective 1: We directly report the p-value of the treatment effect heterogeneity test from the R package. The test is implemented with the test_calibration function, which computes the best linear fit of the conditional average treatment effect using the forest prediction (on held-out data) and the mean forest prediction as the sole two regressors [51]. This test for heterogeneity is motivated by the "best linear predictor" method of Chernozhukov et a.[32]
 - Objective 2: The most predictive biomarker is identified as the one with the largest variable importance score (a depth-weighted average of the number of splits on the biomarker of interest), calculated by the variable_importance function.
 - Objective 3: The individual treatment effect is returned by the model.

Regarding Objective 1(i), as illustrated in Figure 8, only the Multivariate and DR-learner methods achieve a uniform distribution of p-values under the null hypothesis of no TEH. The other methods tend to skew towards higher p-values, making them more conservative. Furthermore, to investigate whether any of the methods lead to inflated false positive rates, we present the results in Table 2. This table shows the estimated false positive rate when the nominal level is $\alpha = 0.10$. The numbers represent the proportion of times that the *p*-value is less than or equal to 0.10. As we can see, all the methods provide estimates lower than the nominal level, indicating that they do not lead to an inflation of type-I error. For Objective 1(ii), Figure 9 demonstrates that our DR-learner consistently performs excellently, ranking in the top two methods across scenarios and degrees of TEH. In contrast, the Causal Forest and Univariate methods do not achieve comparable performance.

Figure 8: Comparison of our proposed DR-learner with competing methods regarding Objective 1(i). Data are simulated under the condition of no treatment effect heterogeneity (i.e., $\beta_1 = 0$). We report the boxplot of the p-values across 500 runs, and we are expected to be uniformly distributed between 0 and 1.

Table 2: Checking whether the methods lead to inflation of type-I error. For the data presented in Figure 8 we estimate the false positive rates for nominal level of $\alpha = 0.10$.

	DR-learner	Univariate	Multivariate	MOB-L	Causal Forest
Scenario 1: 2.30 * (0.5(X1 ==' Y') + X11) + $A\beta_0$	0.08	0.10	0.09	0.09	0.04
Scenario 2: $1.42 * (X14 - (X8 ==' N')) + A\beta_0$	0.09	0.09	0.09	0.08	0.04
Scenario 3: $1.39 * ((X1 == N') - 0.5X17) + A\beta_0$	0.08	0.07	0.09	0.08	0.05
Scenario 4: 2.89 * (X11 – X14) + $A\beta_0$	0.08	0.09	0.09	0.08	0.04

Figure 9: Comparison of our proposed DR-learner with competing methods regarding Objective 1(ii). Data are simulated under various degrees of treatment effect heterogeneity (x-axis). We report the average p-values (across 500 runs) and when there is treatment effect heterogeneity (i.e., $\beta_1 > 0$), the lower the p-value, the more powerful the method.

For Objective 2(i), as illustrated in Figure 10, all methods are unbiased except for the Causal Forest, which shows a clear preference for continuous biomarkers. For instance, in Scenarios 1-3, across 500 runs without TEH, it never selects any of the categorical variables (red circle). Regarding Objective 2(ii), as shown in 11, our DRlearner consistently achieves comparable performance, always ranking among the top 2-3 methods. In contrast, other methods show inconsistent performance across different scenarios. For example, the Causal Forest performs well in Scenarios 1 and 2, where the effect modifiers are continuous, but fails to achieve comparable performance in Scenarios 3 and 4, which include categorical effect modifiers.

Finally, for Objective 3, as illustrated in Figure 12, again we can see that DR-learner achieves comparable performance, very close to Causal Forest that is constantly the top method.

○ categorical + numeric

Figure 10: Comparison of our proposed DR-learner with competing methods regarding Objective 2(i). Data are simulated under the condition of no treatment effect heterogeneity (i.e., $\beta_1 = 0$). We report the average probability (across 500 runs) that each biomarker is selected as the most important predictive biomarker. Since there is no treatment effect heterogeneity, for a method to be unbiased all biomarkers should have probability equal to $1/30 \approx 0.03$, dashed vertical line. The Causal Forest method almost never selected any categorical variables as the most important, which is why there are no red circles in this method.

Figure 11: Comparison of our proposed DR-learner with competing methods regarding Objective 2(i). Data are simulated under various degrees of treatment effect heterogeneity (x-axis). We report the average (across 500 runs) probability that the top selected biomarker is truly predictive, and the higher this probability are the better the performance.

Figure 12: Comparison of two different cross-fitting strategies (presented in Sec. 2.2.4) with respect to Objective 3. Data are simulated under various degrees of treatment effect heterogeneity (x-axis). We report the MSE (across 500 runs) for estimating CATE, and the lower this error is the better the performance of the cross-fitting strategy.

To provide a high-level summary of the results, we have created Table 3. This table shows that the DR-learner is the only method that consistently achieves excellent or competitive performance. In contrast, the other methods fail to achieve competitive performance in at least one objective. Notably, the Causal Forest method performs well only in Objective 3, which makes sense since the method is designed to focus on estimating CATE. The MOB-L method shows mixed results.

Table 3: Comparison of methods across objectives. The symbols used are as follows:

 \checkmark indicates excellent performance, consistently ranking among the top-2 methods in all scenarios across all levels of TEH.

 indicates competitive performance, consistently ranking among the top-3 methods in all scenarios across all levels of TEH.

 \times indicates that the method failed to achieve competitive performance.

Method	Objective 1(i)	Objective 1(ii)	Objective 2(i)	Objective 2(ii)	Objective 3
Univariate	×	×	\checkmark	×	×
Multivariate	\checkmark		\checkmark	×	×
MOB-L			\checkmark	×	
Causal Forest	×	×	×	×	\checkmark
DR-learner	\checkmark	\checkmark	\checkmark		

4 Clinical trial example

Psoriatic arthritis (PsA) is a chronic inflammatory condition that impacts the joints, entheses, and skin, leading to impaired physical function.[52] PsA significantly affects the quality of life for patients, manifesting symptoms in various parts of the body, including the joints, spine, skin, and nails. Early detection and treatment are crucial to prevent permanent joint damage. The primary endpoint for assessing treatment improvement is the binary score ACR50, developed by the American College of Rheumatology.[53] This composite score indicates a 50% improvement in the number of tender and swollen joints, as well as a 50% improvement in three out of five criteria: patient global assessment, physician global assessment, functional ability measure (typically the Health Assessment Questionnaire, HAQ), visual analog pain scale, and high sensitivity C-reactive protein (hsCRP) or erythrocyte sedimentation rate. If these improvements are met, the score is Y = 1; otherwise, it is Y = 0.

Cosentyx (secukinumab) is approved for treating adult patients with active psoriatic arthritis and has been evaluated in several clinical trials. In this study, we analyze data from five Phase III trials: FUTURE 1,[54] FUTURE 2,[52] FUTURE 3,[55] FUTURE 4,[56] and FUTURE 5.[57] Our research objective is to identify markers that indicate treatment heterogeneity for ACR50 at week 16 when comparing Placebo (T = 0) versus Cosentyx (T = 1), regardless of dosage. The estimand of interest is the risk difference, i.e. Pr(Y = 1|T = 1) - Pr(Y = 1|T = 0).

There are three prior studies that analyze FUTURE trials with objectives similar to ours. Sechidis et al.[41] used the knockoff methodology to identify clinical variables that act as effect modifiers. They did a pooled analysis (all trials except FUTURE 1) while controlling the false discovery rate at 20%. They identified eight effect modifiers: C-reactive protein, age, polyarticular arthritis, asymmetric peripheral arthritis, psoriasis nail subset, sex, fatigue score, and body surface area (see Figure 5 in the aforementioned work[41]). Bornkamp et al.[58] used the same data for a subgroup analysis challenge. The teams provided various solutions, and in terms of the effect modifiers, the main insights were very similar to those in the previous work. For example, the variables most commonly used across the teams to define subgroups were C-reactive protein, age, and fatigue score (see Figure 2B in the aforementioned work[58]). Finally, Cardner et al.[59] analyzed proteomics data from serum samples. They trained a stability selection model on all trials except FUTURE 2 and identified beta-defensin 2 (BD-2) in serum as a promising effect modifier; higher baseline levels of BD-2 are robustly linked to better clinical outcomes with Secukinumab, but not with placebo.

For us, it would be insightful to assess TEH in these data using our DR-learner approach, and especially explore whether it identifies similar effect modifiers to those reported in the literature. To achieve this, we compiled a dataset from all trials, including 1937 patients. After preprocessing (e.g., removing covariates with more than 20% missing data and using multiple imputation to fill in missing values for the remaining covariates), we had 70 covariates of mixed type, categorical and numerical. These included a variety of variables, such as demographic information (e.g., age, sex, BMI), medical history (e.g., time since first PsA diagnosis, presence of psoriasis, presence of polyarticular arthritis), treatment and medication details (e.g., corticosteroid use, TNF alpha inhibitors), as well as lab values, clinical measurements, quality of life assessments, efficacy measurements, and the proteomic marker BD-2.

First of all, regarding **Objective 1**, the overall assessment provides a very low p-value (2×10^{-5}) , which is reassuring since we already have evidence from previously published works that various markers modify treatment effects. The more interesting insights come when we move to **Objective 2** and the identification of possible effect modifiers. Figure 13 shows the ranking of the top five variables returned by our DR-learner. The top two variables, C-reactive protein (CRPSI) and Age, are also the top discoveries in two previous works [41, 58], while the Baseline Fatigue Score (FACITSO) was also among the top variables in the previous works. Additionally, our method ranked the proteomic marker BD-2 in the third position, aligning with the previous work that identified BD-2 as a potential effect modifier.[59] Overall, our method effectively identified promising effect modifiers that have been reported in the literature.

Finally, it will be interesting to explore how the identified variables change the treatment effect. Figure 14 provides these visualizations for CRPSI and BD-2. For the first variable, we use the same categories as Sechidis et al.[41] and observe very similar results, i.e., the higher the CRPSI baseline value, the larger the treatment effect. An interesting caveat is that the estimated treatment effect from the DR-learner, which provides an adjusted way for estimation, shrinks the treatment effects in the different subgroups towards the overall effect. We observe a similar trend for the continuous marker BD-2, and again our results are in line with Cardner et al.[59]; patients with above-median levels of BD-2 at baseline had a higher treatment effect.

Figure 13: Variable importance ranking returned from our DR-learner. This figure shows the top 10 variables ranked by their importance, emphasizing their roles as effect modifiers. Higher-ranked variables indicate stronger modification effects.

5 Conclusions

In this work we demonstrated how the DR-learner could be effectively utilized within the WATCH workflow to provide a comprehensive framework for assessing treatment effect heterogeneity. The proposed methods addressed three key objectives: performing global tests for homogeneity, ranking covariates based on their influence on effect modification, and estimating individualized treatment effects.

By employing a non-parametric and robust implementation of the DR-learner with SuperLearner, we derived pseudo-outcomes that can be seen as patient level causal contrast in expectation. These pseudo-outcomes were used to conduct a global assessment against homogeneity using conditional inference permutation test, addressing the first objective. For the second objective, we formulated a regression problem and fitted random forests built with conditional inference trees, deriving permutation-based importance scores that were unbiased towards variable types and captured the strength of baseline covariates in modifying the treatment effect. Finally, the DR-learner was used to estimate the Conditional Average Treatment Effect (CATE), capturing individualized

Figure 14: Displays that capture how treatment effect changes with CRPSI and the proteomic marker (BD-2). We provide (i) our estimated treatment effect from the DR-learner (green symbol/line), (ii) the observed estimates (unadjusted) of the treatment effect (black symbol/line) with confidence intervals, (iii) for reference, the line of no treatment effect (red line), and (iv) for reference, the line of the overall treatment effect (ATE) (blue line).

treatment effects. Our extensive simulation study evaluated the operating characteristics of our methods across various objectives and compared them with several competing methods. While we primarily considered RCT scenarios, it is important to emphasize that the suggested methodology is also applicable to observational settings. This is because the DR-learner can guarantee unbiased estimates under standard assumptions, such as no unmeasured confounders.

Additionally, we applied our workflow to a large pool study of trials in Psoriatic Arthritis, demonstrating its utility in assessing heterogeneity. Through this case study we illustrated also another possible usage of our workflow; it can be used to assess the effect modification strength of omics biomarkers in the context of clinical variables. The importance of this type of approaches has been emphasized in other contexts. For example, Boulesteix and Sauerbrei [60] emphasize the need to evaluate the added predictive value of molecular signatures alongside existing clinical predictors for predicting patient outcomes in clinical settings. Having this type of evaluation in the context of discovering biomarkers that act as effect modifiers is crucial.

Future research should explore the application of our methodologies to a broader range of clinical endpoints. This includes not only continuous and binary, which are the ones we focused in this work, but also time-to-event data or count data. By extending our methods to these diverse endpoints, we can assess their robustness and generalizability across different types of clinical trial data, ultimately enhancing further their utility in real-world settings. To the best of our knowledge, there are no works that directly use the DR-learner to derive pseudo-outcomes for survival endpoints that could be directly integrated into the workflow we presented in this paper. However, there is a wealth of recent research[61, 62, 63, 64] that can serve as a foundation for exploring how a WATCH-type workflow can be applied to analyze survival data in line with our three objectives. Another area worth further exploration is using alternative ways for deriving effect modifiers in objective 2. For example, instead of our approach that relies on marginal permutation, we can leverage conditional randomization inference methods, [65, 66, 67, 68] or other alternatives.[69, 70]

Acknowledgments

The authors would like to thank Alain Marti for his feedback on the manuscript and Torsten Hothorn and Jiarui Lu for the helpful discussions during the course of this work. We also thank the EFSPI Treatment Effect Heterogeneity Special Interest Group (SIG) for their many discussions and feedback.

Dava availability statement

Due to confidentiality and privacy concerns, the patient level data from the application section cannot be shared publicly. The code that implements our DR-learner will be available at: https://github.com/Novartis.

A Prove the equivalence of two expressions of the DR-learner

Kennedy[13] provide an expression that can be seen as a correction of the outcome models:

$$\widehat{\psi}_{\mathrm{DR}:1}(\mathbf{x}_i) = \frac{a_i - \widehat{\pi}(\mathbf{x}_i)}{\widehat{\pi}(\mathbf{x}_i) \left(1 - \widehat{\pi}(\mathbf{x}_i)\right)} \left(y_i - \widehat{\mu}_{a_i}(\mathbf{x}_i)\right) + \widehat{\mu}_1(\mathbf{x}_i) - \widehat{\mu}_0(\mathbf{x}_i)$$

Curth and Van der Schaar[12] provide an expression that can be seen as a correction of the IPWE estimator:

$$\widehat{\psi}_{\text{DR:2}}(\mathbf{x}_i) = \frac{a_i - \widehat{\pi}(\mathbf{x}_i)}{\widehat{\pi}(\mathbf{x}_i) \left(1 - \widehat{\pi}(\mathbf{x}_i)\right)} y_i + \left(\left(1 - \frac{a_i}{\widehat{\pi}(\mathbf{x}_i)}\right) \widehat{\mu}_1(\mathbf{x}_i) - \left(1 - \frac{1 - a_i}{1 - \widehat{\pi}(\mathbf{x}_i)}\right) \widehat{\mu}_0(\mathbf{x}_i) \right)$$

We will show that these two expression are equivalent. Let's start from the first expression:

$$\begin{split} \widehat{\psi}_{\mathrm{DR}:1}(\mathbf{x}_i) &= \frac{a_i - \widehat{\pi}(\mathbf{x}_i)}{\widehat{\pi}(\mathbf{x}_i) \left(1 - \widehat{\pi}(\mathbf{x}_i)\right)} \left(y_i - \widehat{\mu}_{a_i}(\mathbf{x}_i)\right) + \widehat{\mu}_1(\mathbf{x}_i) - \widehat{\mu}_0(\mathbf{x}_i) \\ \widehat{\psi}_{\mathrm{DR}:1}(\mathbf{x}_i) &= \frac{a_i - \widehat{\pi}(\mathbf{x}_i)}{\widehat{\pi}(\mathbf{x}_i) \left(1 - \widehat{\pi}(\mathbf{x}_i)\right)} \left(y_i - a_i \widehat{\mu}_1(\mathbf{x}_i) - (1 - a_i) \widehat{\mu}_0(\mathbf{x}_i)\right) + \widehat{\mu}_1(\mathbf{x}_i) - \widehat{\mu}_0(\mathbf{x}_i) \\ \widehat{\psi}_{\mathrm{DR}:1}(\mathbf{x}_i) &= \left(\frac{a_i}{\widehat{\pi}(\mathbf{x}_i)} - \frac{1 - a_i}{1 - \widehat{\pi}(\mathbf{x}_i)}\right) \left(y_i - a_i \widehat{\mu}_1(\mathbf{x}_i) - (1 - a_i) \widehat{\mu}_0(\mathbf{x}_i)\right) + \widehat{\mu}_1(\mathbf{x}_i) - \widehat{\mu}_0(\mathbf{x}_i) \end{split}$$

Expanding this, we get:

$$\hat{\psi}_{\text{DR:1}}(\mathbf{x}_{i}) = \frac{a_{i}}{\hat{\pi}(\mathbf{x}_{i})}y_{i} - \frac{a_{i}^{2}}{\hat{\pi}(\mathbf{x}_{i})}\hat{\mu}_{1}(\mathbf{x}_{i}) - \frac{a_{i}(1-a_{i})}{\hat{\pi}(\mathbf{x}_{i})}\hat{\mu}_{0}(\mathbf{x}_{i}) - \frac{1-a_{i}}{1-\hat{\pi}(\mathbf{x}_{i})}y_{i} + \frac{(1-a_{i})a_{i}}{1-\hat{\pi}(\mathbf{x}_{i})}\hat{\mu}_{1}(\mathbf{x}_{i}) + \frac{(1-a_{i})^{2}}{1-\hat{\pi}(\mathbf{x}_{i})}\hat{\mu}_{0}(\mathbf{x}_{i}) + \hat{\mu}_{1}(\mathbf{x}_{i}) - \hat{\mu}_{0}(\mathbf{x}_{i})$$

Since a_i takes values 0 and 1, $a_i^2 = a_i$, $(1 - a_i)^2 = 1 - a_i$ and $a_i(1 - a_i) = 0$. Therefore, the expression simplifies to:

$$\begin{split} \widehat{\psi}_{\mathrm{DR}:1}(\mathbf{x}_i) &= \frac{a_i}{\widehat{\pi}(\mathbf{x}_i)} y_i - \frac{a_i}{\widehat{\pi}(\mathbf{x}_i)} \widehat{\mu}_1(\mathbf{x}_i) - \frac{1-a_i}{1-\widehat{\pi}(\mathbf{x}_i)} y_i + \frac{(1-a_i)}{1-\widehat{\pi}(\mathbf{x}_i)} \widehat{\mu}_0(\mathbf{x}_i) + \widehat{\mu}_1(\mathbf{x}_i) - \widehat{\mu}_0(\mathbf{x}_i) \\ \widehat{\psi}_{\mathrm{DR}:1}(\mathbf{x}_i) &= \left(\frac{a_i}{\widehat{\pi}(\mathbf{x}_i)} - \frac{1-a_i}{1-\widehat{\pi}(\mathbf{x}_i)}\right) y_i + \left(1 - \frac{a_i}{\widehat{\pi}(\mathbf{x}_i)}\right) \widehat{\mu}_1(\mathbf{x}_i) - \left(1 - \frac{1-a_i}{1-\widehat{\pi}(\mathbf{x}_i)}\right) \widehat{\mu}_0(\mathbf{x}_i) \\ \widehat{\psi}_{\mathrm{DR}:1}(\mathbf{x}_i) &= \frac{a_i - \widehat{\pi}(\mathbf{x}_i)}{\widehat{\pi}(\mathbf{x}_i)(1-\widehat{\pi}(\mathbf{x}_i))} y_i + \left(1 - \frac{a_i}{\widehat{\pi}(\mathbf{x}_i)}\right) \widehat{\mu}_1(\mathbf{x}_i) - \left(1 - \frac{1-a_i}{1-\widehat{\pi}(\mathbf{x}_i)}\right) \widehat{\mu}_0(\mathbf{x}_i) \\ \widehat{\psi}_{\mathrm{DR}:1}(\mathbf{x}_i) &= \widehat{\psi}_{\mathrm{DR}:2}(\mathbf{x}_i) \end{split}$$
