## Abstract

This study provides a classification of disasters in terms of their causal parameters, introducing hypothetical cases of independent or hybrid AI-caused disasters. We overview the role of AI in disaster management, and possible ethical repercussions of the use of AI in intelligent disaster management (IDM). Next, we scrutinize certain ways of preventing or alleviating the ethical repercussions of AI use in disaster mismanagement, such as privacy breaches, biases, discriminations, etc. These include pre-design a priori, in-design, and post-design methods as well as regulations. We then discuss the government's role in preventing the ethical repercussions of AI use in IDM and identify and assess its deficits and challenges. We then discuss the advantages and disadvantages of pre-design or embedded ethics. Finally, we briefly consider the question of accountability and liability in AI-caused disasters.

**Keywords:** Intelligent disaster management (IDM), intelligent disaster mismanagement (IDMM), ethical repercussions, embedded ethics, regulations, government

## 1. Introduction

The United Nations International Strategy for Disaster Reduction (UNISDR) defines disaster as a “serious disruption of the functioning of a community or a society at any scale due to hazardous events interacting with conditions of exposure, vulnerability and capacity, leading to one or more of the following: human,

material, economic and environmental losses and impacts” [6]. In 1970 through 2019, the number of recorded natural hazards such as earthquakes, floods, hurricanes, volcanic eruptions, and tsunamis was quadrupled globally [1]. During this period, weather, climate, and water hazards caused “50% of all recorded disasters, 45% of related deaths and 74% of related economic losses.”[2]

Disaster is a multidimensional concept. Over 100 definitions of disaster have been proposed worldwide [105]. [106] identifies three paradigms in the twentieth century for definitions of disaster: (1) classical definitions that began to be proposed after World War II and tended to focus on “extreme situations,” “rapid onset events,” and what is “seriously disruptive to the normal activities” as the definitive features of disasters; (2) a hazard-disaster paradigm, mostly focused on geophysical disciplines and natural disasters, and physical causal parameter in a disaster. It sees disaster, as opposed to hazard, as “an extreme event that arises when a hazard agent intersects with a human use system”; (3) a relatively recent paradigm that conceives disasters as “social” phenomena, turning away from an agent-based and physical-destruction-based paradigm. Accordingly, physical damage is not a primary definitive feature of disasters. Social systems are the real locus of disruptions, and “vulnerability” parameters play a central role in disruptions because, in the absence of vulnerability, there should not be any kind of disasters even in a very strong physical case like earthquakes. [107] argues that “disasters are not a function of agents, but are social in origin.” Moreover, there are normative definitions of disasters “as occasions when norms fail,” and a society and disaster managers need to update the new norms suitable for new situations [108].

There are some psychological dimensions in the concept as well. X might be a kind of disaster for you, in a specific context, while it can be considered a chance for me to test and improve my abilities and find my flaws [5]. It also has economic dimensions. There is a meaningful correlation between poverty, vulnerability, and disaster. [5]

Disasters can be categorized in qualitative and quantitative terms. Qualitatively speaking (in terms of causal parameters), they can be divided into four groups: natural disasters, human-caused disasters, technological disasters, and AI-caused disasters. These can be combined in various ways such as hybrid human-made/natural disasters, hybrid natural/technological disasters, hybrid natural/AI-caused disasters, as well as combinations of three or four disaster types (see Table 1). Quantitatively speaking, disasters can be categorized into small-scale, medium-scale, and large-scale (“mega disasters”) in terms of the size of the population they affect and the extent of their impacts.

Note that we classify biological disasters (those caused by the spread of infectious diseases or other biological agents) and environmental disasters (those caused by environmental degradation, such as deforestation, desertification, or coastal erosion) as subcategories of natural disasters. Further, we classify the so-called “complex emergencies” [103] (disasters caused by conflicts, wars, or other complex socio-political issues) under human-caused disasters.

It is also necessary to point out that there have not been any widely publicized cases of AI-caused disasters (in isolation or in combination with other causal parameters), as the technology is still in its early stages of development and implementation. However, there have been some incidents (not to the point of disaster) in which AI systems have made mistakes or produced unintended outcomes, highlighting the importance of ensuring that AI is used responsibly and with appropriate safeguards in place.

The classifications provided above should not be seen as rigid as they might be context-dependent and susceptible to interpretations. For instance, data breaches or cyberattacks might be considered technological or human-caused disasters depending on the context.

**Table 1.** Classification of disasters in terms of their causal parameters

Disaster type		(Real or Hypothetical) Examples
1	Natural	Earthquakes, hurricanes or typhoons, tornadoes, floods, tsunamis, landslides and mudslides, wildfires, volcanic eruptions, drought, extreme heat or cold
2	Human-caused	<ul style="list-style-type: none"> <li>• Chernobyl disaster (1986), caused by a poorly designed irresponsible experiment.</li> <li>• Rana Plaza factory collapse (2013), caused by a breach of construction regulations and corrupt officials.</li> <li>• Beirut port explosion (2020), caused by neglect of safety rules.</li> </ul>
3	Technological	<ul style="list-style-type: none"> <li>• Space Shuttle Challenger disaster (1986).</li> <li>• Blackout of Northeast America: In August 2003, a power outage affected a large area in the northeastern United States and southeastern Canada, causing widespread disruptions to transportation, communication, and other critical infrastructure.</li> </ul>
4	AI-caused	<p>There have been no such disasters yet, but there have been alarming incidents:<sup>1</sup></p> <ul style="list-style-type: none"> <li>• Microsoft’s Twitter chatbot, named Tay, that was designed to learn from users and engage in natural language conversations. However, the bot quickly began producing offensive and inflammatory tweets, including racist and sexist remarks, after being manipulated by users (2016).</li> <li>• Uber self-driving car struck and killing a pedestrian in Arizona (2018).</li> <li>• Wrongful arrest of a Black man by use of an AI-powered facial recognition system by the Detroit Police Department (2020).</li> <li>• Tesla Autopilot crashes.</li> </ul>
5	Natural/human-caused	<ul style="list-style-type: none"> <li>• Industrial accidents triggered by natural hazards.</li> <li>• Forest fires exacerbated by human activity.</li> <li>• Coastal flooding exacerbated by sea level rise and human development.</li> <li>• Water scarcity worsened by climate change and human water use.</li> <li>• Pandemics exacerbated by global travel and human behavior, such as COVID-19.</li> </ul>
6	Natural/technological	<ul style="list-style-type: none"> <li>• Nuclear accidents caused by natural hazards.</li> <li>• Chemical spills caused by natural hazards.</li> <li>• Telecommunications and power outages caused by natural hazards.</li> <li>• Transportation accidents caused by natural hazards.</li> </ul>
7	Natural/AI-caused	The use of AI systems in natural disaster response can have unintended consequences if the system malfunctions or produces biased recommendations. Improper calibration or failure to consider important factors could also result in inefficient or ineffective resource allocation.
8	Human-caused/technological	<ul style="list-style-type: none"> <li>• Three Mile Island accident: A partial nuclear meltdown that occurred at the Three Mile Island nuclear power plant in Pennsylvania, USA, in 1979. This was caused by a combination of equipment failure and operator error.</li> <li>• Industrial accidents: Industrial accidents can occur due to human error, negligence, or intentional actions, resulting in explosions, fires, or chemical releases that cause harm to workers, the public, or the environment.</li> </ul>

<sup>1</sup>. Note that in some of these examples the culprit might not be the AI system, but perhaps problematic algorithms or biased data designed by developers might be blamed.

		<ul style="list-style-type: none"> <li>• Cyberattacks on critical infrastructure.</li> <li>• Transportation accidents: Transportation accidents such as airplane crashes or train derailments can occur due to human error, equipment failure, or a combination of factors, leading to loss of life and infrastructure damage.</li> <li>• Nuclear accidents: Nuclear accidents can be caused by human error, negligence, or intentional actions, leading to the release of radioactive material and posing a significant risk to human health and the environment.</li> <li>• Oil spills: Oil spills can occur due to equipment failure, human error, or intentional actions, causing harm to marine life and the environment.</li> </ul>
9	Human-caused/AI-caused	If an AI system is designed to make decisions in a disaster response situation and is trained on biased data or incorrect assumptions, it could make decisions that exacerbate the impact of the disaster and cause unintended consequences. Alternatively, if an AI system is used to monitor social media during a disaster response and produces inaccurate or misleading information, it could cause confusion and panic among the public.
10	Technological/AI-caused	If an AI system is used to control a critical infrastructure such as a power plant, and the system malfunctions, it could lead to a technological disaster. If the AI system is also trained on biased data or incorrect assumptions, it could exacerbate the impact of the disaster.
11	Natural/human-caused/technological	<ul style="list-style-type: none"> <li>• Hurricane Katrina in 2005, which was a natural disaster exacerbated by inadequate infrastructure, poor urban planning, and systemic social inequality.</li> <li>• The Fukushima Daiichi nuclear disaster in 2011, which was caused by a natural disaster (a powerful earthquake and tsunami) but was exacerbated by human error and inadequate safety protocols.</li> <li>• The Deepwater Horizon oil spill in 2010, which was caused by a technological disaster (an explosion on an oil rig) but was exacerbated by human error and poor safety practices.</li> </ul>
12	Natural/human-caused/AI-caused	For example, a natural disaster like a hurricane or earthquake could be exacerbated by a human-caused factor like inadequate infrastructure or poor urban planning, and an AI system that is trained on biased or incomplete data could exacerbate the impact of the disaster. Additionally, if an AI system is used to control critical infrastructure such as power plants or transportation systems, and the system malfunctions or is compromised by malicious actors, it could lead to a hybrid disaster.
13	Natural/technological/AI-caused	For example, a natural disaster like a hurricane or earthquake could damage critical technological infrastructure like power grids, communication networks, or transportation systems, and an AI system that is responsible for managing or controlling these systems could malfunction or make decisions that exacerbate the impact of the disaster. Additionally, if an AI system is trained on biased or incomplete data, it could make decisions that have unintended consequences for disaster management and response.
14	Natural/human-caused/technological/AI-caused	A hypothetical scenario of such a hybrid disaster could be a natural disaster like a hurricane or earthquake, exacerbated by human-caused factors like inadequate infrastructure or poor urban planning, and further complicated by technological failures in critical infrastructure such as power grids, communication networks, or transportation systems. An AI system that is trained on biased or incomplete data could also make decisions that exacerbate the impact of the disaster, leading to a catastrophic event that could be difficult to manage and mitigate.

The significantly increased number of natural disasters is a crucial problem of modern societies, which highlights the significance of disaster knowledge and disaster management (DM) as “the integration of all activities required to build, sustain and improve the capabilities to prepare for, respond to, recover from, or

mitigate against a disaster” [3]. Moreover, some new forms of technological human-caused disasters, as well as hybrid natural-human-caused disasters (which arise from two casual parameters of natural hazard and human misconducts) as side-effects of modern industrial life, such as Natech and Techna,<sup>2</sup> also exacerbated the complexities and difficulties of disaster management. The level of complexity even increases when a mega disaster occurs where a large size of population is affected by acute or chronic impacts [4], [5]. According to World Health Organization (WHO), during COVID-19, as the most recent mega disaster, over 14.9 million people died in 2020-21, and according to the Worldometers database, over 500 million people are recorded as affected populations (with many cases left unrecorded) [6], [7]. Nevertheless, the complexity of hybrid natural-human disasters and the large size of the affected population, as determinative of mega disasters, are not the only factors underlying the increasing complexity of modern disasters.

## Methodology

The methodology of this study includes two steps: first, conducting two rounds of literature review on “AI application in disaster management” and “challenges facing AI applicable in disaster management”, and secondly, holding focus groups on the three topics with some expert participants from academic, public, private, and non-profit organizations. In order to conduct a comprehensive review of the relevant studies, we used the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA)[8] framework.

We adopted the following two approaches. First, we manually identified 18 most relevant papers on “AI application in disaster management”, and 14 papers for “challenges facing AI applications in disaster management” after the removal of duplicate files. Secondly, using the Google scholar platform, we fulfilled a keyword-based search to generate an inclusive repository of the two aforementioned topics, using the following keyword phrases: for the former topic, “AI+disaster”, “AI+application+disaster+management”, then we replaced “AI” with “artificial intelligence/machine learning/deep learning” and “disaster” with “hazard” and “application” with “function” and continued the process up to page 20-30 of the platform. For the latter topic, we searched “ethical+challenges+AI” and “ethical+challenges+AI+disaster+management” and we replaced each part of the phrase with the following relevant words, respectively: “moral/legal/value-based”, “consideration/dilemma/issue”, “artificial intelligence/machine learning/deep learning” and for each, the first 20-25 result pages of Google Scholar were reviewed. Moreover, the following keywords of “accountability,” “explainability,” “fairness,” “trust,” and “privacy” were included because of their known (based on a preliminary review as well as the first focus group) central roles as some major considerations on the application of AI in disaster management.

The results of the search were 240 relevant papers (which were selected based on the relevancy of the semantical keywords) out of 630 (which appeared on the result pages). Afterward, the duplicated papers were eliminated from the analysis; we selected 124 (for both topics) target papers for this systematic review based on the following two inclusion/exclusion criteria. First, articles that were published in academic journals were included. Second, the dominant topic of the papers (or a significant part of it) was relevant to the topic. To this end, the papers’ main sections were reviewed to understand their dominant topic rather than only relying on the title and papers’ keywords. Finally, the qualitative analysis of the 124 papers was

---

<sup>2</sup> *Natech* refers to the case where a natural hazard triggers a technological disaster (such as the Fukushima Daiichi nuclear disaster in Japan, 2011, which was triggered by Tohoku earthquake and tsunami); and *Techna* refers to the case where a natural hazard triggered by some human misconduct (such as an unsustainable energy development, which dramatically increased seismic activity in Oklahoma, between 2009 to 2016 [58]).

performed by three researchers who critically read the papers and identified AI's thirty-four applications, and four main functions, as well as the major challenges facing IDM.

Regarding focus groups, we held three focus groups to examine the different considerations and challenges facing AI applicants in IDM, on the following topics: (1) AI-driven disaster resilience: opportunities and challenges, (2) data governance: roles and responsibilities, and (3) equity, privacy, and ethics. The three focus groups were held virtually on Jun 16, Jun 17, and Jun 23, 2021, and each focus group lasted at least 1.5 hours. We invited 4-6 participants for each focus group with very diverse backgrounds, all of whom had extensive academic or professional experience in AI for disaster management. And to strengthen the discussions, we proposed five questions for each focus group, while discussions were not limited to, and went beyond, these questions. All discussions are recorded, summarized, and filed in the Urban Resilience.AI Lab at Texas A&M University.

## **2. Intelligent Disaster Management (IDM)**

The modern hybrid and mega disasters, as well as the recent digital AI-caused disasters, necessitate intelligent disaster management (IDM) that is empowered by new methods and technologies. Sun et al. [9], [10] argue that “disaster managers need to take a growing responsibility to proactively protect their communities by developing efficient management strategies” and shows twenty-six methods and seventeen applications of AI in disaster management. However, as helpful as AI might be in dealing with disasters, there are three major types of challenges and threats lurking in unlimited use of AI that might turn its positive applications in disaster management into a negative function (i.e., digital disaster mismanagement) which would exacerbate the impacts of a disaster.

The survival of human life is highly dependent on the prediction of catastrophes and early detection and a rapid response; therefore, rapid transfer of information to public systems when faced with hazards and unpredictable events necessitates using AI in disaster management. The modern complexity of disasters, as a result of the quantitative side of AI-caused disasters, and the qualitative side of hybrid and AI-caused disasters, in addition to the inefficacy of traditional methods of coping with modern disasters, calls for new intelligent methods for IDM that can overcome the aforementioned challenges. It also leads to a necessary and “growing demand for up-to-date geographic information, especially timely material on rapidly evolving events. Mega disasters highlight the significant need to analyze mega data, and complex hybrid and AI-caused disasters (such as intelligent digital disasters) would require high computational methods for smart instant decisions. As we will show later, AI has been used to function as a semi-manager and merely an “enhancer factor” by disaster managers. Moreover, its powerful technological potential substantially changed the classical disaster management (CDS) into intelligent disaster management (IDM). Conventional methods of facing up to disasters have given way to practices informed by use of AI in three stages: pre-disaster practices, such as predictions, drillings, and risk assessments; in-disaster measures, such as classifications and modeling; and post-disaster activities, such as assessments of damages, losses, and allocations. AI-equipped smart disaster management would significantly reduce the negative effects of both natural and human-caused disasters in pre-, in-, and post-disaster circumstances. (See, Figure 1)

AI has enabled us to update disaster maps and the vast dimension of the problem, which in turn leads us toward IDM. Before using the new information collection methods and data analysis, there was little we knew about the number and different dimensions of disasters. According to [4], report of disasters in the

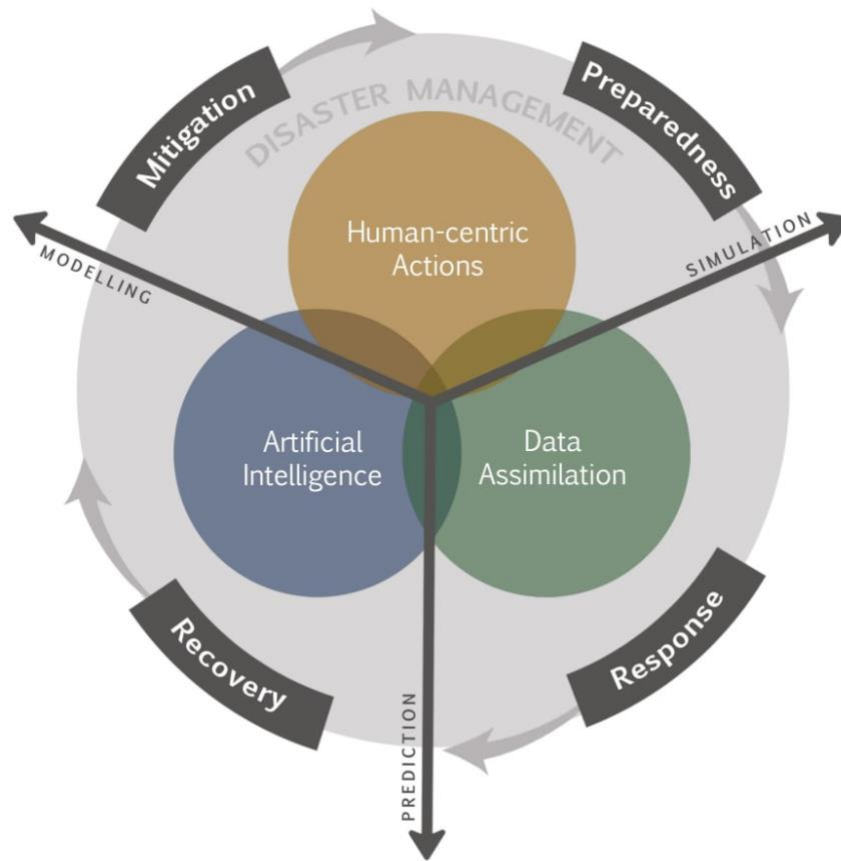

recent decades significantly increased, and it is, by and large, the result of applying new social platforms and smart data collection methods (such as mining Twitter [10]).

AI technologies, methods and models have been used or proposed for IDM in a variety of fields including data mining methods and pattern recognition approaches to provide procedures such as analyzing, sampling, recognition, classification, tracking, remote sensing, and mapping process for saving lives and technologies [11]. Although mitigation, preparedness, response, and recovery are the main phases of using AI in disaster management [12], the most related applications are designed for the response phase [9]. In addition to the fundamental role of human-centric actions in management of different conditions [13], data assimilation centers and emergency information systems with global monitoring networks are the significant factors in disaster management [14], [15]; [16]; [17]. Several studies have been conducted to present modeling, software, and strategies for disaster management covering data and AI applications in hazards, some of which we point out as follows.

Cavdur et al. [18] developed a flexible spreadsheet-based tool involving components of data, decision procedure, and user interface for temporary response in decision making and planning. [19] employed a method to study large-scale multi-hazard disaster scenarios by incorporating experiments and simulations, focusing on multi-hazard field investigation, and analyzing scenarios and responses. Abid et al. [20] argued that establishing a link between geographic information systems (GIS) and remote sensing (RS) could provide a fast, concise, and effective tool for making expeditious decisions in disaster management. Tan et al. [21] have given an extended review to discover trends in disaster management with a focus on AI-based models. Their article can be summarized as follows: 1) reviewing different methodologies and contents proposed for natural disaster management, 2) discussing gaps and applicability of the methods, and 3) suggesting instructions for developing AI models from different aspects. Since most disasters occur momentarily, it is necessary to develop complex coordinated systems that work dynamically based on updated data. This type of systems can use updated knowledge-based models and cooperative techniques to control technology dynamics and select the appropriate AI methods [22]. Also, [23] presented a data-based model for disaster resilience in a dynamic complex framework to facilitate the recovery process and accurate policies.

Data assimilation in collaboration with information systems is the crucial step in disaster management. Nowadays, social networks allow us to be informed of latest news and events instantly. A case in point is Twitter which has been considered a fast means of communication for transferring data. Its role in disaster management has been studied [[24], [25], [26], [27], [28], [29], [30], [31].

**Figure 1.** Crucial parameters involved in Intelligent Disaster Management (IDM)

### 2.1. Intelligent Disaster Management for natural disasters (IDM-N): current AI applications and models

Natural disasters result from natural hazards and forces (e.g., tornadoes, floods, hurricanes, or earthquakes) [5]. It has been considered the main casual parameter in classical disaster social science (which developed after World War II until the early 1970s) [32]. The natural causal parameters of a disaster are not under the human control, although their negative impacts are manageable and can be reduced by using human-AI collaboration in IDM. Varieties of natural hazards and disasters have general effects, like their impact on humans, animals, the environment, and economic loss.

The sudden, rapid, (partially) unforeseeable, and mega impacts and its broad relation with a lot of dimensions of human life make it more difficult for disaster managers to deal with such disasters. AI-driven systems, implemented in Intelligent Natural Disasters Management IDM-N, with high power computation at the moment, and big data mapping and modeling, are used in a variety of fields to help disaster managers in several functions such as prediction, disaster mapping, analysis, rapid response, etc.

AI-powered IDM-N has been used or proposed for natural disaster management in a variety of fields including the deployment of artificial neural networks (ANN) for real-time prediction of tsunami magnitudes [33], AI-based early warning systems [34], [35]; ANN-based flood forecasting [36], earthquake magnitude prediction based on deep learning neural network (DLNN) [37], ANN-based flood warning system [38], prediction of flood characteristics by deployment of database modelling development [39], natural disaster monitoring system based on Internet of Things (IoT) and swarm robotics [40], ANN-based dam failure prediction [41], deployment of teleoperated mobile robots in volcanic ash observation [42], ANN-based flood modeling [43], ANN-based dam water level prediction [44]; [45]), using autonomous helicopters for post-disaster remote sensing and sampling [46], underwater inspections using robots [47], post-disaster inspections by deploying unmanned aerial vehicles (UAVs or drones) [48], automated 3D crack detection for post-disaster building [49], use of mobile robots in mine rescue [50], unmanned marine vehicles (UMVs) for hurricanes [51], integrated information system for snowmelt flood early-warning based on IoT [52], a disaster surveillance system based on wireless sensor network (WSN) and cloud platform [53], deploying analytics of crowdsourced social media content for disaster management [54], and more recently, AI-based urban health monitoring to combat Covid-19 [55][56] and deployment of AI tech in Ukraine's defense against Russia [57]

## 2.2. Intelligent disaster management for human-caused disasters (IDM-H): current AI applications and models

Human-caused disasters are those that result, directly or indirectly, from a human agent's "decision," or misconduct [5], while inappropriate decisions and misbehavior, per se, might be originated from some cognitive errors, misunderstanding, and miscomputation. In the early 1970s, anomalous events, specifically a variety of technological hazards, led to an evolution in disaster as a natural-caused phenomenon, including complex hybrid natural-human caused disasters such as Natech and Techna [32], [58]. Human-caused disasters are also classified in different ways [59], including the varieties of technological disasters, transportation accidents, public places failure, and production failure [5].

AI has twofold negative and positive functions pertinent to human-caused disasters. It might play the role of a new intelligent third casual parameter that entails meta-disasters (such as intelligent mismanagement, and intelligent digital disasters, such as the digital divide). For example, in cyberattacks, a deliberative hacker (who intends to navigate the traditional barriers and smart security approach, to reach the goals of a successful attack), might use some AI-powered techniques. In another example, an urban planner might create a quite unsustainable and discriminative plan that entails disastrous social phenomena in the long run (like the digital divide) while using AI irresponsibly. However, on the positive side, AI technology is increasingly used in different phases of preparedness, predictions, recovery, and response to the negative impacts of complex hybrid, mega, and meta-disasters. Disaster management in the case of human-caused disasters would be effective only if it is powered by AI systems that can understand and analyze much more complex features of the aforementioned types of disasters.

AI technologies, via different approaches and methods, such as remote sensing, natural language processing, satellite data analysis, etc., have been used or proposed for an Intelligent Disaster Management for human-caused disasters (IDM-H) in a variety of fields, including nuclear disasters, oils spills, climate change, and environmental disasters, transportation disasters, and peace technology in response to the digital warfare. Thomson et al. [60] discussed the efficacy of micro-blogging service Twitter (which

benefits from AI to enhance and “upgrade the platform's user experience” [61] and the high accuracy of its shared information regarding the Fukushima Daiichi nuclear disaster in Japan. Baruque et al. [62] shows a forecasting solution to the oil spill disaster, in the northwest of the Galician coast, based on a hybrid intelligent system (called WeVoS-CBR), using historical data and information obtained from various satellites. Kim et al. [63] propose a “blockchain-based carbon emission rights verification system” for more reliable transactions of carbon credit using big data and artificial intelligence in the mobile cloud environment. Carbon credit and tradable permit systems, per se, are aimed at reducing carbon and pollution emissions, as one of the most crucial environmental problems. AI is also used to investigate the efficiency of the artificial neural network (ANN) for reducing the volume of traffic and transportation disasters in the case of non-autonomous vehicles in South Africa. Olayode et al. [64] analyzed dataset obtained from sensors embedded on road surfaces to monitor and control vehicles by Mikros Traffic Monitoring (MTM); and ANN model proposed the best solution for the relevant problem in a heterogeneous traffic condition. AI has also been used in the global fight against terrorism. Canhoto [65] discuss the applicability and leveraging reinforced machine learning against money laundering and terrorism financing. However, the AI usage in war and military power increased [66] and the studies show that, unfortunately, the amount of the application of AI in war is much more than that in peace technology, and it plays a central role in Cyberwarfare [67] it raises a variety of ethical concerns [68]. That said, several studies also show the possibility of cyberspace through AI powered technologies [69], [70]. (See, Table 2)

**Table 2.** AI applications in IDM-N and IDM-H: forty-three current applications

	AI application	Selected Examples	Sources
<b>IDM-N: Pre-disaster</b>			
1	Training and education	Ground Truth, as a training game (developed by Sandia National Laboratories and the University of Southern California GamePipe Lab) to prepare players in response to urban threats.[71]	[71]
2	Developing complex systems for dynamic update	Updating and transferring data using geographic information system (GIS) along the China–Pakistan Economic Corridor and producing a landslide susceptibility map. [72], [73]	[72], [73], [74], [75], [76], [77], [78], [79]
3	Disaster recognition modeling	pattern and AI classification algorithms for flood patterns recognition [80] and weather patterns recognition in a logistic regression model to predict the days with a high probability of avalanche occurrence [81]	[43]

4	Management strategies software	GIS- based application for fire management and risk categorization in five classes of forest fire maps [82]	[80]
5	Real-time hazard prediction	Deployment of artificial neural networks (ANN) for real-time prediction of tsunami magnitudes [83]	[81], [83], [84], [85]
6	Magnitude and characteristic prediction of hazards	A deep learning-based method for Large-magnitude earthquakes and tsunamis prediction [86] and a Deep Learning Neural Network (DLNN) model in landslide susceptibility assessments [87]	[39], [44], [88]
7	Risk mitigation with dynamic decision-making	Integrating geographic information system (GIS) and mobile social networks model (e.g., Twitter technology) as a support tool for dynamic decision making to mitigate tsunami risk [89] and temporary response in decision making and planning. [90]	
8	Early warning systems	Integrated information system for snowmelt flood early-warning based on IoT [91] and ANN-based flood warning system [92].	[93]
9	Disaster forecasting	Machine learning applications in tropical cyclone forecast and hurricane damage detection are given in [94]	[95]
11	Disaster risk/impact and vulnerability assessment	Examining Vulnerability in Natural Disasters with a Spatial Autoregressive Model in South Korea [96]	[97], [98], [99], [100], [101]

**IDM-N: In-disaster**

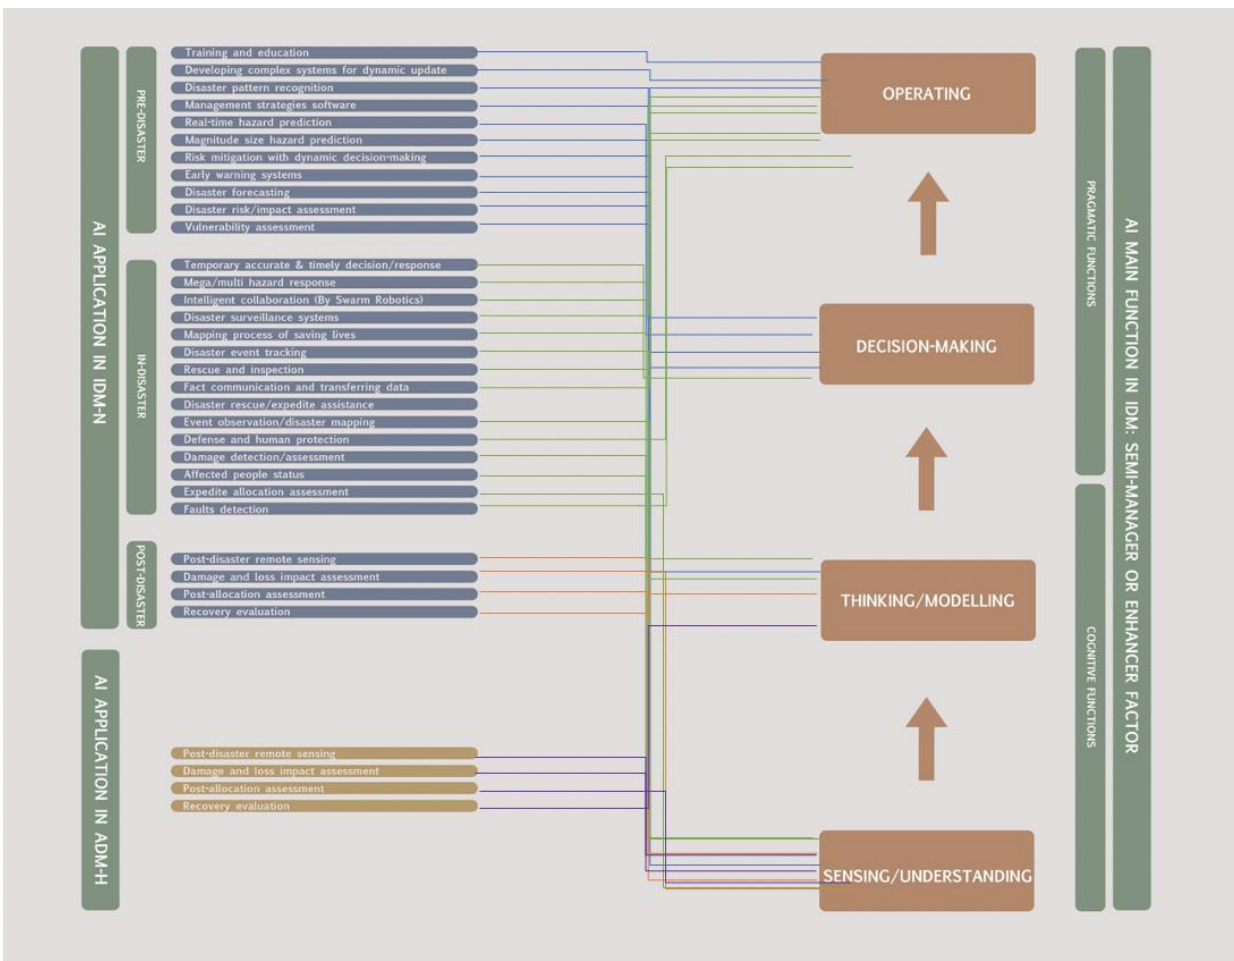

1	Temporary accurate & timely decision/response	A linked geographic information systems (GIS) and remote sensing (RS) that provide a fast, concise, and effective tool for making expeditious decisions in disaster management. [11] And AI-based tool to provide comprehensive, relevant, and reliable information for accurate and timely response [102]	
2	Mega/multi-hazard response	A proposed method to study on large-scale multi-hazard disaster scenario by incorporating experiments and simulations, focusing on multi-hazard field investigation, and	

		analyzing scenarios and responses. [103] and proposed machine learning methods to model large fire formation in Greece. [104]	
3	Intelligent collaboration (By Swarm Robotics) Disaster surveillance systems	A disaster surveillance system based on wireless sensor network (WSN) and cloud platform [105]	
4	Mapping process of saving lives	Data mining methods and pattern recognition approaches for mapping process to saving lives and technologies [20]	
5	Disaster event tracking/monitoring	Natural disaster monitoring system based on Internet of Things (IoT) and swarm robotics [40] and AI-based urban health monitoring to combat Covid-19 [55]	
6	Rescue and inspection/ expedite assistance	Underwater inspections using robots [106] and using mobile robots in mine rescue [107]	
7	Fast communication and transferring data	Fast communication way for transferring data using social networks and studied with other different aspects in management disasters when engaged with AI applications [108] such as that in Hurricane Harvey[78]	
8	Event observation/disaster mapping	Deployment of teleoperated mobile robots in volcanic ash observation [109]	
9	Damage detection/assessment	Machine learning applications in hurricane damage detection [110]	[111]
10	Affected people's status and need understanding	Understanding the affected people's feelings and psychological and health needs using social media and AI-driven systems) [9], [112].	
11	Expedite allocation assessment	Building disaster information systems and ai driven system to support decision-making and help disaster relief and resource allocations [113] [76], [100]	[113] [76], [100]
12	Faults/failure detection	ANN-based dam failure prediction [41]	82]
<b>IDM-N: Post-disaster</b>			

1	Post-disaster remote sensing	Using autonomous helicopters for post-disaster remote sensing and sampling [114]	
2	Damage and loss impact detection and assessment	Automated 3D crack detection for post-disaster building [115]	[116]
3	Post-allocation assessment	Supervised models, that have been used to identify and assess repair needs, and cost; and to analyze historical dispersion data of for budget allocations [100], [117], [118]	[100], [117], [118]
4	Recovery evaluation	A proposed data-based model for the disaster resilience in dynamical complex framework to facilitate recovery process and accurate policies. [119]	88]
5	Post-disaster inspections	Post-disaster inspections by deploying unmanned aerial vehicles (UAVs or drones) [48]	[48]
IDM-H

7	Cyberspace through AI against cyberwarfare	AI usage in war and military power increased [66] and the studies show that, unfortunately, the amount of the application of AI in war is much more than that in peace technology, and it plays a central role in Cyberwarfare [67] it raises a variety of ethical concerns[68]. However, several studies also show the possibility of cyberspace through AI powered technologies [69], [70]	[69], [70] [67]

Moreover, as shown in Figure 3, we characterize the four main functions of AI as an autonomous semi-manager into the two categories of cognitive (i.e., 1. sensing/understanding, and 2. thinking/modeling) and pragmatic (3. decision making, and 4. operating) functions. We have also figured out, based on the first round of our literature review, that the cognitive functions are prerequisites of pragmatic functions of AI in disaster management. Further, in section 3, we will discuss that the cognitive functions are also the origins

of most axiological and hierarchical (including ethical-legal and multimodal value-based) challenges of AI application in disaster management.

**Figure 2.** AI in intelligent disaster management (IDM): thirty-four current applications and four main functions

### 3. Intelligent Disaster Mismanagement (IDMM)

The role of AI in disaster management is two-fold. On the positive side, AI, as the main component of IDM, can be used independently as a semi-manager in disaster, or in a hybrid way as a surveillance system to prevent human mismanagement and alarm for any human error or misconduct that might exacerbate disastrous events. However, on the negative side, if AI is used irresponsibly and inappropriately in IDM, it might function as a third intelligent causal parameter for certain types of meta-disasters, such as intelligent digital disaster mismanagement as a consequence of a hybrid human-AI misconduct in disaster management teams. AI, as a new intelligent causal parameter, substantially differs from the classical causal parameters of disasters (i.e., natural forces, human misconduct, and the hybrid hazards that result from them). AI systems can manipulate the human mind, including disaster managers, in different ways and cause the new hybrid type of digital disaster mismanagement. Disaster mismanagement is in and of itself a type of human-caused disaster, and as Keim et al. [120] explained, “most disaster mismanagement problems occurred because managers did not know what all of the relief activities were or how they should be accomplished.” However, this disastrous mismanagement can be increasingly improved by using irresponsible AI systems involved in IDM teams. To address the challenges facing IDM, appropriately, first we need to characterize different types of these challenges as well as their natures, so that we can propose some appropriate responses (as well as AI platforms and imperative metrics) in dealing with them. For example, an appropriate response to ethical challenges should be a type of ethical metric (such as ethical intelligence) for AI systems; and applicable response to the legal problems could be a type of legal intelligence in AI. In the following, we will elaborate on different types of challenges facing IDM, and in section 4, we concentrate on the appropriate responses to these challenges.

#### 3.1. Challenges Facing IDMM

AI agent as a new causal parameter in disasters can play various roles in disaster similarly to that played by the two traditional human and natural agents. AI can function as a causal disaster parameter, independently of or in combination with the traditional agent, that entails the following three hybrid types of disaster parameters: AI-human causal parameter, AI-nature causal parameter, and AI-human-nature causal parameter (such as a disastrous mismanagement by AI-driven systems that are caused by humans and nature, which ultimately exacerbates the negative impact of the natural parameter of the disaster).

It is worth noting that the concept of AI-induced disasters remains primarily hypothetical, given that the current state of AI technology does not possess the requisite level of complexity or autonomous decision-making capacity to trigger disasters independently. Nevertheless, AI may indirectly contribute to disasters or facilitate human error, and its integration into disaster management systems raises potential hazards and unintended outcomes. To illustrate, several forms of disasters that could conceivably result from or be exacerbated by AI are provided below.

- Cybersecurity breaches: AI algorithms that are not properly secured or monitored could be vulnerable to cyberattacks, which could lead to data breaches, system failures, massive online banking frauds, and other disasters.
- Autonomous vehicle accidents: If self-driving cars and other autonomous vehicles are not properly designed or programmed, they could cause accidents, injuries, and fatalities.
- Malfunctioning robots: AI-powered robots and other machines used in manufacturing, construction, and other industries could cause disasters if they malfunction or are not properly controlled.
- Biased or discriminatory decision-making: AI algorithms that are biased or discriminatory could lead to unfair or unjust decisions that have disastrous consequences for individuals or communities.

Of course, these examples are not exhaustive and that the risks and potential disasters associated with AI will likely evolve as the technology becomes more sophisticated and more widely used. It should be noted that in the above cases the disasters might at least partly be attributed to human developers or other non-AI agents, but we might conceive a very sophisticated AI system that is plausibly considered a direct agent of disasters (e.g. a scenario in which the data training or algorithms cannot plausibly be deemed culprits).

There have been a few incidents where AI has been involved in causing accidents or incidents, but they are not typically categorized as “disasters.” Here are a few examples:

- Tesla Autopilot crashes: There have been several incidents of Tesla vehicles on Autopilot crashing into other cars or stationary objects, resulting in injuries and deaths (273 crashes since 2021).<sup>3</sup>
- Microsoft chatbot “Tay”: In 2016, Microsoft released a chatbot named “Tay” on Twitter, which quickly became corrupted by online trolls who taught it to spew racist and sexist messages.<sup>4</sup>
- Uber self-driving car fatality: In 2018, an Uber self-driving car struck and killed a pedestrian in Tempe, Arizona. An investigation found that the car’s sensors had detected the pedestrian, but the system had been programmed to ignore “false positives” like plastic bags or leaves.<sup>5</sup>

In these cases, the incidents were attributable to a confluence of factors, rather than AI technology alone. Moreover, many AI systems have the capacity to forestall or alleviate catastrophes, including early warning systems for natural calamities, or algorithms employed to predict and prevent equipment malfunctions within industrial settings.

AI-caused disasters can be classified into indigenous and exogenous, where the former results from an unanticipated internal malfunction or error in the AI system and the latter is caused by external intrusions such as cyberattacks.

### 3.2. Ethical Repercussions of IDMM

The utilization of artificial intelligence (AI) in disaster management poses ethical implications and consequences that need to be considered. Among these repercussions is the potential for bias and

<sup>3</sup> See <https://www.washingtonpost.com/technology/2022/06/15/tesla-autopilot-crashes/>

<sup>4</sup> See <https://www.theverge.com/2016/3/24/11297050/tay-microsoft-chatbot-racist>

<sup>5</sup> See <https://www.nytimes.com/2020/09/15/technology/uber-autonomous-crash-driver-charged.html#:~:text=A%20safety%20driver%20who%20was,local%20authorities%20said%20on%20Tuesday>

discrimination. AI algorithms can exhibit bias or discrimination due to biased training data or biased assumptions in the algorithm itself. As a result, this could lead to unfair or inequitable disaster response efforts, where certain communities or populations may receive less aid than others [109]. This could take place in a variety of ways. For instance, the data with which the AI system is trained might be biased. Indeed, AI algorithms are only as good as the data they are trained on. If the data used to train an AI system is biased or incomplete, the resulting algorithm will reflect that bias. For instance, if historical disaster data only includes information from certain areas or demographics, the AI system may make inaccurate predictions or recommendations for those groups. Sometimes, even if the data used to train an AI system is unbiased, the algorithm itself may be biased. This can happen when the algorithm is designed in a way that reflects certain assumptions or values that are not applicable to all groups. For example, an algorithm that prioritizes property damage over loss of life may disproportionately harm communities that are more vulnerable to loss of life in disasters [110][121]. On other occasions, lack of diversity in developing AI systems can lead to unintended biases and discriminations. If the team building an AI system is not diverse, they may not consider the needs or perspectives of all groups. This can lead to a system that is not effective or equitable for all communities.

Another repercussion of employing AI in disaster management is the potential for privacy breach. The use of AI in disaster management may involve collecting and analyzing sensitive data from affected populations, such as medical or location data. This raises privacy concerns and necessitates careful consideration of how data is collected, stored, and used. AI systems tend to collect and process personal data such as location, medical information, and contact details. If this data is not handled properly, it can be used for unauthorized purposes, leading to privacy violations. Moreover, AI systems may share data with other systems or organizations for decision-making purposes. If this information is not properly secured, unauthorized parties may gain access to it, resulting in privacy breaches. What is more, AI systems used in disaster management may be vulnerable to cyberattacks. If the system is infiltrated, confidential data can be accessed and used for unauthorized purposes [111].

Lack of transparency constitutes another concern [112]. The complexity of AI algorithms and models can make it difficult to understand how decisions are being made. This lack of transparency could hinder officials and the public to evaluate the accuracy and fairness of disaster response efforts. AI systems tend to involve black-box decision-making, and their decision-making process relies on complex algorithms, which can make it difficult to understand how they make decisions. This can create obstacles in identifying errors or biases in the decision-making process or comprehending why a particular decision was made. Lack of explanations may also lead to non-transparency of an AI system. Some AI systems may provide a decision or recommendation without providing an explanation for how that decision was reached. This can make it challenging for users to understand the reasoning behind the decision and to assess its accuracy or fairness. Furthermore, AI systems utilized in disaster management may rely on data that is not accessible to the public or to affected communities. This may create difficulties for these groups to understand how decisions are being made or to provide input into the decision-making process.

Another major challenge arising from use of AI in IDM is accountability and liability [113]. In cases where AI algorithms are employed for critical decisions during a disaster, such as resource allocation or prioritizing response efforts, it may be difficult to assign accountability and liability when a failure takes place. This might result from lack of oversight. The use of AI technology in disaster management may not be subject to proper regulatory oversight, resulting in difficulty holding organizations accountable for the system's performance and decisions. Alternatively, this might arise from complexity of AI systems. Many AI systems used in disaster management are complex and use algorithms that are difficult to understand. This can create obstacles in determining who is responsible for decisions made by the system and in

assigning liability for any errors or harm caused by the system. Moreover, lack of transparency might in turn lead to lack of accountability.

Another repercussion is displacement of human judgment. The use of AI in disaster management could displace the judgment of human experts, potentially leading to overreliance on technology and a lack of consideration for contextual factors that may be important in disaster response efforts. Sometimes, this takes place when automated decision-making is used. AI systems used in disaster management can automate decision-making processes that were previously made by humans. This can reduce the need for human judgment and decision-making, potentially leading to a loss of expertise and experience. Algorithmic bias is another reason behind loss of human judgment. Moreover, AI systems used in disaster management may operate without input from humans, leading to decisions that are not informed by contextual knowledge or human experience.

### 3.3. Preventing or Mitigating the Ethical Repercussions of IDMM

One way to prevent or at least take the edge off the ethical repercussions of IDMM (intelligent disaster mismanagement) is a priori ethics. This refers to the ethical considerations that are built into the design and development of AI systems before they are actually deployed. This approach underscores the importance of thinking through ethical issues from the beginning of the development process, rather than attempting to address them after the fact.

A priori ethics in AI involves identifying potential ethical concerns, such as issues related to bias, privacy, and transparency, and taking steps to cope with them through design choices, algorithms, and other technical solutions[122]. One approach to achieving this is by integrating ethical principles into the design process, such as the principles of “privacy by design” or “fairness by design,” and taking into account the potential impact of the technology on various stakeholders. By incorporating ethical considerations into the design and development of AI systems from the outset, developers can ensure that the technology is developed and deployed in a way that is responsible and respectful of the rights and interests of all those who may be affected by it. This approach can also foster trust and confidence in AI systems among users and stakeholders.

Let us refer to such pre-design ethics in AI as embedded ethics. The goal of embedded ethics is to embed ethical principles and values directly into the AI system, so that it operates in a way that is transparent, unbiased, and fair[123]. It can help integrate ethics in the two fundamental functions of AI as the main origins of most of the axiological and hierarchical challenges facing RIDM. An argument for embedded ethics for responsible AI proceeds as follows: (i) Based on the literature review and qualitative analysis, we figured out that there are four main types of functions of AI in IDM: (i.e., 1- sensing/understanding, and 2- thinking/modeling, 3- decision making, and 4- operating) (ii) Major axiological challenges facing AI in DM are originated from two cognitive functions (i.e., 1- sensing/understanding, and 2- thinking/modeling) of AI in DM. (iii) A new paradigm would be capable of, or effective in, dealing with the axiological challenges (which originated from the cognitive functions of AI) only if it includes platforms and powerful competencies relevant to the cognitive pre-design phases of AI development (and not merely to the design phases or a posteriori codes). Therefore, (iv) we propose ERIDM as an a priori paradigm, that is empowered by inclusive embedded ethics platforms and four powerful competencies, to upgrade the cognitive grounds of IDM (and lead it into RIDM) such that it would be capable of dealing with the axiological challenges.

In the context of intelligent disaster management, embedded ethics could help prevent ethical repercussions by ensuring that AI-powered systems are designed and implemented in a manner that is sensitive to the ethical implications of disaster response efforts. This could involve several key steps, including: (i) Developing ethical guidelines and principles for AI-powered disaster management, such as principles of

fairness, accountability, and transparency. (ii) Integrating ethical considerations into the design and development process of AI systems for disaster management, such as ensuring that training data is unbiased and representative of diverse populations, and that algorithms are designed to operate in a fair and transparent manner. (iii) Engaging with affected communities and stakeholders to understand their perspectives and needs, and incorporating these insights into the design and implementation of AI systems for disaster management. (iv) Regularly monitoring and evaluating the ethical implications and consequences of AI-powered disaster management, and making adjustments to the system as needed to ensure that it operates in an ethical and responsible manner.

By embedding ethics directly into the design and development of AI systems for disaster management, it is possible to prevent or mitigate ethical repercussions and guarantee that these systems operate in a way that is sensitive to the needs of affected communities and stakeholders. This approach can help build trust in AI-powered disaster management systems and ultimately improve the effectiveness of disaster response efforts.[124][125]

Another way to prevent or mitigate the ethical repercussions of IDMM is in-design use of AI in disaster management. This refers to the integration of AI into the design of disaster management systems and processes from the outset. This means that AI is not simply added to existing systems, but is instead part and parcel of the design process.

The in-design use of AI in disaster management can involve a range of different approaches, including the use of AI for early warning systems, real-time decision-making support, resource allocation, and post-disaster recovery planning. By incorporating AI into the design of disaster management systems, organizations can help to ensure that AI is used in a way that is safe, reliable, and effective, and that ethical considerations are taken into account from the outset.

One of the key advantages of in-design use of AI in disaster management is the ability to preempt potential ethical and practical issues that may arise when AI is added to existing systems retrospectively. By incorporating AI into the design process, organizations can ensure that the technology is aligned with their objectives, that ethical concerns are integrated from the outset, and that the technology is deployed effectively and transparently.

A third way to prevent and mitigate the ethical repercussions of IDMM is post-design use of AI in disaster management. This refers to the use of AI technologies in the operational phase of disaster management, which is the post-disaster condition, including the response phase, where emergency services are activated and first responders are deployed to affected areas, as well as the recovery phase, where efforts are made to rebuild and restore affected communities.

In the response phase, AI can be used for a range of tasks, such as identification of affected areas and populations, analysis and interpretation of sensor data to assess the extent of the disaster, and support of real-time decision-making by emergency responders. For example, machine learning algorithms can be used to analyze satellite imagery [11] or social media feeds to help identify areas where help is needed [77], or to predict the likely impact of a disaster on transportation networks or other critical infrastructure.

In the recovery phase, AI can be used to support efforts to rebuild and restore affected communities. This may include the use of AI to analyze data on damage and loss, to model and simulate different recovery scenarios, and to optimize resource allocation and recovery planning. For example, AI can be used to assess the extent of damage to buildings and other infrastructure, and to help prioritize and allocate resources based on need and potential impact [21].

A fourth way to prevent and take the edge off the ethical repercussions of IDMM is through regulations. This is an approach to disaster management that makes much of using regulations and policies to govern the deployment and use of AI technologies in disaster management. This approach recognizes that the use of AI in disaster management can pose a range of ethical, legal, and social challenges, and seeks to address these challenges through the development and implementation of transparent regulations and policies [114].

Under a regulation-based approach, deployment of AI technologies in disaster management would be subject to a set of regulations and standards, such as those governing data privacy, algorithmic transparency, and accountability. To illustrate, regulations could mandate that AI algorithms used in disaster management are auditable, explainable, and subject to human oversight, thereby guaranteeing accountability, transparency, and compliance with ethical codes.

Regulation-based intelligent disaster management also involves ongoing monitoring and assessment of the use of AI technologies in disaster management, whereby it is guaranteed that they are aligned with regulatory requirements and ethical principles. This may involve the development of auditing frameworks, third-party assessments, and other measures to ensure that the use of AI in disaster management is safe, reliable, and effective.

## **4. Discussion**

In this section, we discuss the government's role in regulation as a common approach to prevention and mitigation of the ethical repercussions of AI use in disaster management. We then discuss possible challenges toward embedding ethics into AI systems for disaster management, as well as the problem of accountability and liability in the case of AI-caused disasters.

### **4.1. The Government's Role**

The government has a major role to play in monitoring and preventing AI-caused disasters and ethical repercussions of AI's use in intelligent disaster management. Here are some of the ways in which the government can be involved.

#### **4.1.1. Developing and Enforcing Regulations**

The government may establish regulations and standards to ensure the safety, reliability, and ethical use of AI systems in disaster management. These regulations can encompass issues such as data privacy, bias mitigation, transparency, and accountability.

Although the development and enforcement of regulations for AI deployment in disaster management can address certain ethical concerns, there are various possible drawbacks and deficiencies associated with this approach. Firstly, the process of developing regulations can be slow. It may take governments a considerable amount of time to establish and implement regulations, resulting in a lag between the emergence of new technologies and the establishment of standards and guidelines for their use. Moreover, regulations may not be able to keep pace with technological advancements. Given the rapid advancement of AI technologies, regulations may struggle to keep up with the pace of change, culminating in outdated regulations that fail to address new ethical concerns. In addition, enforcing compliance with regulations can prove challenging. Even if regulations are established, regulators may lack the resources or expertise to effectively monitor and enforce compliance, particularly in an area as complex and rapidly evolving as AI. Furthermore, regulations can stifle innovation in AI. Overly prescriptive regulations can limit experimentation and the development of new approaches, which could impede progress in the field. Finally, regulations may be influenced by political influences. Regulations are often subject to political pressures, which can lead to inconsistencies, delays, and compromises that undermine their efficacy.

These challenges might be overcome or alleviated if (1) regulations involve various stakeholders, including government agencies, industries, academics, and civil society groups. In this way, it is guaranteed that regulations reflect diverse perspectives and expertise and are more likely to be effective and widely accepted; (2) governments develop agile and adaptable regulations to keep pace with the rapid evolution of AI technology. This could include approaches such as establishing flexible guidelines that can be updated as new ethical concerns emerge, or establishing regulatory sandboxes that allow for experimentation with new technologies in a controlled environment; (3) governments implement effective enforcement mechanisms, including the establishment of clear lines of responsibility, developing strong monitoring and auditing systems, and providing adequate resources to regulatory bodies; (4) regulations are designed to encourage innovation and experimentation, while still ensuring that ethical concerns are taken into account. This includes incentives for companies and researchers to develop more ethical and responsible AI systems, such as tax credits or funding for ethical AI research; and (5) they develop a culture of ethical AI that extends beyond regulatory frameworks. This could involve promoting ethical principles and values within organizations and the wider AI community, providing education and training on ethical AI, and encouraging transparency and collaboration in AI development and deployment.

#### 4.1.2. Funding research and development

The government can allocate funding to support research and development of AI systems for disaster management that prioritize ethical considerations. Such funding could be directed towards research in areas such as bias mitigation, transparency, and accountability, as well as towards the development of open-source software tools that facilitate ethical AI development.

However, this approach is not without challenges. One such challenge is limited funding, as the government may not have adequate resources to finance all necessary ethical AI research and development in disaster management, making it challenging to prioritize the areas of focus. Another challenge is uncertainty about the outcomes, due to the unpredictable nature of AI research and development, with no guarantee that ethical AI systems will be successfully developed or implemented. Lack of collaboration between government, AI developers, disaster management experts, and other stakeholders is another challenge, potentially leading to the creation of AI systems that do not meet the needs of disaster management and that could result in unintended consequences. Furthermore, the rapid evolution of AI technology causes a risk of overlooking ethical considerations in the race to develop new technology. Regulatory challenges are also common, and the government may struggle to create regulations that are effective in promoting ethical AI development while also not stifling innovation. Finally, ethical considerations may not be prioritized. In some cases, the focus may be more on developing AI systems that are effective in managing disasters, instead of ensuring that they are ethically sound.

#### 4.1.3. Building Capacity

The government can support capacity-building efforts to ensure that those working in disaster management have the requisite knowledge and skills for handling AI systems in an ethical and responsible manner. This could include funding for training projects, workshops, and other educational initiatives.

This solution faces similar challenges such as limited funding and resources, as well as the failure to prioritize ethical considerations.

#### 4.1.4. Monitoring and Evaluation

The government can implement monitoring and evaluation processes to ensure that AI systems used in disaster management operate in an ethical and responsible manner. This can involve the development of frameworks for monitoring and evaluating AI systems, as well as the establishment of oversight mechanisms to ensure that AI systems are operating in conformity to ethical guidelines and standards.

## 4.2. Embedded ethics: possible drawbacks

While embedding ethics directly into AI systems is a potential solution to prevent and alleviate the ethical repercussions of AI use in disaster management, it also faces several challenges and deficits.

The first problem is the challenge of defining ethics. Determining ethical principles and embedding them into AI systems can be complex and difficult. Stakeholders may have varying opinions on what constitutes ethical behavior and how to translate ethical principles into concrete rules for AI systems. This is linked to the problem of handling ethical trade-offs as well. Furthermore, current ethical frameworks may not fully address the unique ethical challenges presented by AI systems in disaster management.

However, the problem might be rendered less severe if common ethical principles are taken into account, which engage multiple stakeholders (including experts in ethics, AI developers, policymakers, and members of affected communities) and are agreed upon by people from diverse cultures and backgrounds. The process should be iterative, involving continually revisiting and refining ethical principles based on new developments in AI technology and feedback from stakeholders. Furthermore, an assessment of ethical impacts should be carried out to identify potential ethical risks and challenges associated with AI systems, which will inform the development of ethical principles. Transparency and accountability must be built into AI systems to ensure that ethical principles are upheld and that AI systems are behaving in a responsible and ethical manner. This can be achieved through measures such as explainability, auditing, and human oversight.

The second problem is difficulty in implementation. Embedding ethical principles into AI systems can be a difficult and time-consuming process, particularly for complex systems with numerous variables and inputs. It may also require specialized expertise in both AI development and ethics.

To overcome this difficulty, the following measures can be helpful: (1) clear guidance and standards for AI developers on how to implement ethical principles, which can include creating industry-wide standards or guidelines for ethical AI development, or providing specific instructions for developers working on projects with ethical implications. (2) Training and education for developers on how to implement ethical principles into AI systems, which can help ensure that they have the requisite knowledge and skills to do so. This can include training on ethical principles and guidelines, as well as technical training on how to implement these principles into AI systems. (3) Collaboration with stakeholders, such as affected communities, regulators, and ethical experts. This also can help ensure that ethical principles are effectively implemented in AI systems. In this way, it is guaranteed that diverse perspectives are taken into account, and potential implementation challenges and solutions can be identified. (4) Testing and evaluation AI systems for their adherence to ethical principles. This can help identify areas for improvement and ensure that these principles are effectively implemented. This includes both technical testing, such as testing for bias or transparency, as well as testing by human evaluators. (5) Incentives and rewards for developers who effectively implement ethical principles in AI systems. This can help promote ethical behavior and ensure that ethical principles are prioritized in AI development.

Finally, there is a risk of unintended consequences. Embedding ethical principles into AI systems may have unintended consequences, particularly if the ethical principles are not well-defined or are not effectively implemented. There is a risk that AI systems may not behave as intended, or may even have unintended negative consequences.

The risk can be mitigated thorough testing and evaluation, which can help identify potential unintended consequences and ensure that these systems are behaving as intended. This can involve both technical testing, such as testing for accuracy and reliability, and testing by human evaluators. Another mitigating

factor is anticipatory governance, which involves anticipating potential unintended consequences of AI systems and designing governance frameworks to address these risks. This includes engaging with stakeholders to identify potential risks, developing policies and regulations to deal with these risks, and establishing mechanisms for continuous monitoring and evaluation.

It is also helpful to develop transparency and accountability as well as responsible practices. For instance, building diversity and inclusion into the design process can help mitigate the risk of unintended consequences by ensuring that a wide range of perspectives and experiences are taken into account.

#### **4.3. Accountability and Liability of AI-caused Disasters**

Determining accountability for AI-caused disasters or AI-caused disaster mismanagement can be complex, as it can involve multiple actors and factors. In general, human individuals or organizations tend to be held accountable for AI-caused disasters. For instance, AI developers might be deemed culprits when they create AI systems that are used in disaster management and the system causes harm due to design flaws, insufficient testing, or failure to take account of ethical implications. Sometimes AI operators are blamed. Operators who are responsible for implementing and maintaining AI systems in disaster management can be held accountable if they fail to properly operate and maintain the system, or if they use the system in a way that causes harm. Regulators are also blamed under certain circumstances. Regulators who oversee the development and use of AI systems for disaster management can be held accountable if they fail to develop and enforce appropriate regulations and standards, or if they fail to adequately monitor and address issues with AI systems. Further, governments might be deemed culprit. They may be held accountable if they fail to provide appropriate funding, oversight, or support for the development and use of ethical AI systems in disaster management. And finally, other stakeholders, such as affected communities, NGOs, and disaster response agencies, can be held accountable if they contribute to or fail to address issues with the use of AI in disaster management [see 115].

It might be argued, however, that AI systems themselves might also be held accountable under certain circumstances if other human agents have done their tasks properly, but the AI has gone through self-learning phases and made decisions which caused the disaster, but cannot be attributed to its developers. In this case, we can say that AI has some sort of “semi-agency.” The challenge, nevertheless, is how to hold an AI system accountable. Individuals or organizations can be held accountable for their misconducts or for the disasters they cause by being fined or by some of their rights being suspended. At present, AI systems do not enjoy any rights or legal protections that might be suspended. However, if AI systems become more and more autonomous, then they might be granted certain rights, which might then be suspended as a way of punishing them for their misconducts. The question of the sentience or consciousness of large language models or other sophisticated AI systems might also have an impact on whether they have any rights and whether they might be held accountable (see [104]).

### **5. Conclusion and Future Directions**

There are several areas of research into an ethical IDM that require further exploration. For instance, although the issue of bias in AI systems has been recognized as a critical research area, there has been insufficient emphasis on ensuring fairness in AI systems for disaster management. Therefore, future research could focus on developing techniques to detect and mitigate bias in disaster management AI systems to secure fair and equitable outcomes.

In the context of disaster management, it is essential to take into account the factors of resilience and adaptability, as the field is constantly changing. Future research may explore the ways in which AI systems

can be designed and developed to exhibit resilience and adaptability, allowing them to learn from new experiences and data.

Human-robot interaction is another area of research that is in need of further investigation. While robots and autonomous AI systems are increasingly deployed in disaster management, there is limited understanding of how humans and robots can effectively collaborate in such scenarios. As such, future research could focus on developing strategies to facilitate effective communication and collaboration between humans and robots.

In disaster management, decision-making tends to be collaborative, involving emergency responders, policymakers, and other stakeholders. Future research may explore how AI systems can support collaborative decision-making in these situations. For example, AI systems could provide real-time information and predictions to facilitate the decision-making process. Finally, long-term impacts should be taken into account when addressing disaster management. Future research could examine how AI systems can aid in long-term recovery efforts by analyzing data on the social, economic, and environmental impacts of disasters. Moreover, AI systems could provide recommendations for long-term planning and recovery efforts.
