

# Deep Learning-Powered Electrical Brain Signals Analysis: Advancing Neurological Diagnostics

Jiahe Li, Xin Chen, Fanqi Shen, Junru Chen, Yuxin Liu, Daoze Zhang, Zhizhang Yuan, Fang Zhao, Meng Li<sup>†</sup> and Yang Yang<sup>†</sup>

**Abstract**—Neurological disorders represent significant global health challenges, driving the advancement of brain signal analysis methods. Scalp electroencephalography (EEG) and intracranial electroencephalography (iEEG) are widely used to diagnose and monitor neurological conditions. However, dataset heterogeneity and task variations pose challenges in developing robust deep learning solutions. This review systematically examines recent advances in deep learning approaches for EEG/iEEG-based neurological diagnostics, focusing on applications across 7 neurological conditions using 46 datasets. We explore trends in data utilization, model design, and task-specific adaptations, highlighting the importance of pre-trained multi-task models for scalable, generalizable solutions. To advance research, we propose a standardized benchmark for evaluating models across diverse datasets to enhance reproducibility. This survey emphasizes how recent innovations can transform neurological diagnostics and enable the development of intelligent, adaptable healthcare solutions.

**Index Terms**—Deep learning, Neural Signal Analysis, Electroencephalography, Neurological Disorder Diagnosis

## I. INTRODUCTION

Neurological disorders represent one of the most significant challenges to global health today, with profound consequences for both individuals and healthcare systems. According to the World Health Organization (WHO), neurological disorders affect over one-third of the global population, making them a leading cause of illness and disability worldwide [1]. Dementia, which affects 47.5 million people worldwide, is a primary concern, with Alzheimer’s disease being the most common form. Seizure impacts more than 50 million individuals, while sleep disorders are widespread yet often underdiagnosed. Other significant disorders, including Parkinson’s disease, schizophrenia, depression, and ADHD, further exacerbate the global burden, placing additional strain on healthcare systems [2]. In low- and middle-income countries,

where limited resources constrain access to neurological care and treatment, the situation is particularly dire.

Practical diagnostic tools are essential to alleviate the growing global burden of neurological disorders, and electrical brain signals are indispensable among them. Electrical brain signals, specifically electroencephalography, are critical for understanding and diagnosing neurological disorders. Electroencephalography evaluates electrical activity in the brain and is categorized into scalp electroencephalography (EEG) and intracranial electroencephalography (iEEG). EEG is non-invasive, recording brain activity from electrodes placed on the scalp. iEEG includes inserting electrodes into the brain (stereo-electroencephalography, SEEG) or onto the brain’s surface (electrocorticography, ECoG), providing more detailed and localized information [3].

The analysis of brain signals such as EEG/iEEG poses significant challenges for traditional machine learning (ML) approaches. These methods typically rely on manually engineered features that may not fully capture the complex patterns in neurophysiological data, while their performance is often compromised by inherent noise and artifacts in raw neural recordings. Deep learning (DL) addresses these limitations by automatically extracting features, modeling temporal dependencies, and improving robustness against signal variability. The ability of DL methods to detect and classify neurological disorders with high accuracy has driven widespread adoption in brain signal analysis. This survey systematically examines the workflow of DL models in brain signal analysis, focusing on their applications in diagnosing neurological disorders.

### A. General Workflow

The general workflow of electrical brain signal analysis in neurological diagnostics, as illustrated in Fig. 1, consists of three main stages: signal collection, signal preprocessing, and analysis and diagnosis.

In the signal collection stage, electrical brain activity is recorded using EEG, ECoG, or SEEG systems (Fig. 1.a). These signals are typically captured across multiple channels at specific sampling frequencies and are often accompanied by labeled tasks and corresponding labels.

The signal preprocessing stage (Fig. 1.b) involves a series of low-level techniques, including denoising, filtering, artifact removal, and normalization. These steps are crucial for reducing noise and artifacts, enhancing relevant patterns, and structuring the data for effective feature extraction.

In the analysis and diagnosis stage (Fig. 1.c), the pre-processed signals undergo feature extraction and neurodiagnostic

Signal Collection:** Acquisition of EEG/iEEG signals from patients using non-invasive scalp electrodes or invasive intracranial electrodes, capturing brain electrical activity for clinical purposes. **b. Signal Preprocessing:** A feasible workflow to process raw signals, ensuring their suitability for subsequent analysis. **c. Analysis and Diagnosis:** Extraction of features from the preprocessed signals, followed by the application of deep learning techniques for model training and neurological classification. **d. Statistical Information:** A statistical summary of related work and publicly available datasets, illustrating their contributions to the field and providing essential resources for future research, model development, and validation.

classification. Feature extraction transforms the signals into representations suitable for diagnosis. Traditional methods extract spatial, temporal, and spectral features manually, while deep learning approaches automatically learn complex, diagnostically relevant patterns. These features are then fed into classifiers for specific neurodiagnostic tasks. The training phase involves careful consideration of network backbones, training paradigms and data partitioning strategies.

Finally, the extracted features are applied to downstream tasks. Fig. 1.d highlights the distribution of related research efforts and publicly available datasets across various neurological conditions, including seizure, sleep disorders, major depressive disorder (MDD), schizophrenia (SZ), Alzheimer’s disease (AD), Parkinson’s disease (PD), and attention deficit hyperactivity disorder (ADHD).

### B. Related Studies and Our Contributions

Existing brain signal analysis surveys exhibit diverse scopes and focuses. Some focus specifically on EEG signals, emphasizing their wide availability [4]–[6]. Others broaden the scope to include brain signals like magnetic resonance imaging (MRI) [7], [8], which differ from EEG and iEEG in acquisition methods, temporal resolution, and preprocessing requirements. From a task perspective, some reviews focus specifically on diseases such as seizure [9], [10], providing in-depth insights into disease-specific applications. Others take a broader view, covering diverse brain-computer interface (BCI)

applications [11], [12], which focus on interaction and control, differing fundamentally from neurological diagnostic tasks.

Our work establishes three foundational contributions to advance deep learning-driven neurodiagnosis: First, we systematically curate and analyze 46 public EEG/iEEG datasets across seven neurological conditions, establishing the most comprehensive data landscape to date. We also unify fragmented methodologies by standardizing data processing, model architectures, and evaluation protocols. Besides, we identify self-supervised learning as the optimal paradigm for developing multi-task diagnostic frameworks, offering a comprehensive overview of pre-trained multi-task frameworks and their advancements. Additionally, we propose a benchmarking methodology to evaluate brain signal models across tasks, providing a foundation for scalable and versatile solutions in EEG/iEEG-based neurological diagnostics applications.

## II. METHODS

### A. Problem Definition

In this survey, we classify neurological diagnostic tasks into sample-level classification and event-level classification, both of which fall under the broader framework of classification problems. Sample-level classification involves assigning a single label to an entire signal, which typically represents a specific subject or sample (e.g., Alzheimer’s disease diagnosis). By comparison, event-level classification focuses on identifying and classifying distinct temporal segments within a more

extended signal, thereby introducing an implicit segmentation process by associating each segment with a specific event or state (e.g., seizure detection or sleep staging).

Electrical brain signals, which capture the brain’s electrical activity over time, can be modeled as multivariate time series. Specifically, let  $\mathbf{X} \in \mathbb{R}^{C \times T}$  represent the EEG/iEEG time series, where  $C$  is the number of channels, and  $T$  is the number of sampling points. Each channel  $\mathbf{x}^c = \{x_1^c, x_2^c, \dots, x_T^c\}$  corresponds to the measurements from a specific source, such as an EEG electrode or a contact of an iEEG electrode.

1) *Sample-Level Classification*: In sample-level classification, the objective is to assign a single label  $y \in \mathcal{Y}$  to the entire signal  $\mathbf{X}$ . This can be formulated as:

$$y = \Phi_{\text{sample}}(\mathbf{X}; \boldsymbol{\theta}), \quad y \in \mathcal{Y},$$

where  $\Phi_{\text{sample}}$  represents the deep learning model parameterized by  $\boldsymbol{\theta}$ , and  $\mathcal{Y}$  denotes the set of possible classes. Here,  $\mathbf{X}$  is treated as a unified entity, capturing sample-level or subject-level characteristics.

2) *Event-Level Classification*: In event-level classification, the goal is to classify smaller temporal segments of the signal. The signal  $\mathbf{X}$  is divided into  $K$  segments  $\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_K$ , where  $\mathbf{X}_k \in \mathbb{R}^{C \times T_k}$  and  $T_k$  is the duration of the  $k$ -th segment. A classification model is applied to each segment to produce a sequence of labels  $\mathbf{Y} = \{y_1, y_2, \dots, y_K\}$ ,  $y_k \in \mathcal{Y}$ :

$$y_k = \Phi_{\text{segment}}(\mathbf{X}_k; \boldsymbol{\theta}), \quad \mathbf{Y} = \bigcup_{k=1}^K \{y_k\},$$

where  $\Phi_{\text{segment}}$  denotes the deep learning model parameterized by  $\boldsymbol{\theta}$ . This process associates each segment  $\mathbf{X}_k$  with a specific label  $y_k$ , allowing the temporal localization of events within the signal. Event-level classification captures natural temporal dependencies between consecutive segments, reflecting the continuity of events in time [13].

## B. Signal Collection

EEG have evolved significantly since Hans Berger first recorded EEG signals from the human scalp in 1924 [14]. While EEG signals are typically collected non-invasively using scalp electrodes placed according to the 10-20 system [15], more recent studies employ higher-density EEG electrode configurations for enhanced spatial resolution and detailed brain activity mapping. EEG captures brain oscillations across frequency bands, each linked to specific neural states: delta (deep sleep), theta (light sleep), alpha (relaxation), beta (focus), and gamma (higher cognition) [16]. Depending on the study, participants may perform tasks or rest to elicit relevant brain activity. Resting-state EEG evaluates baseline activity, while specific tasks can highlight disease-related abnormalities [17].

iEEG involves implanting electrodes either within deep and superficial brain structures via burr holes (SEEG) or on the brain’s surface by placing grids during craniotomy (ECoG). Compared to EEG, iEEG offers excellent spatial resolution and reduced susceptibility to artifacts from scalp muscle activity and eye movements. SEEG allows recording from deep and distributed brain regions with minimal invasiveness, while ECoG provides higher spatial resolution for cortical surface

activity due to its densely packed electrode grids. However, iEEG can still be affected by cardiac artifacts, electrode shifts, and other forms of noise. Rigorous preprocessing techniques are essential to ensure the accuracy and reliability of EEG and iEEG signals in clinical and research applications.

## C. Signal Preprocessing

EEG/iEEG signals require low-level preprocessing to address challenges such as noise and artifact removal, normalization for consistency, and segmentation into analyzable time windows. These steps refine raw data, ensuring it accurately reflects brain activity and provides a robust foundation for analysis. Representative methods are summarized in Table I, with one key work per category highlighted.

1) *Noise Reduction and Filtering*: Filtering techniques, such as Finite Impulse Response (FIR) and Infinite Impulse Response (IIR) filters, are employed to isolate specific frequency components. Advanced methods like MSEC noise reduction and wavelet transforms [21] provide specialized solutions for effective denoising and precise data refinement.

2) *Artifact Removal*: Artifact removal strategies include Blind Source Separation techniques, such as Independent Component Analysis (ICA), Principal Component Analysis (PCA), and Multiple Component Analysis (MCA) [37], along with Artifact Correction methods, including Ocular Correction and Artifact Subspace Reconstruction. Wavelet decomposition is also commonly used mitigate artifacts.

3) *Baseline Correction and Detrending*: Baseline correction and detrending address baseline drift caused by eye movements, breathing, and subject motion. Baseline correction standardizes power data, baseline removal reduces subject-independent noise, and detrending eliminates linear or non-linear trends, enhancing signal reliability.

4) *Channel Processing*: Neurological disorders often affect specific brain regions, making channel processing techniques, including selection, mapping, and re-referencing, essential for enhancing the specificity and interpretability of analyses.

5) *Normalization and Scaling*: Normalization standardizes the amplitude of raw EEG and iEEG signals, which often vary in voltage. Common methods include Z-score and quantile normalization, while linear scaling and shifting minimize spurious amplitude variations across channels.

6) *Sampling Adjustment*: Sampling adjustments optimize data for analysis while reducing computational demands. Downsampling reduces memory and processing requirements, whereas interpolation handles missing data, insufficient training samples, and pulse artifacts [38].

7) *Segmentation*: Segmentation divides EEG and iEEG data into smaller sections for localized information extraction and data augmentation to enhance sample diversity. Overlap windows ensure continuity and capture transitional features, while non-overlapping segments prioritize computational efficiency and maintain distinct temporal boundaries.

8) *Signal Alignment and Synchronization*: Signal alignment ensures temporal consistency across signals from different sources, improving the reliability of findings. Fine-grained temporal alignment further corrects residual discrepancies after initial synchronization, ensuring data precision.

#### D. Feature Extraction

Feature extraction techniques reconfigure data into alternative representations by isolating key features or decomposing it into core components essential for modeling and analysis. This process effectively primes the data for more sophisticated, abstract analytical tasks. Representative methods are summarized in Table II, with one key work per category highlighted.

1) *Data Augmentation*: Data augmentation generates new samples to increase dataset diversity and improve classification

accuracy and stability. Oversampling is commonly used to address class imbalances, while the Extreme Learning Machine Autoencoder (ELM-AE) employs autoencoders to synthesize data by reconstructing input features [39].

2) *Spectral and Power Analysis*: Spectral and power analysis focuses on examining the frequency components and energy distribution of signals. Key techniques include power spectrum calculation, frequency band energy analysis, and partial-directed coherence for evaluating signal causality.

3) *Time Domain Feature Extraction*: Time domain features, such as statistical measures, Hjorth parameters, and Zero-Crossing Rate, effectively represent signal amplitude, time scale, and complexity. These features provide valuable insights into signal distribution, intensity, and rate of change.

4) *Frequency Domain Feature Extraction*: Frequency domain features, such as band power, band energy, median frequency, spectral edge frequency, and power spectral density (PSD), provide insights into the spectral content of signals.

5) *Time-Frequency Feature Extraction*: Time-frequency features capture both temporal and spectral information, providing a comprehensive signal representation. Short-time Fourier Transform (STFT) analyzes frequency variations over time, while Continuous and Discrete Wavelet Transforms (CWT, DWT) offer detailed time-frequency representations. Advanced techniques like FBSE-EWT filter banks [58] and Smoothed Pseudo Wigner Ville Distribution (SPWVD) [59] enhance analysis precision.

6) *Other Feature Extraction*: Nonlinear features, such as entropy measures, fractal dimensions, and Lyapunov exponents, capture complex patterns that linear methods may miss. Spatial features, including Common Spatial Patterns and connectivity measures like phase-locking value (PLV) and phase-lag index (PLI), represent spatial domain activities. Transform-based features further enhance analysis by reconstructing signals into more informative representations.

7) *Signal Decomposition and Transformation*: Signal decomposition and transformation techniques decompose complex signals to facilitate detailed analysis, such as wavelet transforms, Gabor Transform [40], Fast Fourier Transform, Empirical Mode Decomposition, and Hilbert-Huang Transform.

8) *Graph Analysis*: Graph analysis evaluates connectivity between channels. Metrics like degree measure connections and node importance, while the clustering coefficient quantifies local network density, revealing network structure.

#### E. Data Partitioning Strategies

Building on the detailed definition of  $\mathbf{X}^{(i)} \in \mathbb{R}^{C \times T}$  in Section II-A, where  $\mathbf{X}^{(i)}$  represents the EEG or iEEG signal of subject  $i$ , we further introduce additional notations to formalize the data partitioning strategies:

- $\mathcal{P} = \{1, 2, \dots, N\}$ : The set of  $N$  subjects in the dataset.
- $\mathcal{X}_{\text{train}}, \mathcal{X}_{\text{val}}, \mathcal{X}_{\text{test}}$ : The training, validation, and testing sets, respectively.
- $\alpha_{\text{train}}, \alpha_{\text{val}}, \alpha_{\text{test}} \in (0, 1)$ : The proportion of data used for training, validation and test, and  $\alpha_{\text{train}} + \alpha_{\text{val}} + \alpha_{\text{test}} = 1$ .
- $K^{(i)}$ : The total number of temporal segments or events derived from subject  $i$ 's data.

Using these definitions, we classify data partitioning strategies into three categories: subject-specific methods, mixed-subject methods, and cross-subject methods.

1) *Subject-Specific Methods*: Subject-specific methods focus on capturing individual characteristics by partitioning each subject’s data independently into training, validation, and testing sets. Formally,

$$\mathcal{X}_{\text{train}} \cup \mathcal{X}_{\text{val}} \cup \mathcal{X}_{\text{test}} = \{\mathbf{X}_k^{(i)}\}_{k=1}^{K^{(i)}},$$

where  $i$  denotes a specific subject. This method is particularly useful in the early stages of development, as it enables rapid iteration on small datasets and captures individual patient patterns. It is commonly used in closed-loop seizure detection systems, where personalization is critical.

2) *Mixed-Subject Methods*: Mixed-subject methods leverage signals from all subjects in  $\mathcal{P}$  for training, validation, and testing, aiming to create models with broad applicability. The data partitioning method is as follows:

$$\mathcal{X}_{\text{set}} \subset \bigcup_{i \in \mathcal{P}} \bigcup_{k=1}^{K^{(i)}} \{\mathbf{X}_k^{(i)}\}, \quad |\mathcal{X}_{\text{set}}| = \alpha_{\text{set}} \sum_{i=1}^N K^{(i)},$$

where  $\text{set} \in \{\text{train}, \text{val}, \text{test}\}$ . By pooling data across subjects, this approach maximizes training efficiency and improves the model’s robustness to inter-subject variability. However, it also introduces the risk of data leakage, as segments from the same subject may appear in different sets.

3) *Cross-Subject Methods*: Clinical applications demand models that generalize across unseen patients. Cross-subject methods explicitly enforce subject separation between training, validation, and testing by partitioning  $\mathcal{P}$  into disjoint subsets:

$$|\mathcal{P}_{\text{set}}| = \alpha_{\text{set}} |\mathcal{P}|, \quad \mathcal{X}_{\text{set}} = \bigcup_{i \in \mathcal{P}_{\text{set}}} \bigcup_{k=1}^{K^{(i)}} \{\mathbf{X}_k^{(i)}\},$$

where  $\text{set} \in \{\text{train}, \text{val}, \text{test}\}$ . This ensures that models are evaluated on entirely unseen subjects.

Extending subject-level partitioning strategies, dataset-level partitioning includes three approaches: **dataset-specific** (independent partitioning per dataset), **mixed-dataset** (pooling data across datasets), and **cross-dataset** (disjoint datasets for training, validation, and testing). Dataset-specific methods capture individual dataset characteristics, while mixed-dataset methods enhance robustness to inter-dataset variability. Cross-dataset partitioning is crucial for universal models, rigorously assessing generalization and closely aligning with real-world clinical deployment.

### F. Deep Learning Architectures

Neurological data processing relies on several key architectures: **Convolutional Neural Networks (CNNs)** [60] excel at extracting spatial/spectral features through hierarchical convolutions. **Recurrent Neural Networks (RNNs)** [61] capture temporal dependencies via recurrent connections. **Transformers** [62] model long-range spatiotemporal relationships using self-attention. **Graph Neural Networks (GNNs)** [63] analyze functional connectivity in graph-structured data. **Autoencoders (AEs)** [64] learn compressed representations through

encoder-decoder structures. **Generative Adversarial Networks (GANs)** [65] synthesize signals through adversarial training. **Spiking Neural Networks (SNNs)** [66] leverage spike-based computation for temporal dynamics.

### G. Deep Learning Paradigms

Deep learning applications in neurological diagnostics can be categorized into four paradigms: supervised learning, self-supervised learning, unsupervised learning, and semi-supervised learning. Each paradigm addresses specific challenges in processing brain signals by leveraging architectures tailored to data availability and task requirements. These paradigms will be further discussed in detail in Section III.

1) *Supervised Learning*: Supervised learning is the dominant paradigm for neurological diagnostics tasks, training models to map signals  $\mathbf{X} \in \mathbb{R}^{C \times T}$  to labels  $y \in \mathcal{Y}$ .

2) *Unsupervised Learning*: Unsupervised learning is essential for uncovering intrinsic data structures in signals  $\mathbf{X}$ , enabling representation learning without relying on labels.

3) *Semi-Supervised Learning*: Semi-supervised learning combines a small set of labeled examples  $\{(x_i, \hat{y}_i)\}_{i=1}^l$ , where  $\hat{y}_i$  denotes the provided labels, with a larger set of unlabeled examples  $\{x_j\}_{j=l+1}^{l+u}$  to learn a mapping from  $\mathbf{X}$  to  $\mathcal{Y}$ .

4) *Self-Supervised Learning*: Self-supervised learning (SSL) leverages unlabeled EEG/iEEG data by constructing pretext tasks that generate pseudo-labels  $\hat{y}$  from intrinsic properties of the raw signals  $\mathbf{X}$ . These tasks enable models to learn robust representations, which can be fine-tuned for downstream tasks. SSL methods fall into three main categories: contrastive, predictive, and reconstruction-based learning. **Contrastive-based methods**, such as Contrastive Predictive Coding (CPC) [18] and Transformation Contrastive Learning [67], learn by maximizing similarity between related views while minimizing it between unrelated ones, capturing distinguishing signal features. **Predictive-based learning** employs pretext tasks such as Relative Positioning and Temporal Shuffling to extract structural patterns across temporal, frequency, and spatial domains [68], [69]. By predicting transformations applied to the data, it enhances domain-specific feature learning. **Reconstruction-based learning** trains models to reconstruct masked signal segments. Methods like Masked Autoencoders (MAE) reconstruct temporal or spectral components, learning intrinsic patterns in the process [28], [70]. Studies have also explored hybrid methods, which combine elements from contrastive, predictive, and reconstruction-based approaches [18], [71].

## III. APPLICATIONS

This section systematically reviews neurological disease diagnosis methodologies. Each subsection starts with an introduction to the disease’s background, including its characteristics, diagnostic tasks, and relevant public datasets. We will then review representative works for each disease, highlighting disease-specific features in the context of deep learning-based diagnosis, such as data types, frequency bands, brain regions, and methodological trends. Given their extensive research history, seizure detection and sleep staging receive dedicated

TABLE III: Public EEG/iEEG datasets for seizure detection, with **Seizures** indicating the number of episodes, **Length** the duration of each record, and **Size** the total duration of recording.

Dataset	Type	Subjects	Seizures	Length	Size	Frequency (Hz)	Channels
Bonn [72]	EEG	10	-	23.6 sec	≈ 3.3 hours	173.61	1

CCEP [89]	iEEG	74	-	-	89 hours	2048	48-116

sections, while other disorders are analyzed through focused comparative discussions to eliminate redundancy. Technical implementation details across studies (preprocessing pipelines, network architectures, training protocols) are systematically cataloged in supplementary tables.

#### A. Seizure Disorder

1) *Task Description*: Epilepsy, a neurological disorder affecting 50 million people globally, is characterized by recurrent seizures caused by abnormal brain activity. Seizures range from brief confusion or blanking out to severe convulsions and loss of consciousness. According to the World Health Organization (WHO), up to 70% of epilepsy cases can be effectively treated with proper care. However, in low-income regions, limited resources and stigma often hinder access to treatment, heightening the risk of premature death [90].

Seizure detection primarily relies on standardized EEG/iEEG datasets, summarized in Table III. The key challenge is distinguishing seizure events from background activity, typically framed as binary classification where  $y_k \in \{0, 1\}$ . Most approaches segment long EEG sequences into smaller windows for sample-level classification, aggregating segment predictions to form event-level outcomes as  $\mathbf{Y} = \bigcup_{k=1}^K \{y_k\}$  [91], [92]. Another approach detects optimal cut points within continuous recordings to identify the boundaries of meaningful segments  $\{\mathbf{X}_k\}_{k=1}^K$ , and each segment is classified individually [56]. The final event-level prediction is obtained by combining these event-level labels  $\mathbf{Y} = \bigcup_{k=1}^K \{\Phi_{\text{segment}}(\mathbf{X}_k; \theta)\}$ .

More detailed classifications have also been explored, including three-class tasks, where  $y_k \in \{A, D, E\}$  represents interictal (A, the period between seizures), preictal (D, the time before seizure onset), and ictal (E, seizure) states [93]. Five-class tasks refine this further by subdividing the preictal state into early, middle, and late stages [94]. The Temple University Seizure Corpus (TUSZ) [81] supports detailed epilepsy studies, classifying events into pathological patterns

like epileptiform discharges and seizure types (e.g., focal, generalized, tonic-clonic), as well as non-pathological signals such as background activity and artifacts (e.g., eye movements). A detailed overview of all related works is provided in Appendix Table XI.

2) *Supervised Methods*: Supervised seizure detection using EEG/iEEG data has advanced alongside growing datasets and improved technology. Early studies relies on subject-specific or mixed-subject evaluations using short, pre-segmented EEG clips. For example, the Bonn dataset [72] consists of manually labeled seizure/non-seizure segments, leading to models optimized for fixed-length inputs. Approaches based on raw signals employ CNNs or RNNs to automatically extract spatiotemporal features from these standardized segments [29], [95], while feature-based methods derive handcrafted or transformed representations, such as scalograms [94] and wavelet-based features [96], which are more suited for shallow classifiers. These techniques inherently assume limited temporal context and avoided segmentation challenges.

With the adoption of long-term recordings like CHB-MIT [76], the focus shifts toward cross-subject paradigms. These datasets provide extensive seizure examples within continuous, long-term EEG streams, necessitating more flexible detection frameworks capable of handling variable-length inputs and identifying seizure boundaries in unsegmented data. Approaches integrate temporal modeling through sliding windows [91], sequence-aware architectures such as Transformers [97], or hybrid feature fusion techniques [98]. Concurrently, cross-subject validation becomes standard, reflecting clinical requirements that generalize across diverse conditions.

The necessity of cross-subject modeling in seizure detection stems from its critical role in ensuring clinical generalization. The invasive nature of iEEG fundamentally differentiates its modeling requirements from EEG through distinct acquisition paradigms and neurophysiological characteristics, as its patient-specific recording conditions and electrode configurations lead to substantial inter-subject heterogeneity in temporal features and spatial sampling properties, unlike EEG's

standardized scalp placement [99]. Balancing high-resolution spatiotemporal capture with robustness across patients, iEEG requires specialized methodologies to enhance generalizability while addressing its inherent complexities. Spatial modeling is essential for capturing three-dimensional epileptogenic networks with depth electrodes. Graph-based methods model inter-channel dependencies via neuroanatomical [100] or dynamic functional connections [101], while Transformer architectures use attention mechanisms to adapt to varying electrode configurations [102]. DMNet [103] improves domain generalization through self-comparison mechanisms.

3) *Semi- and Unsupervised Methods*: Semi-supervised and unsupervised learning techniques have become increasingly applied in deep learning for seizure detection, particularly when labeled data is limited. A common approach incorporates clustering paradigms for event-level segmentation, allowing the model to identify and segment seizure events [56]. Another notable application involves using models such as Autoencoders, DBNs and GANs to automatically extract relevant features or augment the dataset, thereby enhancing the model's robustness and generalizability [104]–[106].

4) *Self-supervised Methods*: Self-supervised learning has emerged as an effective approach for seizure detection. Contrastive learning captures seizure-related patterns by forming positive pairs through segment augmentation and negative pairs based on feature differences. For example, SLAM [107] generates negative pairs by pairing the anchor with a randomly selected window from a distant time point. SPP-EEGNET [108] calculates the absolute difference between pairs to classify them as positive or negative. Wagh et al. [109] employs cross-domain contrastive learning to mitigate individual differences by comparing subjects based on factors such as age. They use the delta/beta power ratio to estimate EEG-based behavioral states and distinguish pre- and post-seizure characteristics. Zheng et al. [110] employ predictive-based SSL by designing classification pretext tasks that simulate key epileptic features, such as increased amplitude and abnormal frequencies, enabling the model to recognize epilepsy-related patterns. Tang et al. [111] first combine graph-based modeling with pre-training for EEGs, where the model predicts the next set of EEG signals for a given time period.

EpilepsyNet [97] employs reconstruction-based SSL, using Pearson Correlation Coefficients to capture spatial-temporal embeddings while preserving contextual features. Wavelet2Vec [92] utilizes a frequency-aware masked autoencoder that reconstructs wavelet-transformed EEG patches in the time-frequency domain. By leveraging seizure-specific abnormal discharge patterns across frequency bands, it enhances feature extraction for seizure subtype classification. EEG-CGS [57] adopts a hybrid graph-based SSL approach, framing seizure detection as anomaly detection, integrating random walk-based subgraph sampling with contrastive and reconstruction-based learning.

The SSL paradigm is also commonly used in iEEG-based modeling. BrainNet [112] employs bidirectional contrastive predictive coding to capture temporal correlation in SEEG signals. MBrain [71] models time-varying propagation patterns and inter-channel phase delays characteristic of epileptic

TABLE IV: Public Sleep EEG Datasets, where **Recordings** denotes the number of whole-night PSG recordings.

activity through a multivariant contrastive-predictive learning framework, leveraging graph-based representations for spatial-temporal correlations across EEG and SEEG channels. PPI [113] accounts for regional seizure variability, employing a channel discrimination task to ensure the model captures distinct pathological patterns across brain regions rather than treating all channels uniformly.

## B. Sleep Staging

1) *Task Description*: Sleep staging is critical to understanding sleep disorders like insomnia and sleep apnea, as well as the impact on overall health. It is estimated that 20% to 41% of the global population is affected by sleep disorders, which are linked to an increased risk of obesity, cardiovascular diseases, and mental health issues [128]. Therefore, accurately identifying sleep stages is essential for addressing these concerns.

Sleep staging involves segmenting signals into 30-second epochs and classifying them into stages: awake (W), rapid eye movement (REM), and three non-REM (NREM) stages (N1, N2, N3). Wake is characterized by high-frequency  $\beta$  and  $\alpha$  waves. In N1, the transition from wakefulness to sleep, low-amplitude  $\theta$  waves appear. N2, the light sleep stage, is marked by sleep spindles and K-complexes associated with sensory processing and memory consolidation. N3, or deep sleep, features slow-wave  $\delta$  activity. REM sleep, essential for emotional regulation and dreaming, is characterized by rapid, low-voltage brain activities.

Multimodal modeling is fundamental for sleep analysis, as polysomnography (PSG) integrates EEG (e.g., Fpz-Cz, Pz-Oz), Electrooculography (EOG), and Electromyography (EMG) to enhance staging accuracy. The public datasets listed in Table IV are frequently employed in sleep analysis. A detailed overview of all related works is provided in Appendix Table XII.

2) *Supervised methods*: Selecting biosignal modalities is critical for designing supervised learning frameworks in PSG-based sleep staging. Two primary paradigms are widely used. Single-channel EEG methods, preferred in resource-constrained settings, offer hardware simplicity, reduced cross-modal interference, and enhanced computational

TABLE V: Public EEG Datasets for Depression Detection, where **Exp (n)** represents the number of depressed individuals and **Ctrl (n)** represents the healthy control group.

Dataset	Exp (n)	Ctrl (n)	Frequency (Hz)	Channels
HUSM [139]	34	30	256	22
PRED+CT [140]	46	75	500	64

MODMA [142]	24	29	250	128
	26	29		3

efficiency [129], [130]. However, relying solely on EEG limits the detection of complementary cues—such as ocular and muscular activities—essential for identifying ambiguous sleep stages like REM sleep. Multimodal architectures integrating EEG, EOG, and EMG signals emulate the integrative analysis performed by sleep experts [131], [132]. Chambon et al. [131] employs techniques like spatial filtering to mitigate cross-modal interference. These designs align with clinical scoring protocols and compensate for the limited contextual information of individual modalities. Beyond these dominant approaches, hybrid models, such as EEG-EOG, balance diagnostic accuracy with computational efficiency [133].

3) *Self-supervised methods*: Self-supervised contrastive-based methods enhance sleep representation by leveraging temporal and contextual patterns in unlabeled EEG data. Early works explore tasks such as relative positioning, temporal shuffling, and autoregressive latent feature predictions to extract temporal structures from multivariate signals [68], [69]. Jiang and et al. [134] extends these efforts with augmentation-based contrastive learning, generating positive and negative pairs from augmented EEG segments. ContraWR [135] adopts constructing contrastive pairs from distinct time windows, prioritizing window-level temporal dependencies. mulEEG [136] and CoSleep [137] introduce multi-view contrastive strategies to integrate time-series and spectrogram representations of EEG data. mulEEG emphasizes cross-view consistency while encouraging modality-specific features, whereas CoSleep develops a time-frequency dual-view contrastive learning framework that implicitly captures sleep-staging-related temporal dynamics and spectral rhythmic patterns in EEG signals.

Multimodal modeling improves sleep staging accuracy by integrating complementary EEG, EOG, and EMG insights. Brant-X [138] address alignment challenges using EEG foundation models and contrastive learning. By aligning EEG and EXG signals at both the local and global levels, Brant-X effectively bridges the semantic gaps between modalities.

### C. Depression Identification

1) *Task Description*: Depression, particularly Major Depressive Disorder (MDD), is a psychological condition affecting 5% of individuals worldwide, with a higher prevalence among women. In low- and middle-income countries, up to 75% of individuals lack adequate care due to limited resources and stigma, despite effective treatments being available [143].

Depression severity is quantified using standardized scales like the Beck Depression Inventory (BDI) to differentiate clinical depression from normal mood variations. Existing

TABLE VI: Public EEG Datasets for Schizophrenia, where **Exp (n)** represents the number of schizophrenia patients and **Ctrl (n)** represents the control group.

Dataset	Exp (n)	Ctrl (n)	Frequency (Hz)	Channels
CeonRepod [147]	14	14	250	19
NIMH [148]	49	32	1024	64
MHRC [149]	45	39	128	16

studies adopt heterogeneous classification criteria: some focus on binary discrimination (e.g., patients vs. healthy controls), while others stratify cohorts by treatment status (medicated vs. non-medicated) or severity levels (mild vs. moderate/severe). Table V summarizes datasets used in MDD research. A detailed overview of all related works is provided in Appendix Table XIII.

2) *Approach overview*: Depression impacts both superficial and deeper brain structures, presenting challenges for traditional handcrafted features. Acharya introduces the first end-to-end DL model for EEG-based depression detection, showing that right-hemisphere signals are significantly more distinctive than left-hemisphere ones, which aligns with clinical findings [144]. This insight has driven further studies analyzing hemispheric EEG separately, often confirming similar patterns. For example, Ay et al. introduces a hybrid CNN-LSTM architecture, with experimental results revealing a more pronounced performance improvement in the right cerebral hemisphere [21]. DeprNet [35] employs a CNN-based architecture with visualizations highlighting prominent activity in right-hemisphere electrodes for depressed subjects.

Spiking neural networks (SNNs) excel in EEG-based depression diagnosis, capturing brain-inspired spatiotemporal dynamics with biologically interpretable insights. Shah et al. [145] employ the NeuCube SNN framework to encode EEG signals into temporal spike trains, mapping them onto a 3D spiking neural network reservoir (SNNr) aligned with the Talairach brain atlas. The SNNr models spatiotemporal relationships between EEG channels using unsupervised spike-timing-dependent plasticity (STDP), offering interpretable brain connectivity visualizations. Sam et al. [146] integrates a 3D brain-inspired SNN with an LSTM, leveraging SNN’s energy efficiency with LSTM’s temporal modeling capabilities.

### D. Schizophrenia Identification

1) *Task Description*: Schizophrenia (SZ) is a psychiatric disorder affecting 24 million people worldwide, characterized by cognitive impairments, including memory deficits, delusions, and hallucinations [150]. SZ is associated with disruptions in structural and functional brain connectivity, marked by decreased global efficiency, weakened strength, and increased clustering [151]. These abnormalities are detectable in EEG signals, making them useful for binary classification to distinguish SZ patients from healthy controls. Table VI summarizes publicly available datasets for SZ research. A detailed overview of all related works is provided in Appendix Table XIV.

2) *Approach overview*: Transfer learning has emerged as a powerful technique for fine-tuning pre-trained computer

TABLE VII: Public EEG Datasets for Alzheimer’s Diagnosis, where **AD (n)** and **MCI (n)** represent the experimental groups, and **Ctrl (n)** represents the control group.

Dataset	AD (n)	MCI (n)	Ctrl (n)	Frequency (Hz)	Channels
FSA [155]	160	-	24	128	21
AD-65 [156]	36	-	29	250	19
Fiscon [157]	49	37	14	1024	19
AD-59 [158]	59	7	102	128-256	21

vision (CV) models in EEG-based schizophrenia diagnosis, enhancing performance with minimal training. A common approach is converting EEG signals into 2D images for CNN-based models. Aslan et al. [152] feed spectrograms into a pre-trained VGG-16, applying Grad-CAM to highlight critical frequency components. SchizoGoogLeNet [153] fine-tunes the pre-trained GoogLeNet to process 2D EEG feature matrices, which are generated from preprocessed EEG signals through average filtering and resizing to align with the model’s input dimensions. Shalbah et al. [154] transform EEG into scalogram images via CWT, using ResNet-18 and VGG-19 to extract spatial-temporal features for classification.

#### E. Alzheimer’s Disease Diagnosis

1) *Task Description:* Alzheimer’s disease (AD) is a progressive neurodegenerative disorder that starts with mild memory loss and advances to severe cognitive impairment, affecting daily life. While medical interventions can improve quality of life, a definitive cure remains elusive [159]. Alzheimer’s disease (AD) progresses through three stages: preclinical, mild cognitive impairment (MCI), and Alzheimer’s dementia. Classification tasks typically distinguish MCI or Alzheimer’s dementia from healthy controls. EEG abnormalities, such as slowed brain rhythms and desynchronization, serve as biomarkers for AD-related neurodegeneration [160]. Table VII summarizes publicly available datasets. A detailed overview of all related works is provided in Appendix Table XV.

2) *Approach overview:* EEG abnormalities in Alzheimer’s disease, such as disrupted functional connectivity and altered brain rhythms, provide critical insights into the neurological changes. Brain connectivity modeling in AD can be approached from several angles. One approach, as seen in ST-GCN [161], generates functional connectivity matrices that incorporate metrics like wavelet coherence and phase-locking value to simulate spatial and temporal dependencies in EEG signals. Alves et al. [162] uses functional connectivity matrices derived from Granger causality and correlation measures to emphasize the spatial structure of brain networks. Additionally, some studies focus on spectral analysis, such as Morabito et al. [163], who convert EEG data into 2D spectral images using FFT and process these images with techniques like discriminative DCssCDBM to identify hybrid features that highlight EEG patterns associated with AD.

#### F. Parkinson’s Disease Diagnosis

1) *Task Description:* Parkinson’s disease (PD) is a progressive neurodegenerative disorder marked by motor symptoms

TABLE VIII: Public EEG Datasets for Parkinson’s Disease Diagnosis, where **Exp (n)** represents the number of patients and **Ctrl (n)** represents the healthy control group.

Dataset	Exp (n)	Ctrl (n)	Frequency (Hz)	Channels
UCSD [164]	15	16	512	32
UNM [165]	27	27	500	64
UI [166]	14	14	500	59

(tremors, rigidity, bradykinesia) and non-motor symptoms (depression, sleep disturbances, cognitive decline). In 2019, over 8.5 million people worldwide were living with PD [167]. EEG is widely used in PD research due to its noise resistance and sensitivity to neurological changes, such as slowing cortical oscillations and increased low-frequency power [168]. Most studies focus on supervised learning for binary classification, with some incorporating transfer learning. Table VIII summarizes publicly available datasets. A detailed overview of all related works is provided in Appendix Table XVI.

2) *Approach overview:* Transforming raw EEG signals into 2D representations is a well-established approach for PD classification, with various techniques offering distinct insights. Spectrograms, generated via Gabor Transform, as in GaborPDNet [40], preserve time-frequency characteristics while minimizing information loss. Scalograms, created using CWT, provide another effective representation [169]. According to Chu et al. [170], power spectral density (PSD) mapping is another method, where specific frequency bands like high- $\delta$  and low- $\alpha$  can serve as potential biomarkers for early PD diagnosis. Connectivity-based 2D representations can be obtained, like those applied by Arasteh et al. [171], compute directional connectivity and produce heatmaps that effectively capture inter-channel relationships across frequency bands.

#### G. ADHD Identification

1) *Task Description:* Attention-deficit/hyperactivity disorder (ADHD) is a neurodevelopmental disorder affecting around 3.1% of individuals aged 10–14 and 2.4% of those aged 15–19 [174]. It is categorized into three subtypes: Inattentive (ADHD-I), Hyperactive-Impulsive (ADHD-H), and Combined (ADHD-C) [175]. EEG is widely used alongside neuroimaging and physiological measures for ADHD diagnosis. However, deep learning remains underexplored, with most existing approaches relying on supervised learning and feature-based classification. Research focuses on binary classification tasks, and Table IX lists two publicly available datasets. A detailed overview of all related works is provided in Appendix Table XVII.

2) *Approach overview:* Studies on ADHD diagnosis identify distinct EEG neurophysiological markers, particularly

TABLE IX: Public EEG Datasets for ADHD Identification, where **Exp (n)** represents the number of ADHD patients and **Ctrl (n)** represents the healthy control group.

Dataset	Exp (n)	Ctrl (n)	Frequency (Hz)	Channels
ADHD-79 [172]	37	42	256	2
ADHD-121 [173]	61	60	128	19

abnormalities in specific frequency bands. Chen et al. [176] and Dubreuil-Vall et al. [177] demonstrate the effectiveness of CNNs for ADHD detection. Chen et al. report  $\theta$  and  $\beta$  abnormalities in children with ADHD, while Dubreuil-Vall et al. observe altered  $\alpha$  and  $\delta - \theta$  in frontal electrodes during executive function tasks, aligning with medical findings. They also find that EEG data from executive function tasks outperform resting-state EEG for ADHD detection.

#### IV. UNIVERSAL PRE-TRAINED MODELS

In recent years, SSL has revolutionized EEG/iEEG analysis in neurological diagnosis. Emerging methods focus on generalizable SSL frameworks that integrate heterogeneous datasets during pre-training, overcoming the limitations of task- and dataset-specific models and enabling seamless adaptation to multiple downstream tasks. These innovations bring us closer to the development of universal neurodiagnostic models capable of addressing challenges across diverse clinical settings.

Table X summarizes pre-trained SSL frameworks for multi-task neurodiagnosis, organized by the SSL paradigms to align with their technical evolution analyzed in this section. While some frameworks extend to broader time-series data, such as BCI signals and motion sensor data, we focus on datasets and tasks directly relevant to neurological applications. Below, we further explore these frameworks, examining their contributions to unified pre-training strategies, multitask adaptability, and their potential to impact real-world applications.

##### A. Contrastive- and Predictive- Based Learning

*a) Contrastive Predictive Coding:* Early SSL approaches in EEG/iEEG analysis are largely based on the Contrastive Predictive Coding (CPC) paradigm [18], [71], which learns robust representations by predicting signal segments through contrastive learning. While these models employed generic architectures across neurophysiological tasks, they fail to achieve true cross-task generalization. As a result, they are trained separately on specific datasets, limiting their clinical applicability across diverse neurodiagnostic applications. CPC variants like TS-TCC [178] introduce a one-to-one feature transfer mechanism. This framework enables feature migration across tasks such as human activity recognition, sleep staging, and epileptic seizure detection, paving the way for broader multi-domain diagnostic generalization.

Building on the foundational principles of CPC, two distinct approaches have emerged: contrastive learning (CL) and predictive-based variants. CL retains CPC's contrastive framework but emphasizes explicit instance-level discrimination through hand-crafted augmentations for positive/negative pairs, instead of CPC's autoregressive future state prediction. Predictive variants inherit CPC's structure but replace its autolearned latent contexts with manually defined features.

*b) Contrastive-Based learning:* SeqCLR [67], inspired by SimCLR, employs contrastive learning to EEG data, enhancing similarity between augmented views of the same channel through domain-specific transformations. Adopting a mixed-dataset training approach, it unifies diverse EEG

datasets for robust representation learning. TF-C [179] incorporates dual time-frequency contrastive learning with a cross-domain consistency loss to align embeddings across temporal and spectral representations. It further evaluates one-to-many paradigms, highlighting the potential of cross-task feature sharing for universal neural signal models. BIOT [180] integrates contrastive learning, unifying multimodal biosignals (e.g., EEG, ECG) via tokenization and linear attention to learn invariant physiological patterns for cross-task generalization.

*c) Predictive-Based Learning:* Jo et al. [181] proposes a channel-aware predictive-based framework, which leverages stopped band prediction for spectral feature learning and employs temporal trend identification to capture dynamic patterns. By integrating mix-dataset pretraining, it enhances generalization through cross-domain feature fusion. However, the pretraining scale remains limited.

##### B. Reconstruction-Based Learning

*a) Masked Autoencoding:* The paradigm shift from CPC to masked reconstruction in SSL aims for higher data efficiency and scalability, inspired by cross-domain advances like masked language modeling in NLP (e.g., BERT [189]), with MAE's generative approach enhancing classification performance while avoiding complex negative sampling.

Neuro2vec [70] extends masked reconstruction by integrating EEG-specific spatiotemporal recovery and spectral component prediction into a unified framework, utilizing a CNN-ViT hybrid architecture for patch embedding and reconstruction. CRT [182] further introduces multi-domain reconstruction through cross-domain synchronization of temporal and spectral features, replacing conventional masking with adaptive input dropping to preserve data distribution integrity, thereby improving robustness in physiological signal modeling. NeuroBERT [183] introduces Fourier Inversion Prediction (FIP), reconstructing masked signals by predicting their Fourier amplitude and phase, then applying an inverse Fourier transform. The spectral-based prediction framework inherently matches the physiological nature of EEG signals.

*b) Large-Scale Continuous-Reconstruction Models:* Transformer architectures excel in neurodiagnostics due to their scalability and attention mechanisms, which adaptively capture global dependencies in irregular neural signals. BERT-style pretraining, particularly masked reconstruction, enhances neurodiagnostic classification by enforcing robust contextual learning of latent bioelectrical patterns, which is crucial for distinguishing subtle neurological signatures. Their parallelizable training and tokenized time-frequency representations pave the way for scalable foundation models, driving large-scale pretraining in neural signal analysis.

Inspired by Bert, BENDR [28] integrates CPC with MAE-inspired reconstruction for temporal feature learning. Pre-trained on the Temple University Hospital EEG Corpus (TUEG)—a diverse dataset containing 1.5 TB of raw clinical EEG recordings from over 10,000 subjects—BENDR represents the emergence of large-scale pretraining for neurodiagnostics, showcasing the cross-subject scalability of transformers. It demonstrates how foundation models can unify

TABLE X: Summary of pre-trained SSL frameworks for multi-task neurodiagnosis, focusing on relevant datasets and tasks, with paradigms such as Contrastive Learning (CL), Contrastive Predictive Coding (CPC), and Masked Autoencoding (MAE)

heterogeneous neural signal paradigms, advancing generalized and scalable EEG analysis. CBRAMOD [184] introduces a criss-cross transformer framework to explicitly model EEG’s spatial-temporal heterogeneity. Using patch-based masked EEG reconstruction, it separately processes spatial and temporal patches through parallel attention mechanisms, preserving the structural dependencies unique to EEG.

Brant [99] and Brainwave [185] represent a unified effort to establish foundation models for neural signal analysis. Brant focuses on SEEG signals, employing a masked autoencoding framework with dual Transformer encoders to capture temporal dependencies and spatial correlations, enabling applications such as seizure detection and signal forecasting. Brainwave pioneers large-scale pretraining with an unprecedented multimodal corpus of over 40,000 hours of EEG and iEEG data from 16,000 subjects, marking a significant milestone in neural signal foundation models. Its pre-training strategy follows a masked modeling paradigm that randomly masks time-frequency patches of neural signals, and the model is trained to reconstruct the missing regions. To enhance generalizability across different types of neural data, Brainwave employs a shared encoder for both EEG and iEEG, coupled with modality-specific reconstruction decoders. These innovations position Brainwave as the first comprehensive foundation model capable of unifying EEG and iEEG analysis, with transformative implications for neuroscience research.

*c) Large-Scale Discrete-Reconstruction Models:* Vector Quantized Variational Autoencoder (VQ-VAE) is a powerful framework for learning discrete representations of continuous data by mapping inputs to a predefined codebook, which has been widely adopted in domains like speech and image processing [190]. By tokenizing raw data into discrete codes, this approach enhances cross-subject generalization while preserving interpretable spatiotemporal patterns.

LaBraM [187] trains its discrete codebook by reconstructing both Fourier spectral magnitudes and phases of EEG seg-

ments, then pretrains with a symmetric masking task that predicts masked code indices bidirectionally. NeuroLM [188] further extends this approach by introducing VQ Temporal-Frequency Prediction, aligning EEG tokens with textual representations through adversarial training. After tokenization, it employs multi-channel autoregressive modeling, enabling an LLM to predict the next EEG token in a manner analogous to language modeling. EEGFormer [186] focuses on reconstructing raw temporal waveforms for codebook training, followed by BERT-style masked signal reconstruction pretraining. These methods demonstrate how VQ-based tokenization adapts to EEG modeling—whether prioritizing spectral synchrony (LaBraM), fusing time-frequency features (NeuroLM), or preserving temporal fidelity (EEGFormer).

### C. BrainBenchmark

The development of universal pre-trained frameworks represents a transformative advancement in healthcare, enabling the integration of heterogeneous datasets and generalization across diverse diagnostic tasks. To systematically evaluate and advance this field, we have established an open benchmark, currently comprising 8 models and 9 public datasets focused on neurological diagnostics, with ongoing expansions planned. This benchmark supports comprehensive performance evaluation, custom model integration, and dataset extensibility, fostering reproducible research and innovation. The implementation is publicly available at <https://github.com/ZJU-BrainNet/BrainBenchmark>. Future work will include a detailed analysis of benchmark results to further advance universal frameworks in EEG/iEEG analysis.

## V. CONCLUSION

This survey systematically reviews 448 studies and 46 public datasets to advance deep learning-driven analysis of EEG/iEEG signals across seven neurological diagnostic tasks:

seizure detection, sleep staging and disorder, major depressive disorder, schizophrenia, Alzheimer’s disease, Parkinson’s disease, and ADHD. Our work establishes three foundational contributions: First, we unify fragmented methodologies across neurological conditions by standardizing data processing, model architectures, and evaluation protocols. Second, we identify self-supervised learning as the most promising paradigm for multi-task neurodiagnosis, providing a comprehensive overview of pre-trained SSL frameworks and their advancements. Third, we introduce BrainBenchmark to enhance reproducibility by integrating neurological datasets and universal models under standardized evaluations.

Looking back, the pursuit of universal models capable of learning from diverse, multimodal data reflects the field’s growing ambition. It lays the groundwork for a new era of intelligent and adaptable healthcare systems. Over the past decades, significant progress in traditional methods has established a strong foundation for neurological diagnostics based on electrical brain signals. Key contributions include advances in signal preprocessing techniques, curating large-scale, well-annotated datasets, and developing deep learning architectures for specific tasks. Building on this foundation, the integration of self-supervised pretraining marks a paradigm shift, enabling models to extract rich and meaningful representations from vast amounts of unlabeled, heterogeneous data.

Looking forward, the ultimate goal is to develop genuinely universal and adaptable frameworks capable of transcending individual tasks and datasets to address a broader range of neurological disorders. These advancements will pave the way for intelligent diagnostic tools that deliver precise, efficient, and accessible healthcare solutions globally, driving transformative progress in biomedical research and clinical applications.

#### ACKNOWLEDGMENT

This work is supported by NSFC (62322606) and Zhejiang NSF (LR22F020005).

In this section, we provide summaries of deep learning-based frameworks for the seven neurodiagnostic tasks mentioned earlier. These summaries include details on preprocessing methods, extracted features, deep learning backbones, training paradigms, downstream task datasets, classification tasks, data partitioning strategies, and reported performances. The relevant tables are as follows: seizure detection in Table XI, sleep staging in Table XII, depression identification in Table XIII, schizophrenia identification in Table XIV, Alzheimer’s disease diagnosis in Table XV, Parkinson’s disease diagnosis in Table XVI, and ADHD identification in Table XVII.

TABLE XI: Summary of deep learning frameworks for seizure detection
