# Millimeter-Wave ISAC Testbed Using Programmable Digital Coding Dynamic Metasurface Antenna: Practical Design and Implementation

Abdul Jabbar<sup>\*</sup>, Mostafa Elsayed, Jalil Ur-Rehman Kazim, Zhibo Pang, Julien Le Kernec, Muhammad Imran, Hadi Larijani, Masood Ur-Rehman, Qammer Abbasi<sup>\*</sup>, and Muhammad Usman

Abstract-Dynamic Metasurface Antennas (DMAs) are transforming reconfigurable antenna technology by enabling energy-efficient, cost-effective beamforming through programmable meta-elements, eliminating the need for traditional phase shifters and delay lines. This breakthrough technology is emerging to revolutionize beamforming for nextgeneration wireless communication and sensing networks. In this paper, we present the design and real-world implementation of a DMA-assisted wireless communication platform operating in the license-free 60 GHz mmWave band. Our system employs high-speed binary-coded sequences generated via field programmable gate array (FPGA), enabling real-time beam-steering for spatial multiplexing and independent data transmission. A proof-of-concept experiment successfully demonstrates high-definition OPSK modulated video transmission at 62 GHz. Moreover, leveraging the DMA's multi-beam capability, we simultaneously transmit video to two spatially separated receivers, achieving accurate demodulation. We envision the proposed mmWave testbed as a platform for enabling the seamless integration of sensing and communication by allowing video transmission to be replaced with sensing data or utilizing an auxiliary wireless channel to transmit sensing information to multiple receivers. This synergy paves the way for advancing integrated sensing and communication (ISAC) in beyond 5G and 6G networks. Moreover, our testbed demonstrates its potential for real-world use cases including mmWave backhaul links and massive MIMO mmWave base stations.

*Index Terms*—Dynamic metasurface antenna, beamforming, FPGA, ISAC, mmWave, wireless communication testbed.

## I. INTRODUCTION

YNAMIC metasurface antennas (DMA) are envisioned as a groundbreaking class of next-generation reconfigurable antennas offering remarkable beamforming and beam-steering capabilities through their innovative architecture and performance. Unlike conventional phased array antenna systems and active electronically scanned array antennas that rely on complex feed networks and phase shifters, DMAs eliminate these components and leverage software-controlled programmability of individual metaelements for real-time beam-steering capabilities. The readily available dynamic control of their constituent metaelements helps to achieve adaptive radiation control and manipulate beams in a variety of ways [1]–[3]. DMAs have shown the potential to enable efficient and flexible beamforming while consuming approximately 30% less power compared to traditional phased array antenna systems [3], [4]. This versatile radiative capability of the metasurface aperture through software control is the hallmark of DMAs, making them a highly promising and enabling candidate for cutting-edge future sixth-generation (6G) wireless networks [5].

Metasurfaces are realized as two-dimensional artificial structures composed of precisely engineered subwavelength elements, which exhibit remarkable capabilities in controlling the amplitude, phase, and polarization of electromagnetic (EM) waves across both transmission and reflection modes [6]-[8]. Beyond their diverse physical phenomena such as invisible cloaking, polarization conversion, and imaging, metasurfaces are highly anticipated to play a crucial role in next-generation wireless technologies [9]. Their applications extend to wireless communication, standalone sensing. and Integrated Sensing and Communication (ISAC), offering unprecedented dynamic control over the electromagnetic environment [10]-[12]. Such metasurfaces are referred to by various nomenclatures in the literature, such as programmable coded metasurfaces, or reconfigurable intelligent surfaces (RIS) [13], [14]. These programmable metasurfaces have primarily been explored in wireless communications as passive reflective devices, assisting conventional transceivers in manipulating and optimizing the propagation environment mainly in non-lineof-sight (NLoS) scenarios [11], [15]-[17].

Fig. 1. (left) Application scenario of coded reflective metasurfaces (such as RIS) for signal redirection. (right) Active DMA architecture for enhanced signal transmission and reception. Moreover, DMA is exhibited to provide a dedicated feed signal towards RIS for NLoS cases. This enables to devise a DMA-assisted RIS-enabled robust wireless communication and sensing paradigm.

Programmable metasurfaces are often reflective in nature, though certain design considerations also enable transmissive configurations [18], [19]. Reflection and transmission-type metasurfaces are typically fed by external antennas, such as a horn antenna, which introduces several limitations such as obstruction of the reflected wave and reducing efficiency. Additionally, both types require a certain free-space distance for proper illumination, leading to bulky and high-profile designs. These constraints make traditional reflective and transmissive metasurface-based systems unreasonable for compact and lightweight applications.

Unlike externally illuminated reflective metasurfaces, DMAs are radiative in nature and circuit-fed from the side of the waveguide aperture in a series-fed manner to generate EM waves [4], [5], [20]–[23]. The EM wave propagates along the metasurface aperture and excites the DMA metaelements one by one at their designed operational frequency band, leading to the phenomenon of holographic beamforming [4], [5]. Hence, large DMA arrays result in a significantly simpler wiring layout using standard printed circuit board (PCB) technology compared to traditional corporate-fed phased arrays [24]. The traditional corporate-fed antenna systems require individual feeding lines for each antenna element in a parallel configuration which are complex and often lossy in nature.

In light of the increasingly rigorous demands of 6G wireless networks where array gain, diversity gain, and interference mitigation are essential for enhancing capacity and spectral efficiency, DMAs offer the potential to integrate a large number of radiating elements within a compact surface area [1]. This leads to their enabling role in the evolution of gigantic/ultra-massive multiple-input

multiple-output (mMIMO) technology for intelligent base stations [24]–[26]. More specifically, at high-frequency regime where path loss is high and antenna size is reduced, large antenna arrays are highly desired where DMA-based base stations have the potential to employ a large array of antennas with a simplified feed structure and less expensive hybrid beamforming. Consequently, systems can achieve significant enhancements toward spectral efficiency and spatial beamforming gain while maintaining relatively simple signal processing [23], [25], [27].

It is important to emphasize that DMAs can complement reflective coded metasurfaces/RIS, particularly at highfrequency bands, by enhancing RIS functionality and enabling seamless wireless connectivity. For instance, a DMA can serve as an intelligent excitation antenna source with predefined beamforming and coding information that could steer the beam dedicated to the RIS location. Consequently, in NLoS scenarios, a reliable wireless communication link can be guaranteed as the DMA dynamically steers its beam toward the RIS in real-time. This synergy holds the potential to enable the development of a robust future communication framework, which can be envisioned as a *DMA-assisted RIS-enabled* wireless communication paradigm, as illustrated in Fig. 1.

Furthermore, ISAC can be effectively realized using DMA, where a DMA-assisted link for RIS can facilitate sensing around the corners and blind spots, while the other unobstructive DMA beams can be strategically utilized for direct LoS communication, enabling seamless integration of sensing and communication within the same framework.

## A. A brief Outlook of State-of-the-Art

In recent years, DMAs have gained significant attention

Fig. 2. (a) The meta-atom of the programmable DMA depicting radiation mechanism. (b) Radiated power profile during on and off states across the operating frequency band.

for their potential in next-generation wireless applications. DMAs are also referred to by other nomenclatures in the literature such as reconfigurable holographic surfaces [2], [28], and programmable/universal metasurface antenna [5] due to diverse wave manipulation phenomena. More recently, some other architectures such as fluid antenna systems have been introduced to perform radiation pattern diversity and MIMO applications [29], [30]. While most existing studies on DMA-based communications are primarily limited to theoretical analyses [27], [31], their system model assumption is often made through an arbitrary number of meta-elements in simulation environments based on idealized microstrip apertures. Usually, these studies tend to overlook the impact of realistic planar waveguide-based hardware structures on radiation characteristics.

It is noticeable that the majority of the reported DMA designs to date (using varactor or PIN diodes) operate below 30 [4], [5], [21], [22], [29], [32]–[36]. Likewise, a DMA architecture based on liquid crystals has been demonstrated at 110 GHz [37]. However, despite these advancements on the antenna prototype level, a full-fledged end-to-end DMA-based wireless communication testbed has not been demonstrated to date at higher mmWave bands, such as 60 GHz and sub-THz. Although *reflective* coded metasurfaces

have shown some testbed implementations below 30 GHz [7], [11], [16], nevertheless, the *radiative* DMA-based testbed implementation is still in its infancy. Therefore, beyond theoretical considerations and prototype-level designs, the development of system-level real-world DMA-assisted wireless communication platforms at higher frequencies remains a practical research challenge. This underscores the need for their system-level implementation and validation to realize their full potential in next-generation wireless networks.

## B. Contribution

In this paper, we present a compelling practical validation of a proof-of-concept DMA-assisted wireless communication testbed operating in the license-free 60 GHz industrial, scientific, and medical (ISM) band. Our previous work [38] proposed the fundamental prototype construction of the 60 GHz mmWave DMA and showed its dynamic beam patterns. While it provided the hardware foundation for potential applications involving dynamic beam-steering operations, it did not establish a complete end-to-end wireless communication system or experimentally validate real-time DMA-assisted communication capabilities in a 60 GHz mmWave system, as previously mentioned.

Here, we meticulously establish a complete end-to-end mmWave communication 60 GHz testbed and experimentally demonstrate reliable and real-time quadrature phase-shift keying (QPSK) modulated high-definition (HD) video transfer through the DMA-assisted wireless link at over-the-air (OTA) carrier frequency of 62 GHz. Utilizing a field programmable gate array (FPGA)-controlled reconfiguration speed of approximately 10 ns, the proposed DMA-assisted setup can dynamically steer beams at a rate significantly higher than the symbol frequency. This enables efficient space diversity for multi-receiver communication, reducing outage probability and enhancing system reliability.

This work advances DMA technology from the prototype level to that of the real-world system-level application, and introduces new degrees of freedom, thereby enhancing the diversity and spatial multiplexing performance for future wireless communications. Notably, the conventional digital, analog, and hybrid beamforming architectures which rely on time delay lines or power-hungry phase shifters are fundamentally redefined through DMA by eliminating these phase shifting techniques [39]. Instead, versatile beamforming is entirely performed through controlling the state of constituent meta-elements, enabling highly flexible operation. This transformation is particularly advantageous in applications where size, weight, and power (SWaP) constraints are critical, such as satellite communications.

In a wider application scenario, our contribution offers advanced reconfigurable beamforming antenna solution and its seamless connectivity with third-party 60 GHz mmWave connectorized modules. Notably, the license-free 60 GHz mmWave band enables localized high-capacity links and is expected to play a more prominent role in beyond 5G and 6G networks, such as in 60 GHz mmWave Wi-Fi venue hotspots, small cell wireless backhaul, fixed wireless access systems, license-free mmWave indoor healthcare monitoring and sensing systems, and integrated radar sensing [40]. Strategically placed DMA-based hotspots can significantly offload traffic from lower-frequency bands and macrocells, enhancing overall network performance [41].

Another potential solution offered by our DMA-assisted platform exists in next-generation ultra-reliable and low-latency mmWave industrial wireless communication[40]. These systems are envisioned as crucial enablers for meeting the stringent reliability and performance demands of Industry 4.0/5.0 use cases. [42]–[46]. Our proposed DMA-assisted testbed sets the foundation to support various indoor test scenarios for customized mmWave industrial wireless protocols, such as WirelessHP [47]. We envision that our 60 GHz DMA-assisted mmWave experimental testbed will provide a practical and scalable pathway to meet the stringent demands of beyond 5G and 6G communication systems while also serving as a catalyst for validating future sub-THz (such as D-band) 6G systems.

The rest of this paper is organized as follows. In Section II, we introduce the hardware design and radiation mechanism of DMA. In Section III, we elucidate the spatial dynamic beam-steering performance of the DMA through full-wave simulations and measurement results, and the beamforming control through FPGA. In Section IV, we thoroughly describe the implementation of DMA-assisted mmWave wireless communication setup, baseband modulation process, up/down-conversion to/from 60 GHz mmWave band, and experimental evaluation of the received video signal. Finally, the conclusion is presented in Section V.

## II. HARDWARE DESIGN AND RADIATION MECHANISM OF DMA

## A. Construction and Properties of Fully Addressable and Tunable Digital Meta-element

We first realized a DMA element using a specially designed digital coding meta-element integrated with a substrate integrated waveguide (SIW) structure, shown in Fig. 2(a). A low-loss V-band SIW structure was designed to host the meta-element [38]. The meta-element is a complementary electric inductive-capacitive (CELC) resonant element that responds to the in-plane magnetic field component (dominant TE<sub>10</sub> mode) of the EM wave propagating in the SIW. A CELC resonator is a pure magnetic dipole resonant structure that couples and responds to the in-plane magnetic field, resulting in an absorbing profile at its resonant frequency.

The dipole moment representing a metamaterial element  $(\mu)$  can be calculated as the product of the incident magnetic field (H) and the element's polarizability  $(\alpha)$  [48]:

$$\boldsymbol{\mu} = \boldsymbol{H}\boldsymbol{\alpha} \tag{1}$$

The magnetic polarizability of a CELC element manifests a

Lorentzian shape curve as a function of the operating frequency ( $\omega$ ), resonant frequency ( $\omega_0$ ), coupling factor (*F*), and damping factor ( $\gamma$ ) in the SIW structure:

$$\alpha = \frac{F\omega^2}{\omega_0^2 - \omega^2 + j\omega\gamma}$$
(2)

The full wave simulations of the CELC element in Fig. 2(b) reveal such Lorentzian resonance profile (bell-shaped with transmission phase reversal) of the CELC element during the coupled mode. The reference wave exciting the CELC has the dependence:

$$Hi = H_0 e^{-j\beta x_i} y \tag{3}$$

where H<sub>0</sub> is the initial magnetic field flowing into the SIW structure,  $\beta$  is the effective waveguide propagation constant in SIW (given as  $\beta = \frac{2\pi}{2}$ ).

To achieve fully addressable 1-bit ON-OFF spatial modulation of the CELC element, it is integrated with two PIN diodes (two diodes maintain the symmetry and suppress the radiation well in the element-off state). Since a PIN diode only has two states (ON/OFF), the meta-element loaded with PIN diodes achieves binary discrete amplitude control. The switching states of diodes are controlled through a carefully designed DC biasing network interfaced with the FPGA, ensuring precise modulation between the ON and OFF states [38].

An arrangement of such tunable meta-atoms in the SIW structure with intelligently designed biasing network leads to DMA array formation. By utilizing different biasing states (coding combinations) of PIN diodes controlled through FPGA programming, the phase difference between the radiating elements can be dynamically changed, thereby realizing versatile antenna-pattern generation and reconfiguration in real-time.

The far-field beam pattern of the constituent CELC metaelement at a distance (r) from the source is given by the farfield magnetic field vector **H** as [20]:

$$\boldsymbol{H} = \frac{\omega^2 m}{4\pi r} \cos\theta \left[ e^{-jkr+j\omega t} \right] \widehat{\boldsymbol{\theta}}$$
(4)

where *r* is the approximated magnitude of the difference between the location of the radiation source and the observation point at a far-field distance,  $\hat{\theta}$  is the unit vector in the direction of the radiated wave, and *k* is the free-space wave number ( $k = 2\pi/\lambda_0$ ). In the array topology, these metamaterial elements can be treated as selecting the excitation wave (also termed as reference wave) at their locations on the SIW aperture by  $x_n = nd$ , where *n* is an integer and *d* is the spacing between any two adjacent CELC elements. Then the far-field radiation pattern from the 1-D DMA can be approximated by superimposing the fields sourced by all of the elements as:

Fig. 3. Proposed schematic diagram of 1-D DMA along with fabricated prototype, internal biasing circuitry, and PCB layer stack-up view.

$$\boldsymbol{H_{rad}} = H_0 \frac{\omega^2}{4\pi r} e^{-jkr} \cos\theta \sum_{1}^{N} \alpha_n(\omega) e^{-jx_n(\beta + k\sin\phi)} \,\widehat{\boldsymbol{\theta}} \quad (5)$$

Here  $\cos\theta \sum_{1}^{N} \alpha_n(\omega) e^{-jx_n(\beta+k\sin\phi)}$  is the array factor of 1-D DMA, with  $\phi$  being the angle of propagation normal to the surface of the 1-dimensional (1-D) DMA surface.

#### B. Radiation Mechanism of DMA

Figure 2(a) illustrates the radiation mechanism of the CELC element, demonstrating how the coding meta-element interacts with EM waves under different digital states, resulting in distinct electromagnetic responses. The induced surface currents reveal physical digital coding states '0' and '1', (practically zero voltage will show the diode 'OFF', and meta-element 'ON' or 'state 1'; whereas 1.33 V switches the diode 'ON', meta-element 'OFF' or 'state 0'). To put this into physical context, when the diode is switched on, the CELC element is effectively shorted with the outer SIW structure. In this state, it loses radiation properties and does not couple with the waveguide mode (as it becomes analogous to the part of a transmission line). Conversely,

when the diode is switched off, the CELC element is effectively isolated from the outer SIW structure, presenting an open circuit. It then couples the portion of the wave through the gap complement of the SIW, and radiates it into the free space at its designed operating frequency.

It is worth mentioning here that such radiation phenomenon of DMA makes them energy efficient because the CELC elements manifest their antenna (radiative) properties when the diode is switched off. Consequently, PIN diodes consume negligible current in their off state, significantly reducing the overall power consumption of the DMA.

The PIN diode (MADP-000907-14020W) has fast switching speed of 2–3 ns and was modelled as a lumped circuit element with series resistor-inductor-capacitor (RLC) circuit parameters  $R = 5.2 \Omega$ , L = 30 pH, and C = 0 pF for the 'diode ON' state and  $R = 10 k\Omega$ , L = 30 pH, and C = 25fF for the 'diode OFF' state. The radiated power profile of the CELC meta-atom during on and off states is shown in Fig. 2(b). Notably, the designed CELC element radiates around 9 times more than that of its non-radiation state at 60.6 GHz, which confirms a 1-bit response.

## C. Implemented 1-D DMA Hardware Prototype

As shown in Fig. 3, the implemented 4-layer DMA prototype consists of a 1-D array of 16 digitally controllable elements and has a total size of 4.36 cm  $\times$  3.6 cm  $\times$  0.154 cm. Further detailed dimensions are provided in [38]. The RF metasurface layer was designed using a high-performance Rogers 3003 substrate, with a dielectric constant of 3, thickness of 0.25 mm, and copper cladding of 17.5 microns. The DMA is fed through a 1.85 mm standard connector from one side of the SIW. The reference wave generated from the feed propagates to each DMA element and can radiate energy to the free space. The residual energy of the EM waves is absorbed by a high frequency 50  $\Omega$  matched load impedance attached to the other end of the SIW.

The radiation amplitude of each DMA element is controlled through FPGA (Digilent Arty S7-25T) in which a custom-made software program was pre-loaded to control the binary coded sequence. The DMA design consists of 4 layers where the top layer includes meta-elements, second layer is RF ground, while third layer is dedicated to the DC biasing and isolating network, as shown in Fig. 3. The DC output of FPGA is +3.3 V which is converted to +1.33 V using a voltage regulator IC embedded on the bottom layer for switching PIN diodes. The biasing network for all PIN diodes is designed in a parallelized manner. This means that the digitally coded signal from FPGA is simultaneously provided to all meta-elements which significantly reduces the beamforming switching time and offers low-latency mmWave beam-steering. In the case where all PIN diodes are OFF, the meta-elements would be in a radiating state with minimal power consumption and pointing the main beam direction towards the broadside (nearly  $0^{\circ}$ ) at 62 GHz.

Fig. 4. Schematic diagram of the parallelized FPGA control scheme, and the customized GUI.

However, this scenario represents a trivial case and does not fully exploit the reconfigurability of the DMA. The operating region of the DMA is mainly between 60 GHz to 62 GHz.

#### III. IMPLEMENTED DYNAMIC BEAM-STEERING

The beam-steering mechanism of the proposed DMA is fundamentally based on the phase accumulation of the guided wave, which sequentially excites the meta-elements along the aperture with the necessary phase variation to form directional beams. By employing different diode tuning schemes from FPGA, the effective phase difference between radiating elements is dynamically changed, enabling the generation of diverse radiation patterns.

## A. Digital Control through FPGA Programming

We controlled dynamic beam-steering by simultaneously controlling the radiation state of 16 CELC elements using an FPGA. The FPGA includes a synchronization subcircuit that generates clocks and sync signals while receiving azimuth control inputs from the graphical user interface (GUI). It can reconfigure beam steering within 10 ns using a 100 MHz clock frequency.

The FPGA receives steering codes in binary format via the UART (universal asynchronous receiver-transmitter) protocol, along with control messages that configure transmission parameters, including switching beam steering on/off, selection of single or multiple codes, and defining the switching time between different codes. The schematic design of FPGA control scheme is presented in Fig. 4. The program is developed in VHDL using Xilinx Vivado software.

We designed a user-friendly custom-made GUI to

Table I. Beamforming Codes for Directional and Multiple Beams.

Code- book	Coding sequence	No. of Beams	MLD°/ (Gain (dBi))	HPBW°
Code 1	1001001001001001	2	-49°, +23° 11.12, 11.85	13°, 11°
Code 2	0001000100010001	2	-16°, +31° (7.97, 7.95)	10°, 17.5°
Code 3	101010101010101010	1	-9° (8.53)	8°
Code 4	1001100110011001	1	-8° (8.5)	24°
Code 5	1010101010000000	1	+36° (10.2)	13.5°

facilitate steering code transmission in multiple formats, including binary, hexadecimal, and decimal. The GUI was designed using MS Visual Basic and a snapshot is shown in Fig. 4. The GUI allows users to input control codes, toggle beam steering on/off, switch between single and multiple azimuth steering modes, as well as adjust the timing between code switches according to symbol update rates.

#### B. Dynamic Beam-steering Performance of DMA

For a 16-element linear DMA, the possible coding space contains  $2^{16}$ =65,536 binary-coded combinations. Among these, many configurations produce narrow beams, while others can generate wider beams or even multi-beam patterns. This versatility is the hallmark of DMA, enabling it for flexible beamforming capabilities. However, it should be noted that from a wireless communication perspective, many of these codes may not meet performance requirements if they result in high side lobe levels or exhibit unmatched input impedance.

For proof of concept, here we utilize two sets of coding sequences at 62 GHz, one for generating a single directional beam, while the other for producing dual beam. The corresponding binary coding combinations are presented in Table I in which the binary state corresponds to the radiation state of the meta-elements. The inverse of these coding sequences was applied through the FPGA, as the forwardbiased state of the PIN diode corresponds to state-1 (high voltage) in FPGA program. Similarly, in simulations, the diode switching states were implemented on the metaelements of the DMA's top RF layer using full-wave analysis in CST Microwave Studio, following the above specified operating bias conditions of the diode model.

As shown in Fig. 5, code 1 and code 2 produce dual beams that can be utilized for point-to-multipoint (P2MP) multiuser links. Code 3, code 4, and code 5 generate directional single beams for point-to-point (P2P) single user links towards  $-9^{\circ}$ ,  $-8^{\circ}$ , and  $+36^{\circ}$  respectively. Furthermore, the half-power beamwidth (HPBW), main lobe direction (MLD) and the corresponding gain values of such codes are given in

Fig. 5. Simulated beam patterns with different beamforming coding combinations tested at 62 GHz.

Table I. The simulated beams are validated through measurements using the far-field method as explained in [38]. The MLD of the measured radiation patterns is in good agreement with the simulated results, as presented in Fig. 6(a). Note that for the proof-of-concept demonstration in this work, two such beams are sufficient to validate our testbed. Nevertheless, the DMA can generate various other beams (narrow, wider, dual and tri beams) using versatile binary-coded sequences programmed through FPGA. The -10 dB input impedance (reflection coefficient) for code 1 and code 3 remains below -10 dB, indicating efficient input power acceptance of DMA for these coding sequences around 62 GHz, as shown in Fig. 6(b).

## IV. IMPLEMENTATION AND EVALUATION OF DMA-Assisted Communication Platform

## A. Implementation of 60 GHz mmWave Test Setup

The implemented testbed consists of various stages and hardware modules on the transmitter (Tx) and receiver (Rx) sides, as demonstrated in Fig. 7. The description of these modules is explained below.

Transmitter-Side Setup: The Tx side comprises a mmWave programmable DMA prototype, an FPGA to generate binary sequences with dedicated GUI, a universal software radio peripheral (USRP, a commercial softwaredefined radio (SDR) transceiver) for baseband signal processing and RF signal source. A host personal computer (PC) was used to control the parameters of Tx USRP B200 as the source of data bits through the GNU Radio software development kit. The Tx USRP performs baseband signal processing and RF modulation (to generate a QPSKmodulated video stream) with carrier frequency centered at 1 GHz. The Tx host computer can control the parameters such as the carrier frequency, gain, sampling rate, and modulation mode. The 1 GHz modulated carrier signal is transmitted to the mmWave module for up-conversion using a phase-matched SMA-to-MCX cable at the baseband interface of the mmWave module.

For mmWave up-conversion, we used Analog Devices

Fig. 6. (a) Measured beam patterns for four different beamforming coding combinations at 62 GHz. (b) Input impedance of code 1 and code 3.

(ADI) HMC6350 evaluation board which consists of an HMC6300 transmitter integrated circuit (IC) that provides a mmWave signal within the range 57–64 GHz. The Tx IC has an integrated frequency synthesizer that creates a low phase noise local oscillator (LO) signal between 16.3 GHz and 18.3 GHz, with a step size of 250 MHz. The synthesized LO is divided by two to produce an intermediate frequency (IF) range of 8 GHz to 9.1 GHz. The IF signal is filtered and amplified with a variable gain of 14 dB before it is mixed with three times the LO frequency, upconverting it to an RF frequency range of 57 GHz to 64 GHz. We controlled the mmWave module's Tx parameters such as RF attenuation, IF attenuation, and mmWave frequency, using its dedicated GUI, accessed through the module's USB interface.

The output of mmWave module is connected to the DMA input using an MMPX-to-1.85 mm standard cable. The DMA then transmits this mmWave signal over the air.

*Receiver-Side Setup:* The Rx setup mainly consists of a down-conversion module and a Rx USRP for demodulation.

Fig. 7. Conceptual schematic diagram of the mmWave DMA-assisted wireless communication system. By applying different coded sequences from the FPGA to PIN diodes, the overall phase distribution on the DMA aperture can be manipulated which is used to encode the signal information directly and transmit different coding streams to multiple designated users at different locations simultaneously and independently.

A V-band linear polarized horn antenna with 15.5 dBi gain was used to capture the mmWave signal. It was connected to HMC6301 Rx module integrated on a separate HMC6350 board using a 1.85 mm-to-MMPX cable.

The HMC6301Rx module has an integrated frequency synthesizer that generates a low phase noise LO between 16.3 GHz and 18.3 GHz. As any of the 57 GHz to 64 GHz signal enters the module through its integrated low-noise amplifier input, the LO is multiplied by three and mixed with the LNA output with a gain of 20 dB. It is then down-converted to an 8.14 GHz to 9.1 GHz sliding IF signal with variable gain of 12 dB. This IF signal is then down-converted by mixing with the synthesized LO divided by two.

The down-converted signal from the mmWave module is then provided to the input receiving port of USRP X300 using an MCX-to-SMA cable. The baseband signal processing and demodulation is performed at Rx USRP which was connected to the host PC through a crossover Ethernet cable. SDRAngel software was used to analyze the received signal and real-time video reception.

## B. Experimental Evaluation of Real-time Communication Testbed

We implemented the digital video broadcast (DVB) standard for video data transmission. The transmitted signal first passes into multiplexer adaptation and energy dispersal, then encoded by a serial concatenated coder which is a concatenation of an inner coder and an outer coder to control

Fig. 8. Functional block diagram of DVB QPSK modulated Tx signal scheme.

errors. Specifically, the Reed-Solomon coder and the convolutional coder are performed as the outer coder and inner coder, respectively, and connected via an outer interleaver to separate bursts of errors. After that, the encoded signal is processed by a bit and symbol inner interleaving and bit interleaved baseband frames are then treated by the DVB constellation mapping to form the QPSK modulated signal with a code rate of 5/6. Finally, the modulated signal is passed through a decimating filter using the fast convolution method through Fast Fourier Transform (FFT). The block diagram of DVB signal scheme is depicted in Fig. 8. The modulated carrier frequency was set at 1 GHz, and the symbol rate was set to 2 MSymbols/s at Tx USRP. This signal was fed to the input of HMC6300 up-conversion module. The DMA-assisted communication platform was deployed in an open lab environment to evaluate real-world wireless communication scenario, as shown in Fig. 9.

Fig. 9. Experimental testbed setup for mmWave wireless communication based on DMA. A QPSK-modulated video signal is transmitted through DMA (shown bottom left Tx terminal) to the receiving end (shown towards the bottom right) in real-time with  $1280 \times 720$  resolution, over mmWave carrier frequency of 62 GHz.

We configured the DMA for two use cases. First, by applying code 3 from FPGA, we generated a single beam from DMA to serve a single channel wireless link. In the second experiment, we used code 1 to generate dual beams to serve two users simultaneously at an angular separation. The distance between the Tx DMA and Rx horn antenna was set to 1 meter. As the DMA was positioned to produce narrow beam coverage in the azimuth (fan-shaped), the antennas were aligned using a laser beam.

First, the modulated Tx signal was examined using a realtime spectrum analyzer (Siglent SSA 3075X-R) to verify the waveform shape and ensure a safe RF power level before being fed into the mmWave module, as demonstrated in Fig. 10 (top). The 1 GHz modulated signal was fed to the HMC6300 mmWave module and its frequency was locked at 62 GHz with a transmit power of +7 dBm.

On the Rx side, OTA mmWave signal was received by a V-band horn antenna. The HMC6301 receiver IC was locked at 62 GHz using its GUI. The Rx horn antenna was aligned for best constellation recovery through laser beam alignment. The down-converted signal was fed to Rx USRP. The gain of the modulated signal was fine-tuned using the GUI of the Tx USRP to prevent receiver saturation and enhance the quality of received constellation, based on real-

time observations of the Rx waveform. The real-time HD video stream was received and analyzed through SDRangel software on Rx host PC. The important parameters such as the received signal waveform, QPSK constellation points, and real-time video snapshot are displayed in Fig. 10 (bottom). The real-time video transmission was received with a resolution of  $1280 \times 720$  and an average transmission rate of 3.2 Mbps. Other key parameters of the communication testbed are listed in Table II. As shown in the constellation diagram, the four points are equispaced around a circle, implying that the received signal is demodulated successfully. This validates that our DMAassisted communication platform supports real-time transmission of HD video and data.

To observe the performance of the communication testbed under extended distances, the distance between the transmitting and receiving terminals was increased from 1 m to 1.6 m, and the constellation points were less affected within this communication distance and video stream was still recovered, as far as the antenna alignment remained intact. In order to test multi-user links through DMA, we generated code 1 from FPGA to produce two beams towards  $-49^{\circ}$  and  $+23^{\circ}$  (as per simulations and measured patterns) to serve two independent receivers simultaneously.

Fig. 10. (Top) experimental validation of Tx signal on spectrum analyzer. (bottom) graphical interface of received signa profile at the Rx USRP revealing spectrum, constellation, and real-time video snapshot.

Fig. 11. Measured decoded constellation diagrams at different receiver directions (code 3 for top, and code 1 for bottom figure) at 62 GHz. This validates the inherent security of DMA by directional beams at the fundamental frequency. Only the intended user(s) within the main beam can successfully decode the transmitted information with the correct constellation, while eavesdroppers at other locations are unable to recover it, enhancing physical layer security.

Because of unavailability of the another down-conversion mmWave module, we analyzed and retrieved the real-time video for two channels one by one through aligning the Rx horn antenna at directions  $\theta = -49^{\circ}$  and  $+23^{\circ}$ , with respect to the normal of the DMA. It was experimentally examined that the received video streams demodulated at these two different locations are same as the transmitted one.

Table II. Key Parameters of the Wireless Communication Testbed.

Parameter	Value	
Baseband (Low) frequency at Tx and Rx USRPs	1 GHz	
RF Power From Tx USRP to HMC6350 module	-25 dBm	
OTA mmWave frequency	62 GHz	
OTA mmWave output Tx power	+7 dBm	
Tx DMA gain	8 to 10 dBi	
Tx-Rx distance	1 m	
Path loss	68.28 dB	
Rx horn antenna gain	15.5 dBi	
Rx gain at LNA and IF stage of HMC6301	32 dB	
Modulation scheme	QPSK	
Code rate	5/6	
Symbol rate	2 MS/s	
Achieved average transmission rate	3.2 Mbps	

Moreover, when the receiver antenna location was changed (say Rx positioned at  $\theta = -15^{\circ}$  or  $+12^{\circ}$ ), the synthesized signals from the two physical channels cannot be correctly demodulated, even with a significant increase in Tx gain, as demonstrated in Fig. 11.

A key advantage of the DMA-assisted mmWave system is its ability to enhance physical layer security. Through precisely controlling the directional radiation pattern, the transmitted signal can be steered toward the intended user while significantly degrading reception for unintended users (or eavesdroppers). As demonstrated in Fig. 11, the measured radiation pattern and decoded constellation diagrams confirm that only the receiver within the main beam direction can successfully decode the transmitted information, while eavesdroppers positioned outside the beam experience severe signal degradation, rendering the constellation unintelligible. This directional amplitude modulation effect provides a robust security mechanism, effectively mitigating eavesdropping threats by establishing inherent mmWave physical layer security.

Finally, the proposed DMA-assisted system holds the potential for practical implementation of ISAC by allowing video transmission to be replaced with sensing data or enabling one channel for communication while combining another for sensing on a single shared hardware platform. This integration facilitates the seamless transmission of sensing information alongside communication signals to multiple receivers through dynamic FPGA coding control. Moreover, the high sensing resolution of 60 GHz mmWave signals empowers ISAC technology to mitigate LoS blockages and support user mobility. However, full implementation of this concept is beyond the scale of this work due to brevity.

## V. CONCLUSION

In this paper, we present a proof-of-concept practical implementation of a DMA-based mmWave wireless communication testbed, demonstrating real-world operation at 62 GHz. The hardware design of the mmWave DMA with software controllable radiation patterns was elucidated, alongside the implementation of amplitude-controlled beamforming through a high-speed FPGA. The proposed testbed integrates a DMA-based setup with an HMC6350 motherboard and HMC6300/6301 up/down-conversion modules for high-frequency mmWave signal transmission and reception. Additionally, it utilizes commercial USRPs for low-frequency signal generation and processing, providing a robust framework for mmWave wireless communication. To validate the DMA-assisted testbed, a QPSK-modulated HD video signal was successfully transmitted over-the-air at 62 GHz via the DMA, both over a single-user link and simultaneously across two independent physical channels to separate legitimate receivers, ensuring accurate demodulation and retrieval at each receiver

The directional modulation and spatial diversity of DMA-generated beams enhance physical-layer security by restricting signal decoding to intended users within the main beam, while significantly degrading signal quality for potential eavesdroppers. This approach offers a robust, low-complexity solution for secure and adaptive next-generation mmWave wireless communications.

In the future, we aim to unlock the full potential of DMAassisted systems for emerging next-generation use cases, including ISAC, mmWave multi-subject contactless sensing, as well as dynamic spatio-temporal modulation through space-time coding techniques from FPGA at the 60 GHz ISM band, enabling secure and encrypted multi-user indoor wireless links.
