Abstract

Gradient-based methods are well-suited for derivative-free optimization (DFO), where finitedifference (FD) estimates are commonly used as gradient surrogates. Traditional stochastic approximation methods, such as Kiefer-Wolfowitz (KW) and simultaneous perturbation stochastic approximation (SPSA), typically utilize only two samples per iteration, resulting in imprecise gradient estimates and necessitating diminishing step sizes for convergence. In this paper, we first explore an efficient FD estimate, referred to as correlation-induced FD estimate, which is a batch-based estimate. Then, we propose an adaptive sampling strategy that dynamically determines the batch size at each iteration. By combining these two components, we develop an algorithm designed to enhance DFO in terms of both gradient estimation efficiency and sample efficiency. Furthermore, we establish the consistency of our proposed algorithm and demonstrate that, despite using a batch of samples per iteration, it achieves the same convergence rate as the

KW and SPSA methods. Additionally, we propose a novel stochastic line search technique to adaptively tune the step size in practice. Finally, comprehensive numerical experiments confirm the superior empirical performance of the proposed algorithm.

Key words: derivative-free optimization; finite-difference; batch optimization; adaptive sampling; convergence rate

1 Introduction

Stochastic optimization aims to find the minimization (or maximization) of a function in the presence of noise. Specifically, in this paper, we consider solving the following unconstrained stochastic optimization problem:

$$\min_{\mathbf{x}\in\mathcal{X}} F(\mathbf{x}) = \mathbb{E}[f(\mathbf{x})],\tag{1.1}$$

where $\mathcal{X} \subseteq \mathbb{R}^d$ is a convex set, $F : \mathcal{X} \to \mathbb{R}$ is the true performance, and f is a noisy function. This problem has a wide range of application, including simulation optimization (see, e.g., Chang et al., 2013; Hu and Fu, 2024) and reinforcement learning (see, e.g., Fazel et al., 2018; Mania et al., 2018). Among problem (1.1), a difficult but important case lies in the lack of the closed form of $F(\mathbf{x})$, and only estimates of the output function are available. That is, for any $\mathbf{x} \in \mathcal{X}$, we can only get an unbiased but noisy estimate of $F(\mathbf{x})$, i.e., $f(\mathbf{x})$. Such problem is derivative-free optimization (DFO, sometimes referred to as black-box optimization). As the problem becomes complex, the DFO will become increasingly important, and Golovin et al. (2017) mention that "any sufficiently complex system acts as a blackbox when it becomes easier to experiment with than to understand".

Much literature has discussed the methodology development of DFO. The first category of algorithms are heuristic methods. For instance, the Nelder-Mead simplex algorithm, a direct-searchbased method, is widely applied in practical scenarios (Barton and Ivey Jr, 1996). A key limitation of these algorithms is the lack of theoretical convergence guarantees (Spall, 2005). Another line involves transforming stochastic problems into deterministic ones, taking advantages of deterministic optimization. For examples, sample average approximation (Kim et al., 2015) generates many sample paths and uses the sample mean to estimate the unknown expectation; metamodels such as response surface methodology and Gaussian process are also used to fit the unknown function (Hong and Zhang, 2021). Recently, model-based trust region methods, which integrate model fitting and trust region techniques, have been developed to address simulation optimization problems. Notable examples include the stochastic trust-region response-surface method (Chang et al., 2013) and model-based trust-region derivative-free algorithms (Shashaani et al., 2018). Interested readers may refer to Audet and Hare (2017) and Larson et al. (2019) for a survey of these methods.

Although our focus is on derivative-free approaches, Audet and Hare (2017) comment that "if gradient information is available, reliable and obtainable at reasonable cost, then gradient-based methods should be used." On the other hand, Shi et al. (2023) perform lots of experiments, showing the efficiency of gradient-based methods with finite-difference gradient surrogates. Therefore, we would like to consider gradient-based stochastic search algorithm to solve (1.1) in this paper. Note that under some smoothness conditions (the assumption ensures the application of the gradientbased methods), solving (1.1) is equivalent to finding the zero of the true gradient $\nabla F(\mathbf{x})$. Then, gradient-based methods are same as the stochastic approximation (SA) and take the general form:

$$\mathbf{x}_{k+1} = \Pi_{\mathcal{X}} \left(\mathbf{x}_k - a_k \widehat{\nabla} F(\mathbf{x}_k) \right), \tag{1.2}$$

where \mathbf{x}_k and \mathbf{x}_{k+1} are the current solution and next prediction, respectively, $\widehat{\nabla}F(\mathbf{x}_k)$ is the estimate of the true gradient $\nabla F(\mathbf{x}_k)$ at k-th iteration, $a_k > 0$ is the step size, and $\Pi_{\mathcal{X}}(\cdot)$ is the projection operator onto the feasible region \mathcal{X} .

Under the black-box setting, the gradient estimate in (1.2) is usually substituted by finite difference (FD) gradient and in this case, (1.2) can date back to the Kiefer-Wolfowitz stochastic approximation (KWSA) algorithm (Kiefer and Wolfowitz, 1952). Due to the variance of the FD estimate, the step size should tend to 0 to ensure the convergence. A similar method in high dimension is the simultaneous perturbation stochastic approximation (SPSA) method (Spall, 1992, 1997). In practice, the initial step size is crucial for the performance. For example, if the step size is too large, the solution may jump to a distant position, whereas if it is too small, the convergence rate of the KWSA and SPSA algorithms will be extremely slow, especially when the true performance is flat (see Section 3.1.2 in Broadie et al., 2011).

To choose a proper step size, especially avoid the degradation of convergence rate, Broadie et al. (2011) present a scaled-and-shifted KW (SSKW) algorithm, adaptively tune the step size as well as the perturbation by introducing extra 9 hyperparameters. Firstly, they scale up the initial step size to avoid it is too small. Then, in the "shifted" procedure, they reduce the step size until the iteration falls into \mathcal{X} . Another straightforward method lies in stochastic line search (see, e.g., Berahas et al., 2019), using the simulated function values to adjust the step size. Similarly, stochastic line search

shrinks the step size until the stochastic Armijo condition is satisfied. Compared with SSKW method, stochastic line search is more flexible because the step size is not a fixed form, even not required to tend to 0. Consequently, this method necessitates the accuracy of the descent direction, and thus a batch of samples should be utilized at each iteration for gradient estimate. In this paper, we aim to introduce batch-based optimization to enhance the accuracy of gradient estimation, while using a larger step size to preserve the algorithm's effectiveness.

Batch-based optimization is inspired by the mini-batch method, which serves as an improvement over stochastic gradient descent or the Robbins-Monro (RM) algorithm (Robbins and Monro, 1951). By utilizing a batch of samples to enhance the precision of stochastic gradient estimates, the minibatch method is better suited for training neural networks. When using the FD gradient, the challenge lies in the construction of an accurate batch-based FD estimate. Fox and Glynn (1989) and Zazanis and Suri (1993) study the convergence of the standard batch-based FD estimator and provide the theoretically optimal perturbation size by minimizing the mean squared error (MSE). However, the optimal perturbation is related to the structure information of the blackbox and we do not know it when using the FD estimator. To overcome this issue, Li and Lam (2020) propose a two-stage method, estimating the perturbation in the first stage and then generating remaining samples at the estimated perturbation to give the expectation-minimization FD (EM-FD) estimator. Recently, Liang et al. (2024) propose a correlation-induced FD (Cor-FD) estimator, using all samples in a batch to estimate the perturbation and then recycling them to estimate the gradient. Cor-FD is available when the batch size is small and it is shown that Cor-FD possesses a reduced variance, and in some cases a reduced bias, compared to the optimal FD estimator.

Given that Cor-FD is efficient when the budget is limited, it is suitable for batch-based DFO algorithm (Wang et al., 2024). However, selecting an appropriate batch size in each iteration is crucial. Specifically, if the batch size is too small, the descent direction may lack sufficient accuracy, limiting adjustments to minor corrections along this direction. Conversely, if the batch size is too large, samples may be wasted, as the descent direction does not require excessive precision. In fact, the most efficient algorithms should employ a progressive batching approach in which the batch size is initially small, and increases as the iteration progresses (Bollapragada et al., 2018). For this purpose, the adaptive sampling condition called the *norm condition* (see, e.g., Bollapragada et al., 2024) has been proposed, which sets the batch size based on the *signal-to-noise ratio* (i.e., the ratio

between the true gradient and the gradient estimate error).

By using the Cor-FD estimate and the adaptive sampling condition, the gradient estimate in (1.2) has been determined. Another challenge lies in the determination of the step size. The classical stochastic line search method introduces a relaxed Armijo condition (Berahas et al., 2019; Shi et al., 2023). However, step sizes that meet this condition are suboptimal and fall short of being ideal. Consequently, the algorithm converges only to a neighborhood of the optimal value, the size of which depends on the noise level in the black-box function (Berahas et al., 2019). Ensuring convergence requires allocating additional samples to determine a suitable step size. To address this, the paper proposes increasing the number of simulations for step sizes that meet the relaxed Armijo condition, enabling a more precise assessment of their suitability.

In summary, the main contributions of this paper are as follows:

- 1. We propose an adaptive Cor-FD algorithm for DFO. We explore an efficient surrogate of $\hat{\nabla}F(\mathbf{x}_k)$ in (1.2): the Cor-FD estimate, and propose an adaptive sampling strategy for solving DFO. Specifically, the Cor-FD estimator exhibits a variance reduction property, enabling it to perform as well as, or even better than, the theoretically optimal FD estimate. That is, the Cor-FD estimator achieves a relatively small estimation error, and thus enhance the estimation of $\hat{\nabla}F(\mathbf{x}_k)$. Furthermore, the proposed adaptive sampling strategy dynamically determines an appropriate batch size for constructing the Cor-FD estimate at each iteration, thereby further enhancing the efficiency and accuracy when solving DFO.
- 2. We provide the consistency and convergence rate of our proposed algorithm. We prove that if the step size is set as some appropriate constants, the sequence of iterates generated by (1.2) converges linearly in expectation to the optimal solution. This result generalizes that of the deterministic (full-batch case in machine learning) gradient descent. Moreover, it is surprising that although we consume a batch of samples to estimate the gradient, the algorithm maintains the optimal sample complexity in the sense that it reaches the optimal convergence rate of the KWSA algorithm.
- 3. We revise the stochastic Armijo condition, establish an efficient DFO algorithm, and demonstrates its practical benefits through numerical experiments. We demonstrate that when step sizes are selected based on the relaxed Armijo condition, the algorithm converges only to a

neighborhood of the optimal value. Subsequently, we heuristically propose new conditions to evaluate the suitability of step sizes. Using these conditions, we design an efficient algorithm and perform extensive numerical experiments. The results indicate that, compared to traditional methods, the new approach yields solutions closer to the optimal value.

The rest of the paper is organized as follows. In Section 2, we give some backgrounds about the gradient-based stochastic optimization and batch-based CFD estimate. Section 3 presents the adaptive sampling condition, the stochastic line search and the complete algorithms based on constant and line-search step sizes. In Section 4, we present the main results about the algorithm in Section 3. Sections 5 applies our algorithm to solve DFO problems, followed by conclusions in Section 6. Proofs are provided in the appendix.

2 Preliminaries

2.1 Gradient-Based Stochastic Optimization

To find the optimal solution \mathbf{x}^* of (1.1), the classical method is gradient-based stochastic search (also known as stochastic approximation). Specifically, \mathbf{x}^* can be obtained by the recursion (1.2). Without loss of generality, we assume that $\mathcal{X} = \mathbb{R}^d$ and remove the projection operator. Then, the recursion is

$$\mathbf{x}_{k+1} = \mathbf{x}_k - a_k \nabla F(\mathbf{x}_k). \tag{2.1}$$

There are two pivotal roles in (2.1): the step size a_k and the gradient estimate $\widehat{\nabla}F(\mathbf{x}_k)$. If the unbiased gradient estimate $\nabla f(\mathbf{x}_k)$ can be obtained, then (2.1) is the RM algorithm, which is the origin of the stochastic gradient descent. In this paper, we assume that one can only get the zeroth-order information with noise and the first-order information is unavailable. In this case, the gradient estimate $\widehat{\nabla}F(\mathbf{x}_k)$ is usually substituted by the FD method. Such methods include the KW and SPSA methods, which obtain $\widehat{\nabla}F(\mathbf{x}_k)$ with only 2 samples at each iteration. Consequently, the variance of $\widehat{\nabla}F(\mathbf{x}_k)$ is large and the step size a_k should tend to 0 to ensure the recursion goes towards the optimal solution \mathbf{x}^* . Although it is shown that the convergence rate of the KW and SPSA algorithms can reach $\mathcal{O}(1/k^{2/3})$, where k is the iteration number (the sample complexity is similar because these 2 methods consume 2 samples at each iteration), the convergence rate may be unattainable in practice. Even when there is no noise, using the diminishing step size may lead to degeneration, as can be seen in Example 2.1 (Broadie et al., 2011).

Example 2.1. Consider finding the infimum point of the deterministic function $f(x) = 0.001x^2$ with the KW method:

$$x_{k+1} = x_k - a_k \frac{f(x_k + h_k) - f(x_k - h_k)}{2h_k}$$

If we set $a_k = \theta_a/k$ and $h_k = \theta_h/k^{1/4}$ with $\theta_a = 1$ and $\theta_h = 1$, respectively, then the KW algorithm becomes $x_{k+1} = x_k(1 - 1/(500k))$. Starting with $x_1 = 1$, we have

$$x_{k+1} = \prod_{i=1}^{k} \left(1 - \frac{1}{500i} \right) = \exp\left(\sum_{i=1}^{k} \log\left(1 - \frac{1}{500i}\right) \right) \ge \exp\left(-\sum_{i=1}^{k} \frac{1}{500i} \right) \ge \mathcal{O}\left(\frac{1}{k^{0.002}}\right),$$

where the first inequality is because for any $x \in (0,1)$, $\log(1-x) \ge -x$. Therefore, the MSE cannot converge faster than $\mathcal{O}(k^{-0.004})$, which is significantly slower than the theoretically optimal rate of the KW algorithm $\mathcal{O}(k^{-2/3})$. The reason is that the step size is too small, which limits the algorithm's rate of descent.

To address the problem in Example 2.1, one approach is to carefully adjust the initial value of the step size, θ_a , to prevent degeneration in the algorithm's convergence rate. Along this line, Broadie et al. (2011) propose the SSKW method, which adaptively tunes both the step size and perturbation by introducing 9 additional hyperparameters. Another approach is to use a constant step size, which demands a highly accurate gradient estimate, requiring more samples or a batch of samples to compute $\widehat{\nabla}F(\mathbf{x}_k)$. In this paper, we focus on the second method, where the first challenge lies in constructing the batch-based FD estimator.

Remark 2.1. Estimating gradient with a batch of samples and then optimizing with the gradientbased method have been considered for a long time. In large-scale optimization, mini-batch method that utilizes a small batch of data to decrease the variance of stochastic gradient is thought as a promising alternative for traditional stochastic gradient descent. However, it is seldom used in the field of black-box optimization because of the bias inherent in the gradient estimate. Due to the linearity of the expectation, simply increasing the sample size often fails to reduce the bias in the gradient estimate, which results in the algorithm converging to the neighborhood of the optimal solution (Bollapragada et al., 2024). Therefore, the challenge of applying batch optimization in black-box environments lies in constructing an effective unbiased (at least asymptotically unbiased) gradient estimator.

2.2 Gradient Estimation

In this section, we review the standard batch-based CFD estimator and then introduce a specific estimator – the Cor-CFD estimator (Liang et al., 2024) which has the variance-reduction property and is suitable as the surrogate of $\widehat{\nabla}F(\mathbf{x}_k)$ in (2.1). Throughout this section, we assume $d = 1^1$ and x_0 is the point of interest.

2.2.1 Standard Finite Difference

To estimate the gradient $\nabla F(x_0)$, the CFD method chooses a perturbation h and generates nindependent and identically distributed (i.i.d.) samples at $x_0 + h$ and $x_0 - h$, denoted by $\{f_1(x_0 + h), ..., f_n(x_0 + h)\}$ and $\{f_1(x_0 - h), ..., f_n(x_0 - h)\}$, respectively. Then, the CFD estimator is defined as

$$g_{n,h}(x_0) = \frac{1}{n} \sum_{i=1}^n \frac{f_i(x_0+h) - f_i(x_0-h)}{2h}.$$

If we assume that the function F(x) is thrice continuously differentiable at x_0 , then according to the Taylor expansion of $F(x_0 + h)$ and $F(x_0 - h)$ at x_0 , we have

$$\mathbb{E}[g_{n,h}(x_0)] = \frac{F(x_0+h) - F(x_0-h)}{2h} = \nabla F(x_0) + Bh^2 + o(h^2), \qquad (2.2)$$

where $B = \nabla^3 F(x_0)/6$ is related to the third-order information. On the other hand, if we assume the noise of f(x), denoted by $\sigma(x)$, is continuous at x_0 , we have

$$\operatorname{Var}[g_{n,h}(x_0)] = \frac{\sigma^2(x_0+h) + \sigma^2(x_0-h)}{4nh^2} = \frac{\sigma^2(x_0) + o(1)}{2nh^2}.$$
(2.3)

From (2.2) and (2.3), it is obvious that h controls the performance of the standard CFD estimator. When h is too large, the bias will be unacceptable (see (2.2)) and when h is too small, the variance will explode (see (2.3)). By minimizing the mean squared error (MSE, equal to

¹When d > 1, we can estimate the gradient at each coordinate or choose only one coordinate as the descent component. Therefore, we set d = 1 for the save of simplicity.

Bias² + Variance), we find that the optimal perturbation is $h^* = (\sigma^2(x_0)/(4nB^2))^{1/6}$.² However, we do not know the constants B and $\sigma^2(x_0)$, leading the standard CFD method to be inefficient in practice. A common approach involves using pilot samples to estimate the unknown constants, constructing an estimate of the optimal perturbation, and then plugging it in the CFD estimator to generate the gradient estimator with new samples (Li and Lam, 2020). This method divides the total sample into two subsets: one for estimating the constants and the other for estimating the gradient. Consequently, when the sample size is limited, this method becomes inefficient because only a small portion of the sample is allocated for constant estimation, leading to significant errors in perturbation estimation.

2.2.2 Correlation-Induced Finite Difference

The Cor-CFD method also includes two stages but utilizes the entire sample set for both perturbation estimation and gradient construction. Unlike previous approaches that divide the samples into separate subsets, this method leverages the same complete sample set for both tasks, thereby ensuring the accuracy of perturbation estimation while simultaneously maintaining the precision of the gradient estimation.

Specifically, Cor-CFD method divides the total sample pairs n by $K \times n_b$, where K is the number of the perturbations generated from a user-specific distribution \mathcal{P} (denoted by $h_1, ..., h_K$), and n_b is the number of the sample pairs at each perturbation (denoted by $\{f_1(x_0 + h_k), f_1(x_0 - h_k)\}$, ..., $\{f_{n_b}(x_0+h_k), f_{n_b}(x_0-h_k)\}$ at $h_k, k = 1, ..., K$). Then, we have K standard CFD estimators based on perturbations $h_1, ..., h_K$, respectively, denoted by $g_{n_b,h_1}(x_0), ..., g_{n_b,h_K}(x_0)$. From (2.2) and (2.3), the expectation and variance of $g_{n,h}(x_0)$ are linear with respect to (w.r.t.) $(1, h^2)$ and $1/(nh^2)$, respectively. Therefore, using the bootstrap technique, we can get the estimates of $\mathbb{E}[g_{n_b,h_k}(x_0)]$ and $\operatorname{Var}[g_{n_b,h_k}(x_0)]$, respectively. Performing the linear regression gives the estimates $\left(\widehat{\nabla}F(x_0), \widehat{B}\right)$ and $\widehat{\sigma}^2(x_0)$.

Although the unknown constants B and $\sigma^2(x_0)$ have been estimated, there is no extra sample to estimate the gradient, so the Cor-CFD method resorts to recycling the samples $\{f_1(x_0+h_k), f_1(x_0-h_k)\}, ..., \{f_{n_b}(x_0+h_k), f_{n_b}(x_0-h_k)\}$ for k = 1, ..., K. Specifically, for a sample pair $\{f_j(x_0+h_k), f_{n_b}(x_0-h_k)\}$

²Note that here we implicitly assume that $B \neq 0$. If B = 0, the CFD estimator is unbiased and the optimal perturbation is ∞ . In this case, we prefer to choose a very large perturbation to approximate the optimal CFD estimator or utilize the forward and backward FD method.

 h_k , $f_j(x_0 - h_k)$, $j = 1, ..., n_b$, k = 1, ..., K, they use the transformation

$$g_{h_k,j}^{cor}(x_0) = \frac{h_k}{\hat{h}_n} \times \left(\frac{f_j(x_0 + h_k) - f_j(x_0 - h_k)}{2h_k} - \widehat{\nabla}F(x_0) - \widehat{B}h_k^2\right) + \widehat{\nabla}F(x_0) + \widehat{B}\hat{h}_n^2 \tag{2.4}$$

to get an *adjusted version* of the CFD estimate with a sample pair $\{f_j(x_0 + h_k), f(x_0 - h_k)\}$ and $\hat{h}_n = \left(\widehat{\sigma}^2(x_0)/\left(4n\widehat{B}^2\right)\right)^{1/6}$. In (2.4), $\widehat{\nabla}F(x_0) + \widehat{B}h_k^2$ and $\widehat{\nabla}F(x_0) + \widehat{B}h_n^2$ are used to adjust the expectation and h_k/\widehat{h}_n is used to adjust the variance. This transformation is shown in Figure 1, in which we estimate the gradient of $f(x) = 10\sin(x) + \text{noise at } x = 0$.

Figure 1: Comparison of the pilot samples, transformed samples and optimal samples for $f(x) = 10\sin(x) + \text{noise}$.

The upper two subplots of Figure 1 illustrate the case where the noise follows $\mathcal{N}(0,1)$, while the lower two subplots represent the case where the noise follows $\mathcal{U}(-\sqrt{3},\sqrt{3})$. To estimate the gradient, we set n = 100, K = 10, and $n_b = 10$. Here, ' \triangle ' represents the realistically generated CFD samples (n_b samples at each perturbation), 'o' indicates the CFD samples at the optimal perturbation (n samples), and 'x' denotes the samples obtained by transforming ' \triangle ' one by one using (2.4). As shown in the left panel, ' \triangle 's cannot be used as the gradient estimate directly due to

their volatility or offset. However, they explicitly indicate the relationships like (2.2) and (2.3), and can be used to estimate the optimal perturbation efficiently. Then, (2.4) transforms the ' \triangle 's to 'x's and the transformed samples closely approximate the real samples, making them viable substitutes. The right panel displays the distributions of the optimal and transformed samples, estimated from n data points. Although the two densities are not identical, they exhibit strong overall similarity. In the end, the Cor-CFD estimator is defined as the average of all *adjusted version* (i.e., 'x' in Figure 1):

$$g_n(x_0) = \frac{1}{n} \sum_{k=1}^{K} \sum_{j=1}^{n_b} g_{h_k,j}^{cor}(x_0).$$

Proposition 2.2 (Theorem 4.1 in Liang et al. (2024)). Assume that F(x) is fifth differentiable at x_0 with non-zero fifth derivative, and the noise $\sigma(x) > 0$ is continuous at x_0 . For any k = 1, ..., K $(K \ge 2)$, let $h_k = c_k n_b^{-1/10}$ $(c_k \ne 0)$ and for any $j \ne k$, $c_j \ne c_k$. If $n \rightarrow \infty$, then we have

$$\mathbb{E}\left[g_n(x_0)\right] = \alpha'(x_0) + \left(\frac{B\sigma^2(x_0)}{4n}\right)^{1/3} + \left(\frac{4B^2}{\sigma^2(x_0)}\right)^{1/6} \frac{D\Lambda}{\sqrt{K}} n^{-1/3} + o\left(n^{-1/3}\right), \quad (2.5)$$

$$\operatorname{Var}\left[g_{n}(x_{0})\right] = \left(\frac{B^{2}\sigma^{4}(x_{0})}{2n^{2}}\right)^{1/3} + \left(\frac{B^{2}\sigma^{4}(x_{0})}{2}\right)^{1/3}\frac{q-K}{K}n^{-2/3} + o\left(n^{-2/3}\right), \quad (2.6)$$

where $\mathbf{c} = [|c_1|, ..., |c_K|]^{\top}$, $\mathbf{c}^4 = [c_1^4, ..., c_K^4]^{\top}$, $\Lambda = \mathbf{c}^{\top} \mathbf{P} \mathbf{c}^4$, $\mathbf{P} = \mathbf{I} - \mathbf{X}_e (\mathbf{X}_e^{\top} \mathbf{X}_e)^{-1} \mathbf{X}_e^{\top}$, the first and second columns of \mathbf{X}_e are $[1, ..., 1]^{\top}$ and $[h_1^2, ..., h_K^2]$, respectively, $q = \|\text{Diag}(\mathbf{c}^{-1})\mathbf{P}\mathbf{c}\|_2^2$, $\text{Diag}(\mathbf{c}^{-1}) = \text{Diag}(1/|c_1|, ..., 1/|c_K|)$, and $||\mathbf{v}||_2 = \left(\sum_{k=1}^K v_k^2\right)^{1/2}$ for any $\mathbf{v} \in \mathbb{R}^K$.

From Proposition 2.2, the second term on the right hand side (RHS) of (2.5) and the first term on the RHS of (2.6) are the same as the optimal bias and variance (this can be verified by taking h^* back into (2.2) and (2.3), respectively), and the asymptotic bias and variance of the Cor-CFD estimate are slightly different. Usually, the variance will be reduced because the projection matrix P will make q in (2.6) smaller than K. On the other hand, it follows from (2.5) that the bias may also be reduced if the signs of B and $D\Lambda$ are opposite. Therefore, the performance of Cor-CFD estimate is similar to (or even better than) the optimal case and is suitable for batch-based optimization.

3 Proposed Algorithm

Here and after, at k-th iteration, we denote n_k by the number of sample pairs at each coordinate and $g_k(\mathbf{x}_k)$ by the corresponding Cor-CFD estimate. Back to (1.2), although we have demonstrated an appropriate method to surrogate the gradient, there are still two questions should be addressed. The first question is how to set n_k at k-th iteration and the second question is how to set the step size a_k . In Section 3.1, we consider the first question and propose an algorithm with constant step sizes, and in Section 3.2, we consider the second question and provide a more practical algorithm.

3.1 Adaptive Sampling

For the first question, note that we aim to ensure that the estimated gradient aligns with the descending direction, meaning the angle between $g_k(\mathbf{x}_k)$ and $\nabla F(\mathbf{x}_k)$ is acute. However, this is not fully achievable due to the inherent uncertainty in gradient estimation. To address this, we incorporate the uncertainty by defining a confidence region for $\nabla F(\mathbf{x}_k)$, ensuring that all *d*-dimensional vectors within this region align with the descending direction. Specifically, let $\mathcal{F}_k = \sigma\{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_k\}$ be the σ -field generated by $\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_k$. Denote $\mathbf{b}_k = \mathbb{E}[g_k(\mathbf{x}_k)|\mathcal{F}_k] - \nabla F(\mathbf{x}_k)$ and $\boldsymbol{\epsilon}_k = g_k(\mathbf{x}_k) - \mathbb{E}[g_k(\mathbf{x}_k)|\mathcal{F}_k]$, which are the bias and noise terms, respectively. Consider the confidence region

$$[\boldsymbol{l}, \boldsymbol{u}] := \left[g_k(\mathbf{x}_k) - \boldsymbol{b}_k - \sqrt{\mathbb{E}[\boldsymbol{\epsilon}_k \circ \boldsymbol{\epsilon}_k | \mathcal{F}_k]} / \theta, g_k(\mathbf{x}_k) - \boldsymbol{b}_k + \sqrt{\mathbb{E}[\boldsymbol{\epsilon}_k \circ \boldsymbol{\epsilon}_k | \mathcal{F}_k]} / \theta\right],$$

where \circ denotes the element-wise product, $\sqrt{\mathbb{E}[\boldsymbol{\epsilon}_k \circ \boldsymbol{\epsilon}_k | \mathcal{F}_k]}$ is a *d*-dimensional vector and each element denotes the standard deviation of the corresponding element in $g_k(\mathbf{x}_k)$, and θ is a userspecified hyperparameter. Then, we let min $\{\mathbb{E}[\boldsymbol{l}|\mathcal{F}_k]^\top \nabla F(\mathbf{x}_k), \mathbb{E}[\boldsymbol{u}|\mathcal{F}_k]^\top \nabla F(\mathbf{x}_k)\} \geq 0$ to ensure all *d*-dimensional vectors that lie in the confidence region are the decent direction. Without loss of generality, we assume all the elements of $\nabla F(\mathbf{x}_k)$ are positive. Therefore, we only require $\left(\nabla F(\mathbf{x}_k) - \sqrt{\mathbb{E}[\boldsymbol{\epsilon}_k \circ \boldsymbol{\epsilon}_k | \mathcal{F}_k]}/\theta\right)^\top \nabla F(\mathbf{x}_k) \geq 0$, which can be derived from

$$\mathbb{E}[||\boldsymbol{\epsilon}_k||^2 |\mathcal{F}_k] \le \theta^2 ||\nabla F(\mathbf{x}_k)||^2$$
(3.1)

using the Cauchy-Schwarz inequality.

In fact, (3.1) represents an efficient sampling condition, indicating that the variance must be sufficiently small. This condition controls the *noise-to-signal ratio* in gradient estimation, thereby improving its reliability. (3.1) is called the norm condition and has been considered by Bollapragada et al. (2018) and Bollapragada et al. (2024). To apply this condition, we need to identify surrogates for $\mathbb{E}[||\boldsymbol{\epsilon}_k||^2|\mathcal{F}_k]$ and $||\nabla F(\mathbf{x}_k)||$. Note that $\mathbb{E}[||\boldsymbol{\epsilon}_k||^2|\mathcal{F}_k]$ represents the sum of variances across all coordinates. we can employ sample variance to estimate the variance of each component of $g_k(\mathbf{x}_k)$ and subsequently $\mathbb{E}[||\boldsymbol{\epsilon}_k||^2|\mathcal{F}_k]$. Despite the existence of the correlation, it is efficient to use the sample variance because from Proposition 2.2, the correlation tends to reduce the variance. For $||\nabla F(\mathbf{x}_k)||$, $||g_k(\mathbf{x}_k)||$ can be chosen as an appropriate surrogate. Specifically, the estimated version of (3.1) is

$$\frac{\sum_{i=1}^{d} \widehat{\sigma}_i^2}{n_k} \le \theta^2 ||g_k(\mathbf{x}_k)||^2, \tag{3.2}$$

where $\hat{\sigma}_i^2$ denotes the sample variance of the transformed samples (2.4) at *i*-th coordinate. Then the algorithm with constant step size is proposed (see Algorithm 1). Some key points of Algorithm 1 to note:

- 1. The detailed description of the Cor-CFD method is omitted here, as the algorithm primarily focuses on optimization. The parameter settings of Cor-CFD method used in the experiments are provided in the appendix.
- 2. From Liang et al. (2024), the sample pairs n_k is an integer multiple of the number of pilot perturbations. In Algorithm 1, if $\left|\sum_{i=1}^{d} \hat{\sigma}_i^2 / (\theta^2 ||g_k(\mathbf{x}_k)||^2)\right| + 1$ does not meet this condition, it can be slightly increased to ensure compliance.
- 3. Because n_k is the sample pairs number at each coordinate, we should add $2dn_k$ when updating the number of function evaluations s.
- 4. The parameters a and θ should satisfy specific constraints to ensure the efficiency of the algorithm, which will be detailed in Section 4.

3.2 Stochastic Line Search

In practice, it is difficult to set an appropriate step size because the optimization problem is a blackbox. To address this issue, a stochastic line search method has been proposed to adjust the step size (Berahas et al., 2019; Shi et al., 2023), inspired by the backtracking line search in deterministic optimization.

Specifically, the classical stochastic line search begins with an initial step size $a_k = \tilde{a}$ and determine whether

$$f(\mathbf{x}_k - a_k g_k(\mathbf{x}_k)) > f(\mathbf{x}_k) - l_1 a_k ||g_k(\mathbf{x}_k)||^2 + 2\sigma_f$$

$$(3.3)$$

holds, where $0 < l_1 < 1$ is a parameter. If (3.3) holds, then the function value at the next predicted step is significantly larger than that at the current step and the step size should not be chosen. In this case, we shrink $a_k \rightarrow l_2 a_k$, where $l_1 < l_2 < 1$. The procedure will stop until (3.3) does not hold. Note that σ_f can be substituted by the upper bound of the function noise. For example, if it is very large, then (3.3) will never hold and the stochastic line search outputs the constant step size \tilde{a} .

After the stochastic line search (3.3), we get a step size which is not too "bad" (a "bad" step size means that the next predicted value is much larger than the current value), but is not guaranteed

Algorithm 1: Cor-CFD-based DFO Algorithm with Constant Step Size
Input:
\mathcal{S} : Total number of function evaluations,
n_0 : Initial sample pairs,
s: Number of function evaluations,
\mathbf{x}_0 : Starting point,
θ : Adaptive sampling threshold,
a: Step length $(a > 0)$.
Output:
The ultimate estimate \mathbf{x}_k .
Initialization: Set $k \leftarrow 0, s \leftarrow 0$.
while $s < S$ do
foreach coordinate $i = 1,, d$ do
Compute gradient estimate $g_{k,i}(\mathbf{x}_k)$ using Cor-CFD with n_k sample pairs, where $g_{k,i}(\mathbf{x}_k)$
denotes the <i>i</i> -th component of $g_k(\mathbf{x}_k)$.
Compute the sample variance $\hat{\sigma}_i^2$.
if (3.2) does not hold then
Increase n_k to $\left \sum_{i=1}^d \widehat{\sigma}_i^2 / (\theta^2 g_k(\mathbf{x}_k) ^2)\right + 1$, where $\lfloor \cdot \rfloor$ represents the largest integer that
does not exceed \cdot .
Add $\left \sum_{i=1}^{d} \widehat{\sigma}_{i}^{2} / (\theta^{2} g_{k}(\mathbf{x}_{k}) ^{2})\right + 1 - n_{k}$ sample pairs to update gradient estimate $g_{k}(\mathbf{x}_{k})$.
Set $n_k = \left[\sum_{i=1}^d \widehat{\sigma}_i^2 / (\theta^2 g_k(\mathbf{x}_k) ^2)\right] + 1.$
Update $\mathbf{x}_{k+1} \leftarrow \mathbf{x}_k - ag_k(\mathbf{x}_k)$.
Update $s \leftarrow s + 2dn_k$ and $k \leftarrow k + 1$.
$\mathbf{return}\;\mathbf{x}_k$

to be "good" (a "good" step size means that the next predicted value is smaller than the current value). In other words, (3.3) is conservative and only used to exclude the "bad" cases. Similar to (3.3), we present a new criterion:

$$f(\mathbf{x}_k - a_k g_k(\mathbf{x}_k)) \le f(\mathbf{x}_k) - l_1 a_k ||g_k(\mathbf{x}_k)||^2 - 2\sigma_f.$$
(3.4)

The intuition of (3.4) is that it indicates that the function value at the next predicted step is significantly smaller than that at the current step. Note that condition (3.4) may not always hold, particularly when the current solution is near the optimal value. However, increasing simulation replications to reduce the black-box function's uncertainty will eventually satisfy condition (3.4).

Specifically, there exists a value N such that

$$\frac{1}{N}\sum_{i=1}^{N}f_i(\mathbf{x}_k - a_k g_k(\mathbf{x}_k)) \le \frac{1}{N}\sum_{i=1}^{N}f_i(\mathbf{x}_k) - l_1 a_k ||g_k(\mathbf{x}_k)||^2 - 2\frac{\sigma_f}{\sqrt{N}}$$
(3.5)

because when $N \to \infty$, it is identical to $F(\mathbf{x}_k - a_k g_k(\mathbf{x}_k)) \leq F(\mathbf{x}_k) - l_1 a_k ||g_k(\mathbf{x}_k)||^2$ which closes to the standard line search criterion and holds under mild conditions. Conditions (3.4) and (3.5) require using many samples to assess the appropriateness of the step size. This effort is justified because, near the optimal solution, maintaining algorithmic progress demands highly accurate stepsize selection. Note that when $N \to \infty$ and $a_k \to 0$, (3.5) always tends to hold. That is, if a step size is small enough, it is also a "good" step size (see Theorem 4.1 for the theoretical evidences). Thus, in practice, it is enough to evaluate condition (3.4) for a finite number of times. If it remains unsatisfied, we shrink the step size. Additionally, we enforce a lower bound on the step size to avoid it becoming too small. The specific algorithm is shown in Algorithm 2.

Remark 3.1. Stochastic line search is similar to the "shifted" procedure in Broadie et al. (2011), as both methods reduce a "too large" step size until it becomes appropriate. However, these two methods are fundamentally different. The "shifted" procedure in Broadie et al. (2011) is based on KWSA, with the step size sequence defined as θ_a/k^{γ} , where $\gamma > 0$ is a hyperparameter, and only θ_a is reduced. In contrast, stochastic line search is based on the standard line search used in deterministic optimization. In stochastic line search, the step size does not necessarily decrease at a fixed rate and it may decrease, not change or even increase. The only requirement is that the predicted value of the next iteration is smaller than the current function value to some extent. As a result, stochastic line search is more flexible.

4 Theoretical Results

In this section, we present the convergence results of Algorithm 1 and stochastic line search (3.3). Firstly, we state some assumptions, which suppose that the objective function $F(\mathbf{x})$ is smooth and strongly convex, satisfying the following regularity conditions.

Algorithm 2: Cor-CFD-based DFO Algorithm with Stochastic Line Search Input: \mathcal{S} : Total number of function evaluations, n_0 : Initial sample pairs, s: Number of function evaluations, $(l_1, l_2, \underline{\mathbf{a}}, N_0)$: Parameters of stochastic line search, \mathbf{x}_0 : Starting point, θ : Adaptive sampling threshold, \tilde{a} : Initial step size ($\tilde{a} > 0$). **Output:** The ultimate estimate \mathbf{x}_k . **Initialization:** Set $k \leftarrow 0, s \leftarrow 0, a_k \leftarrow \tilde{a}$. while s < S do foreach coordinate i = 1, ..., d do Compute gradient estimate $g_{k,i}(\mathbf{x}_k)$ using Cor-CFD with n_k sample pairs, where $g_{k,i}(\mathbf{x}_k)$ denotes the *i*-th component of $g_k(\mathbf{x}_k)$. Compute the sample variance $\hat{\sigma}_i^2$. if (3.2) does not hold then Increase n_k to $\left\lfloor \sum_{i=1}^d \widehat{\sigma}_i^2 / \left(\theta^2 ||g_k(\mathbf{x}_k)||^2 \right) \right\rfloor + 1$, where $\lfloor \cdot \rfloor$ represents the largest integer that does not exceed $\cdot.$ $\begin{array}{|c|c|} & \text{Add } \left[\sum_{i=1}^{d} \widehat{\sigma}_{i}^{2} / \left(\theta^{2} || g_{k}(\mathbf{x}_{k}) ||^{2}\right)\right] + 1 - n_{k} \text{ sample pairs to update gradient estimate } g_{k}(\mathbf{x}_{k}). \\ & \text{Set } n_{k} = \left[\sum_{i=1}^{d} \widehat{\sigma}_{i}^{2} / \left(\theta^{2} || g_{k}(\mathbf{x}_{k}) ||^{2}\right)\right] + 1. \end{array}$ while (3.3) holds do while $a_k > \underline{a}$ do if (3.5) holds for some $N \leq N_0$ then Break the loop. else Shrink $a_k \leftarrow l_2 a_k$. Count the number of function evaluations for stochastic line search n_{ls} . Update $\mathbf{x}_{k+1} \leftarrow \mathbf{x}_k - a_k g_k(\mathbf{x}_k)$. Update $s \leftarrow s + 2dn_k + n_{ls}$ and $k \leftarrow k + 1$. return \mathbf{x}_k

Assumption 4.1 (Differentiability). The function $F(\mathbf{x})$ is fifth continuously differentiable on \mathcal{X} and $\nabla^5 F(\mathbf{x}) \neq 0$.

Assumption 4.2 (Lipschitz smoothness). The gradient of $F(\mathbf{x})$ is *M*-Lipschitz, i.e., there exists a constant M > 0 such that $||\nabla F(\mathbf{x_1}) - \nabla F(\mathbf{x_2})|| \le M ||\mathbf{x_1} - \mathbf{x_2}||$ for all $\mathbf{x_1}, \mathbf{x_2} \in \mathcal{X}$, where $|| \cdot ||$ denotes the Euclidean norm.

Assumption 4.3 (Strongly convex). There exists a constant m > 0 such that $\lambda(\mathbf{x}) \ge m$ for all $\mathbf{x} \in \mathcal{X}$, where $\lambda(\mathbf{x})$ denotes the smallest eigenvalue of the Hessian matrix $H(\mathbf{x}) := \nabla^2 F(\mathbf{x})$.

Assumption 4.1 is a relatively strong condition, which is used for the theoretical completeness of the Cor-CFD method. Note that when \mathcal{X} is a compact set, Assumption 4.2 holds automatically if Assumption 4.1 holds. Assumption 4.3 ensures that (1.1) has a unique solution \mathbf{x}^* . Assumptions 4.2 and 4.3 are standard conditions when studying the convergence results of the gradient-based method (see, e.g., Ghadimi and Lan, 2012; Scheinberg, 2022). Specifically, these two assumptions mean that M and m are the upper and lower bounds for all eigenvalues of the Hessian matrix.

In the following, we present Theorem 4.1 to show the convergence result of Algorithm 1 and the proof is provided in Appendix A.1. Note that in Theorem 4.1, we use the condition $\max\{\mathbb{E}[||\boldsymbol{b}_k||^2|\mathcal{F}_k], \mathbb{E}[||\boldsymbol{\epsilon}_k||^2|\mathcal{F}_k]\}$ $\theta^2 ||\nabla F(\mathbf{x}_k)||^2$ which is different from (3.1). This condition is introduced solely for the convenience of the proof. It is reasonable because if we use Cor-CFD gradient estimate, $\mathbb{E}[||\boldsymbol{b}_k||^2|\mathcal{F}_k]$ and $\mathbb{E}[||\boldsymbol{\epsilon}_k||^2|\mathcal{F}_k]$ have the same order (see Proposition 2.2).

Theorem 4.1. Suppose that Assumptions 4.1, 4.2 and 4.3 hold. Let \mathbf{x}_0 be the initial point and at k-th iteration, let $\max\{\mathbb{E}[||\mathbf{b}_k||^2|\mathcal{F}_k], \mathbb{E}[||\mathbf{e}_k||^2|\mathcal{F}_k]\} \le \theta^2 ||\nabla F(\mathbf{x}_k)||^2$, where $0 < \theta < m/(2M)$ is a threshold. If $0 < a_k = a \le 1/((2\theta^2 + 2\theta + 1)M)$ for any $k \ge 0$, then we have

$$\mathbb{E}\left[||\mathbf{x}_k - \mathbf{x}^*||^2\right] \le (1 - (m - 2\theta M)a)^k ||\mathbf{x}_0 - \mathbf{x}^*||^2.$$

$$(4.1)$$

Observe that $0 < (m - 2\theta M)a < 1$ when $0 < \theta < m/(2M)$ and $a \leq 1/((2\theta^2 + 2\theta + 1)M)$. Under these conditions, \mathbf{x}_k converges linearly in expectation to the minimum point \mathbf{x}^* . Theorem 4.1 generalizes the convergence result of standard gradient descent. Notably, as $\theta \to 0$, the gradient estimate in each iteration approaches the true gradient at the current solution. Consequently, the RHS on (4.1) converges to $(1 - ma)^k ||\mathbf{x}_0 - \mathbf{x}^*||^2$, where 0 < a < 1/M. The optimal case occurs as $a \to 1/M$, with $\mathbb{E}[||\mathbf{x}_k - \mathbf{x}^*||^2]$ converging to 0 at a rate comparable to a geometric series, featuring an exponent approaching m/M. This result aligns perfectly with deterministic gradient descent. While Theorem 4.1 assumes $0 < \theta < m/(2M)$, this condition can be relaxed to $0 < \theta < m/M$. Under this relaxation, a larger gradient estimation error is permissible, but a smaller step size is required, leading to a slower convergence rate (see Corollary 4.2).

Corollary 4.2 (A weak version of Theorem 4.1). Suppose that Assumptions 4.1, 4.2 and 4.3 hold. Let \mathbf{x}_0 be the initial point and at k-th iteration, let $\max\{\mathbb{E}[||\mathbf{b}_k||^2|\mathcal{F}_k], \mathbb{E}[||\mathbf{\epsilon}_k||^2|\mathcal{F}_k]\} \leq \theta^2 ||\nabla F(\mathbf{x}_k)||^2$, where $0 < \theta < m/M$ is a threshold. If $0 < a_k = a \leq (m - \theta M)/((2\theta^2 + 2\theta + 1)M^2)$ for any $k \geq 0$, then we have

$$\mathbb{E}\left[||\mathbf{x}_{k} - \mathbf{x}^{*}||^{2}\right] \le (1 - (m - \theta M)a)^{k}||\mathbf{x}_{0} - \mathbf{x}^{*}||^{2}.$$
(4.2)

The proof of Corollary 4.2 is provided in Appendix A.2. According to Corollary 4.2, the optimal scenario occurs when the constant step size is given by $a = (m - \theta M)/((2\theta^2 + 2\theta + 1)M^2)$. While Corollary 4.2 guarantees that \mathbf{x}_k converges linearly in expectation to the minimum point \mathbf{x}^* , the convergence rate is slower compared to Theorem 4.1, as the step size is smaller. However, the step size proposed in the corollary is well-suited for larger thresholds, reducing the number of samples needed to meet the adaptive sampling condition.

It is important to note that focusing solely on the convergence rate of \mathbf{x}_k is insufficient. For instance, when $\theta \to 0$, the gradient descent result is recovered (at least, the convergence rate is faster), but this requires the batch size to be infinity at each iteration to satisfy the adaptive sampling condition. Therefore, it is crucial to consider both the convergence rate of \mathbf{x}_k and the associated sample complexity, i.e., the total stochastic function evaluations required to get an ϵ -accurate solution. We employ the metric that \mathbf{x}_k is said to be an ϵ -accurate solution if $\mathbb{E}\left[||\mathbf{x}_k - \mathbf{x}^*||^2\right] \leq \epsilon$. Note that the number of stochastic function evaluations at any iteration k is $S_k = 2dn_k$, where n_k is the number of sample pairs at each coordinate. In the following, we present Theorem 4.3 to analyze the sample complexity of Algorithm 1 and the proof is provided in Appendix A.3.

Theorem 4.3 (Sample complexity). Under the same conditions as those in Theorem 4.1. Let $d = \mathcal{O}(1)$. Denote $\mathcal{S}(\epsilon)$ by the total stochastic function evaluations to get an ϵ -accurate solution. If the third derivative $\nabla^3 F(\mathbf{x})$ and the function noise $\sigma(\mathbf{x})$ are bounded, then we have

$$\mathcal{S}(\epsilon) \geq \mathcal{C}_1 \epsilon^{-3/2} + \mathcal{C}_2,$$

where C_1 and C_2 are constants that depends on the threshold θ , step size a, problem dimension d, unknown function and the simulation error. Specifically,

$$\mathcal{C}_1 = \frac{4d(\bar{\mathcal{C}}M^2)^{-3/2}}{3\bar{a}^{-3/2}\log(1/\bar{a})}, \quad \mathcal{C}_2 = \frac{4d(\bar{\mathcal{C}}M^2||\mathbf{x}_0 - \mathbf{x}^*||^2)^{-3/2}}{3\log(1/\bar{a})},$$

where $\bar{a} = 1 - (m - 2\theta M)a$, $\bar{\mathcal{C}} = \theta^2 / \mathbb{E}[\mathcal{C}]$ and $\max\{\mathbb{E}[||\boldsymbol{b}_k||^2 |\mathcal{F}_k], \mathbb{E}[||\boldsymbol{\epsilon}_k||^2 |\mathcal{F}_k]\} \le \mathcal{C}n_k^{-2/3}$.

According to Theorem 4.3, achieving an ϵ -accurate solution requires at least $\mathcal{O}(\epsilon^{-3/2})$ function evaluations. In other words, for a given total budget S, the MSE of our algorithm is $\mathcal{O}(S^{-2/3})^3$, matching the optimal performance of the KW algorithm (Hu and Fu, 2024). This result stems from combining the Cor-CFD estimate with the adaptive sampling condition, which ensures that an appropriate number of samples are generated at each iteration, maximizing the use of sample information. For a fixed total budget, reliable gradient estimation allows the algorithm to maintain consistently sufficient descent, even with a reduced number of iterations. Furthermore, because the step size does not need to approach 0, the algorithm circumvents the degeneration scenario illustrated in Example 2.1.

In the following, we present the convergence result when using (3.3) in the optimization algorithm. Our analysis relies on the following extra assumption.

Assumption 4.4 (Boundedness of function noise). There is a constant $\bar{\epsilon}_f > 0$ such that $|f(\mathbf{x}) - F(\mathbf{x})| \leq \bar{\epsilon}_f$ for all $\mathbf{x} \in \mathcal{X}$.

Although Assumption 4.4 does not hold exactly in general, it can be ensured to hold with a high probability. For instance, if the noise in the function $f(\mathbf{x})$ follows a normal distribution $\mathcal{N}(F(\mathbf{x}), \sigma^2(\mathbf{x}))$ and the upper bound of the standard deviation $\sigma(\mathbf{x})$ is denoted by σ . Then, setting $\bar{\epsilon}_f = 3\sigma$ ensures that Assumption 4.4 holds with a probability exceeding 99%. Moreover, it is easy to observe that if condition (3.4) holds, the current step size is guaranteed to decrease the objective function under Assumption 4.4. Next, we present the line-search result with condition (3.3), i.e., Theorem 4.4. In Theorem 4.4, we assume that $||g_k(\mathbf{x}_k) - \nabla F(\mathbf{x}_k)|| \leq \theta |\nabla F(\mathbf{x}_k)|$, which is stronger than the adaptive sampling condition that appears in Theorem 4.1.⁴

³Because d is assumed to be $\mathcal{O}(1)$, it only appears on constants \mathcal{C}_1 and \mathcal{C}_2 , and has little influence on the convergence rate. When d is related to the total sample budget, the sample complexity is different from that in Theorem 4.3 and we do not consider it in this paper.

⁴To obtain a similar result to Theorem 4.4, it is enough to assume that the gradient estimate error is bounded

Theorem 4.4. Suppose that Assumptions 4.1, 4.2, 4.3 and 4.4 hold. Let \mathbf{x}_0 be the initial point and at k-th iteration, a_k is chosen by (3.3) from \tilde{a} . Let $||g_k(\mathbf{x}_k) - \nabla F(\mathbf{x}_k)|| \le \theta |\nabla F(\mathbf{x}_k)|$, where $0 < \theta < 1$ is a threshold. If $0 < l_1 \le (1 - \theta)/(2(1 + \theta)) \le l_2 < 1$, then we have $a_k > l_2/M$ and

$$F(\mathbf{x}_k) - F(\mathbf{x}^*) - \frac{4\bar{\epsilon}_f}{1-\rho} \le \rho^k \left(F(\mathbf{x}_0) - F(\mathbf{x}^*) - \frac{4\bar{\epsilon}_f}{1-\rho} \right), \tag{4.3}$$

where $\rho = 1 - \min\{2ml_1\tilde{a}(1-\theta)^2, 2ml_1l_2(1-\theta)^2/M\}.$

The proof of Theorem 4.4 is provided in Appendix B.1. From Theorem 4.4, under specific assumptions, the classical stochastic line search method ensures the existence of a step size larger than l_2/M . Consequently, the line search procedure can terminate within a finite number of steps. However, the step size obtained through this process does not guarantee a monotonic decrease in the function value. Instead, the function value tends to fluctuate and converge within a neighborhood of the optimal value, rather than achieving precise convergence to the optimum (see (4.3)). This limitation arises because the optimization problem involves a noisy black-box function. In such cases, the presence of inherent noise hinders the accurate identification of the optimal step size within a limited number of iterations, leading to inevitable fluctuations.

5 Numerical Experiments

In this section, we test the performance of our algorithm on some examples. It is important to note that the examples presented may not strictly satisfy the assumptions provided in Section 4. For instance, if the support set of the black-box noise distribution is unbounded, Assumption 4.4 does not hold. However, the assumptions we present are primarily intended to support the theoretical results. Even when these assumptions are violated, the algorithm still performs well under certain "stress tests". In this section, the main focus is on the algorithm's output, and we are less concerned with whether the tested function satisfies all the assumptions exactly.

5.1 Test Problems

We consider three types of problems which are all constructed from deterministic optimization with added noise. We choose these test problems because when comparing with real simulation like Berahas et al. (2019) and the boundedness condition can be ensured to hold with a high probability by using the adaptive sampling condition (3.1) and Markov's inequality. experiments, the true values of our test problem can be obtained easily, allowing us to investigate the strengths and limitations of the algorithm (Chang et al., 2013). The first type of problem is a simple power function $F(x) = x^4$, but we add varying levels of noise to control the difficulty of the optimization problem. Specifically, we denote $f(x) = F(x) + \mathcal{N}(0, \sigma(x)^2)$, where $\sigma(x) = 0.1, 1, 10$. This problem is also used as a test for the performance of the SSKW algorithm (Broadie et al., 2011). The second type of problem is the Rosenbrock function defined as

$$F(x_1, x_2) = 100(x_2 - x_1^2)^2 + (x_1 - 1)^2.$$

The unique minimum (1,1) lies in a narrow, parabolic valley (x_1, x_1^2) . Although the valley is easy to find, it is difficult to find the minimum even when there is no noise. In this problem, we set $f(x_1, x_2) = F(x_1, x_2) + \mathcal{N}(0, 1)$. The last type of problem is a 64-dimensional function (Schittkowski, 2012) defined as

$$F(\mathbf{x}) = \sum_{i=1}^{32} \left[10(x_{2i} - x_{2i-1})^2 + (1 - x_{2i-1})^2 \right]^4.$$

This function is steep when far from the optimal solution and becomes flat near the optimum. In this problem, we set $f(\mathbf{x}) = F(\mathbf{x}) + \mathcal{N}(0, \sigma(\mathbf{x})^2)$, where $\sigma(\mathbf{x}) = 0.1, 1, 10$.

5.2 Performance Measures

For the first type of problem (d = 1), we compare Algorithm 2 with KWSA algorithm. For other types of problem, we compare Algorithm 2 with SPSA algorithm. We present all the involved performance measures in the following.

- Solution error. The solution error is defined as $||\mathbf{x}_k^* \mathbf{x}^*||$, where \mathbf{x}^* and \mathbf{x}_k^* are the optimal solution and the last solution before the algorithm terminates, respectively.
- Optimality gap. The optimality gap (OG) is defined as $F(\mathbf{x}_k^*) F(\mathbf{x}^*)$.
- Length of oscillatory period. The oscillatory period is defined as the number of sample pairs until the algorithm stops oscillating between boundary points. Mathematically, it is represented by the cardinality of the set $\{k \ge 2 : \mathbf{x}_{k-1}, \mathbf{x}_k \in \partial \mathcal{X} \text{ and } \mathbf{x}_k \neq \mathbf{x}_{k-1}\}$, where $\partial \mathcal{X}$ is the boundary of \mathcal{X} .

5.3 Parameter Settings

The parameter settings are as follows:

- Parameters in Algorithm 2. For all problems, we set the initial sample pairs $n_0 = 10$. The parameters of stochastic line search are set as $l_1 = 10^{-4}$, $l_2 = 0.5$, $\underline{\mathbf{a}} = 0$ and $N_0 = 10$. The adaptive sampling threshold is set as $\theta = 0.7$. The initial step size is set as $\tilde{a} = 1$.
- Parameters in KWSA. When using KWSA, we set the step size and perturbation as θ_a/k and $\theta_c/k^{1/4}$, respectively, which are suggested in Broadie et al. (2011). The results of $\theta_a = \theta_c = 1$ are reported.
- Parameters in SPSA. The SPSA algorithm is instructed by http://www.jhuapl.edu/SPSA/Pages/MATLAB.h Specifically, we set the step size and perturbation as θ_a/(k + 50)^{0.602} and θ_c/k^{0.101}. We run 20 macroreplications for θ_a = {10⁻⁹, 10⁻⁸, ..., 1, 10, 100}, {θ_c = 10⁻⁴, 10⁻³, ..., 1, 10, 100} with 2000d function evaluations and obtain the parameters (θ_a, θ_c) with minimal average OG.

5.4 Results

Algorithm 2 is marked as "AdaDFO" across all the experiments. For the first type of problem, we set $\mathcal{X} = [-50, 50]$, $x_0 = 30$, and the results are reported in Table 1. As shown in the table, the solution error of our algorithm decreases with an increasing function evaluation budget. It is important to note that when $\sigma(x) = 10$, the solution error does not decrease with an increasing sample size. This is because as the noise level rises, the sample size needed to satisfy the adaptive sampling condition also increases (see (3.2)). As the sample pairs grow from 100 to 1,000, the adaptive sampling condition may be not satisfied, causing the solution to fluctuate within a small range rather than strictly decrease. Furthermore, the table reveals that the KWSA algorithm oscillates at the boundaries and begins to converge after about 5000 iterations. This suggests that the traditional KWSA algorithm requires careful parameters tuning before it can be effectively applied. In contrast, the length of oscillatory period of our algorithm remains zero, indicating steady descent and demonstrating the algorithm's reliability.

Figure 2 illustrates the average OG between our algorithm and SPSA on the Rosenbrock function. For this type of problem, we set $\mathbf{x}_0 = (-1.9, 2)^{\top}$. Figure 2 includes 6 numbers representing the success rate of the SPSA algorithm across 1000 macroreplications, where the success rate is

		So	Solution error			Length of oscillatory period		
$\sigma(x)$	Method	100	1,000	10,000	5%	Median	95%	
0.1	AdaDFO	0.18	0.12	0.10	0	0	0	
	KWSA	50.00	50.00	0.42	5000	5000	5000	
1	AdaDFO	0.23	0.20	0.14	0	0	0	
	KWSA	50.00	50.00	0.42	4999	5000	5000	
10	AdaDFO	0.35	0.38	0.33	0	0	0	
	KWSA	50.00	50.00	0.38	4999	4999	5000	

Table 1: Comparison of Algorithm 2 with KWSA algorithm for first type of problem.

defined as the probability that the OG is less than $F(\mathbf{x}_0) - F(\mathbf{x}^*)$. The average OG of SPSA is calculated as the mean of the OGs from all successful macroreplications. As shown in the figure, our algorithm provides better results relative to the SPSA algorithm. Furthermore, our algorithm consistently avoids failures, steadily converges to the optimal solution, and is more robust than the SPSA algorithm.

Similar results are exhibited in Table 2, where we optimize the third type of problem from the initial point $\mathbf{x}_0 = (3, 1, ..., 3, 1)^{\top}$. Note that the number of sample pairs used is d times the value listed in the table and the initial gap $F(\mathbf{x}_0) - F(\mathbf{x}^*)$ is approximately 10^8 , which is extremely large. It follows from Table 2 that our algorithm is remarkably successful, giving results that are better than SPSA. For instance, when the sample pairs are 1000d and the noise level is 1, the average OG of SPSA is approximately 10^5 times higher than that of our algorithm. Additionally, SPSA struggles to optimize functions with sharp changes in steepness, and its performance remains almost the same across different noise levels. The reason is that in the initial stage, the step size must be very small to ensure convergence. Otherwise, the algorithm will diverge from the optimal solution ⁵. As a result, when the algorithm reaches the flat region, it is difficult to make further progress towards the optimum due to the small step size. In contrast, our algorithm employs a line search that gradually shrinks the step size from \tilde{a} at each iteration, effectively avoiding this issue.

⁵To clarify, we assume no noise. Then, at \mathbf{x}_0 , the true gradient is approximately $5.24 \times 10^6 \times (1, -1, ..., 1, -1)^\top$. If the step size is too large, the predicted next step will be significantly farther from the optimal solution $(1, 1, ..., 1)^\top$.

		Solution error			Optimality gap		
$\sigma(\mathbf{x})$	Method	1,000	$5,\!000$	10,000	1,000	5,000	10,000
0.1	AdaDFO	4.42	3.49	3.09	0.37	0.11	0.07
	SPSA	8.98	8.86	8.84	$2.17{\times}10^5$	$1.12{ imes}10^5$	$8.53{ imes}10^4$
1	AdaDFO	5.84	4.40	3.68	3.59	1.01	0.62
	SPSA	8.98	8.86	8.84	$2.17{\times}10^5$	$1.11{\times}10^5$	$8.50{\times}10^4$

6 Conclusions

In this paper, we address the limitations of batch-based optimization in gradient-based stochastic search methods for DFO. Specifically, to overcome the challenges associated with selecting the batch size and constructing an effective batch-based gradient estimator, we propose a novel approach that combines the Cor-FD gradient estimate with an adaptive sampling condition. This combination allows us to obtain an appropriate gradient surrogate for KW-type stochastic approximation method. We prove that, under mild conditions, the use of a properly chosen constant step size ensures convergence. Additionally, we derive the sample complexity of our method, which demonstrates that its convergence rate does not deteriorate compared to the KWSA method. In the black-box scenario, we introduce a new stochastic line search technique to adaptively tune the step size. Numerical experiments confirm the effectiveness of our proposed algorithm, showing that it outperforms both the KWSA and SPSA algorithms when solving DFO problems.

A Proof of Algorithm 1

A.1 Proof of Theorem 4.1

Let $\eta_k := \mathbf{x}_k - \mathbf{x}^*$. We can write (1.2) as

$$\boldsymbol{\eta}_{k+1} = \boldsymbol{\eta}_k - a_k \nabla F(\mathbf{x}_k) - a_k (g_k(\mathbf{x}_k) - \nabla F(\mathbf{x}_k)).$$

Then we have

$$||\boldsymbol{\eta}_{k+1}||^{2} = ||\boldsymbol{\eta}_{k}||^{2} + a_{k}^{2}||\nabla F(\mathbf{x}_{k})||^{2} + a_{k}^{2}||g_{k}(\mathbf{x}_{k}) - \nabla F(\mathbf{x}_{k})||^{2} - 2a_{k}\boldsymbol{\eta}_{k}^{\top}\nabla F(\mathbf{x}_{k}) - 2a_{k}\boldsymbol{\eta}_{k}^{\top}(g_{k}(\mathbf{x}_{k}) - \nabla F(\mathbf{x}_{k})) + 2a_{k}^{2}\nabla F(\mathbf{x}_{k})^{\top}(g_{k}(\mathbf{x}_{k}) - \nabla F(\mathbf{x}_{k})).$$
(A.1)

According to Assumption 4.3 and Taylor expansion, we have

$$F(\mathbf{x}^*) \ge F(\mathbf{x}_k) - \nabla F(\mathbf{x}_k)^\top \boldsymbol{\eta}_k + \frac{m}{2} ||\boldsymbol{\eta}_k||^2,$$

which indicates that

$$\boldsymbol{\eta}_{k}^{\top} \nabla F(\mathbf{x}_{k}) \geq \frac{m}{2} ||\boldsymbol{\eta}_{k}||^{2} + (F(\mathbf{x}^{*}) - F(\mathbf{x}_{k})).$$
(A.2)

In addition, according to Assumption 4.2 and Taylor expansion, we have

$$F\left(\mathbf{x}_{k} - \frac{1}{M}\nabla F(\mathbf{x}_{k})\right) \leq F(\mathbf{x}_{k}) - \frac{1}{M}||\nabla F(\mathbf{x}_{k})||^{2} + \frac{M}{2}\frac{1}{M^{2}}||\nabla F(\mathbf{x}_{k})||^{2}$$
$$= F(\mathbf{x}_{k}) - \frac{1}{2M}||\nabla F(\mathbf{x}_{k})||^{2},$$

which indicates that

$$||\nabla F(\mathbf{x}_k)||^2 \le 2M\left(F(\mathbf{x}_k) - F\left(\mathbf{x}_k - \frac{1}{M}\nabla F(\mathbf{x}_k)\right)\right) \le 2M(F(\mathbf{x}_k) - F(\mathbf{x}^*)).$$
(A.3)

It follows from (A.1), (A.2) and (A.3) that

$$||\boldsymbol{\eta}_{k+1}||^{2} \leq (1 - ma_{k})||\boldsymbol{\eta}_{k}||^{2} - (2a_{k} - 2Ma_{k}^{2})(F(\mathbf{x}_{k}) - F(\mathbf{x}^{*})) + a_{k}^{2}||g_{k}(\mathbf{x}_{k}) - \nabla F(\mathbf{x}_{k})||^{2} - 2a_{k}\boldsymbol{\eta}_{k}^{\top}(g_{k}(\mathbf{x}_{k}) - \nabla F(\mathbf{x}_{k})) + 2a_{k}^{2}\nabla F(\mathbf{x}_{k})^{\top}(g_{k}(\mathbf{x}_{k}) - \nabla F(\mathbf{x}_{k})).$$

Taking conditional expectation on both sides gives

$$\mathbb{E}[||\boldsymbol{\eta}_{k+1}||^2 |\mathcal{F}_k] \le (1 - ma_k) ||\boldsymbol{\eta}_k||^2 - (2a_k - 2Ma_k^2)(F(\mathbf{x}_k) - F(\mathbf{x}^*))$$

$$+ a_{k}^{2} \mathbb{E}[||\mathbf{b}_{k}||^{2}|\mathcal{F}_{k}] + a_{k}^{2} \mathbb{E}[||\mathbf{\epsilon}_{k}||^{2}|\mathcal{F}_{k}] - 2a_{k} \boldsymbol{\eta}_{k}^{\top} \mathbf{b}_{k} + 2a_{k}^{2} \nabla F(\mathbf{x}_{k})^{\top} \mathbf{b}_{k}$$

$$\leq (1 - ma_{k})||\boldsymbol{\eta}_{k}||^{2} - (2a_{k} - 2Ma_{k}^{2})(F(\mathbf{x}_{k}) - F(\mathbf{x}^{*})) + a_{k}^{2} \mathbb{E}[||\mathbf{b}_{k}||^{2}|\mathcal{F}_{k}]$$

$$+ a_{k}^{2} \mathbb{E}[||\mathbf{\epsilon}_{k}||^{2}|\mathcal{F}_{k}] + 2a_{k} \left(||\boldsymbol{\eta}_{k}||^{2} \mathbb{E}[||\mathbf{b}_{k}||^{2}|\mathcal{F}_{k}]\right)^{1/2} + 2a_{k}^{2} \left(||\nabla F(\mathbf{x}_{k})||^{2} \mathbb{E}[||\mathbf{b}_{k}||^{2}|\mathcal{F}_{k}]\right)^{1/2}$$

$$\leq (1 - ma_{k})||\boldsymbol{\eta}_{k}||^{2} - (2a_{k} - 2Ma_{k}^{2})(F(\mathbf{x}_{k}) - F(\mathbf{x}^{*})) + 2\theta^{2}a_{k}^{2}||\nabla F(\mathbf{x}_{k})||^{2}$$

$$+ 2\theta a_{k} \left(||\boldsymbol{\eta}_{k}||^{2}||\nabla F(\mathbf{x}_{k})||^{2}\right)^{1/2} + 2\theta a_{k}^{2}||\nabla F(\mathbf{x}_{k})||^{2}$$

$$\leq (1 - ma_{k})||\boldsymbol{\eta}_{k}||^{2} - (2a_{k} - 2Ma_{k}^{2})(F(\mathbf{x}_{k}) - F(\mathbf{x}^{*})) + 2\theta^{2}a_{k}^{2}||\nabla F(\mathbf{x}_{k})||^{2}$$

$$\leq (1 - ma_{k})||\boldsymbol{\eta}_{k}||^{2} + 2\theta a_{k}^{2}||\nabla F(\mathbf{x}_{k})||^{2}$$

$$\leq (1 - ma_{k})||\boldsymbol{\eta}_{k}||^{2} + 2\theta a_{k}^{2}||\nabla F(\mathbf{x}_{k})||^{2}$$

$$\leq (1 - ma_{k} + 2\theta Ma_{k})||\boldsymbol{\eta}_{k}||^{2} - 2a_{k}(1 - a_{k}(2\theta^{2} + 2\theta + 1)M)(F(\mathbf{x}_{k}) - F(\mathbf{x}^{*})), \quad (A.4)$$

where the second inequality is due to the Cauchy-Schwarz inequality, the third inequality is because we have the threshold condition $\max\{\mathbb{E}[||\boldsymbol{b}_k||^2|\mathcal{F}_k], \mathbb{E}[||\boldsymbol{\epsilon}_k||^2|\mathcal{F}_k]\} \leq \theta^2 ||\nabla F(\mathbf{x}_k)||^2$, the last inequality is due to (A.3). From (A.3), Assumption 4.2 and Taylor expansion, we have

$$||\nabla F(\mathbf{x}_k)||^2 \le 2M(F(\mathbf{x}_k) - F(\mathbf{x}^*)) \le 2M\left(\nabla F(\mathbf{x}^*)^\top \eta_k + \frac{M}{2}||\eta_k||^2\right) = M^2||\eta_k||^2,$$

which is the reason of the fourth inequality of (A.4).

Because $0 < a_k = a \le 1/((2\theta^2 + 2\theta + 1)M)$ and $F(\mathbf{x}^*) = \underset{\mathbf{x}\in\mathcal{X}}{\min}F(\mathbf{x})$, it follows from (A.4) that for any $k \ge 0$

$$\mathbb{E}[||\boldsymbol{\eta}_{k+1}||^2] \le (1 - (m - 2\theta M)a) \mathbb{E}[||\boldsymbol{\eta}_k||^2].$$

Then we have

$$\mathbb{E}\left[||\mathbf{x}_k - \mathbf{x}^*||^2\right] \le (1 - (m - 2\theta M)a)^k ||\mathbf{x}_0 - \mathbf{x}^*||^2.$$

The proof is complete.

A.2 Proof of Corollary 4.2

Let $\eta_k := \mathbf{x}_k - \mathbf{x}^*$. Note that

$$F(\mathbf{x}_{k}) - F(\mathbf{x}^{*}) = \nabla F(\mathbf{x}^{*})^{\top} (\mathbf{x}_{k} - \mathbf{x}^{*}) + \frac{1}{2} H(\mathbf{x}_{k}^{\dagger}) ||\mathbf{x}_{k} - \mathbf{x}^{*}||^{2} = \frac{1}{2} H(\mathbf{x}_{k}^{\dagger}) ||\boldsymbol{\eta}_{k}||^{2},$$

where \mathbf{x}_k^{\dagger} lies on the line segment between \mathbf{x}_k and \mathbf{x}^* , and the second equality is because $\nabla F(\mathbf{x}^*) = 0$. Then from Assumptions 4.2 and 4.3, we have

$$\frac{m}{2}||\eta_k||^2 \le F(\mathbf{x}_k) - F(\mathbf{x}^*) \le \frac{M}{2}||\eta_k||^2.$$
(A.5)

Taking (A.5) back into (A.4) gives

$$\begin{split} \mathbb{E}[||\boldsymbol{\eta}_{k+1}||^2 |\mathcal{F}_k] &\leq (1 - ma_k + 2\theta M a_k) ||\boldsymbol{\eta}_k||^2 - 2a_k (1 - a_k (2\theta^2 + 2\theta + 1)M) (F(\mathbf{x}_k) - F(\mathbf{x}^*)) \\ &\leq (1 - ma_k + 2\theta M a_k) ||\boldsymbol{\eta}_k||^2 - ma_k ||\boldsymbol{\eta}_k||^2 + (2\theta^2 + 2\theta + 1)M^2 a_k^2 ||\boldsymbol{\eta}_k||^2 \\ &= (1 - (2m - 2\theta M)a_k + (2\theta^2 + 2\theta + 1)M^2 a_k^2) ||\boldsymbol{\eta}_k||^2 \\ &\leq (1 - (m - \theta M)a_k) ||\boldsymbol{\eta}_k||^2, \end{split}$$

where the last inequality holds when $0 < a_k = a \leq (m - \theta M)/((2\theta^2 + 2\theta + 1)M^2)$. Therefore,

$$\mathbb{E}[||\boldsymbol{\eta}_{k+1}||^2|\mathcal{F}_k] \le (1 - (m - \theta M)a)||\boldsymbol{\eta}_k||^2.$$

Then, we can get

$$\mathbb{E}\left[||\mathbf{x}_k - \mathbf{x}^*||^2\right] \le (1 - (m - \theta M)a)^k ||\mathbf{x}_0 - \mathbf{x}^*||^2.$$

The proof is complete.

A.3 Proof of Theorem 4.3

Let $\eta_k := \mathbf{x}_k - \mathbf{x}^*$. Denote $\mathcal{K}(\epsilon)$ by the number of iteration to get an ϵ -accurate solution. From Theorem 4.1, we should let

$$(1 - (m - 2\theta M)a)^{\mathcal{K}(\epsilon)} ||\boldsymbol{\eta}_0||^2 \le \epsilon,$$

which is equivalent to

$$\mathcal{K}(\epsilon) \ge \frac{\log \epsilon - \log ||\boldsymbol{\eta}_0||^2}{\log \bar{a}},\tag{A.6}$$

where we denote $1 - (m - 2\theta M)a$ by \bar{a} for the sake of convenience. Then, $S(\epsilon) = \sum_{k=0}^{\mathcal{K}(\epsilon)-1} S_k = 2d \sum_{k=0}^{\mathcal{K}(\epsilon)-1} n_k$. From Proposition 2.2, $\max\{\mathbb{E}[||\mathbf{b}_k||^2|\mathcal{F}_k], \mathbb{E}[||\mathbf{\epsilon}_k||^2|\mathcal{F}_k]\} \leq Cn_k^{-2/3}$, where C is a constant depending on the third derivative $\nabla^3 F(\mathbf{x})$, the function noise $\sigma(\mathbf{x})$ and the dimension d. To satisfy the adaptive sampling condition, we should let $Cn_k^{-2/3} \leq \theta^2 ||\nabla F(\mathbf{x}_k)||^2$. Because the third derivative $\nabla^3 F(\mathbf{x})$ and the function noise $\sigma(\mathbf{x})$ are bounded, taking expectation about \mathbf{x}_k gives $n_k^{-2/3} \leq \bar{C}\mathbb{E}[||\nabla F(\mathbf{x}_k)||^2]$, where $\bar{C} = \theta^2/\mathbb{E}[C]$. Therefore, we get $n_k \geq \bar{C}^{-3/2} \left(\mathbb{E}[||\nabla F(\mathbf{x}_k)||^2]\right)^{-3/2}$. According to Taylor expansion

$$\nabla F(\mathbf{x}_k) = \nabla F(\mathbf{x}^*) + H(\mathbf{x}_k^{\dagger})\boldsymbol{\eta}_k = H(\mathbf{x}_k^{\dagger})\boldsymbol{\eta}_k,$$

where \mathbf{x}_{k}^{\dagger} lies on the line segment between \mathbf{x}_{k} and \mathbf{x}^{*} , and the second equality is because $\nabla F(\mathbf{x}^{*}) = 0$. Then we have

$$\mathbb{E}\left[\left|\left|\nabla F(\mathbf{x}_{k})\right|\right|^{2}\right] = \mathbb{E}\left[\boldsymbol{\eta}_{k}^{\top}H^{\top}(\mathbf{x}_{k}^{\dagger})H(\mathbf{x}_{i}^{\dagger})\boldsymbol{\eta}_{k}\right] \leq M^{2}\mathbb{E}\left[\left|\left|\boldsymbol{\eta}_{k}\right|\right|^{2}\right] \leq M^{2}\bar{a}^{k}||\boldsymbol{\eta}_{0}||^{2}.$$

Therefore,

$$n_k^{-2/3} \le \bar{\mathcal{C}}\mathbb{E}[||\nabla F(\mathbf{x}_k)||^2] \le \bar{\mathcal{C}}M^2 \bar{a}^k ||\boldsymbol{\eta}_0||^2,$$

which gives that

$$n_k \ge (\bar{\mathcal{C}}M^2 \bar{a}^k || \eta_0 ||^2)^{-3/2}.$$

Because $S(\epsilon) = 2d \sum_{k=0}^{\mathcal{K}(\epsilon)-1} n_k$, we have

$$\begin{split} \mathcal{S}(\epsilon) &\geq 2d(\bar{\mathcal{C}}M^2||\boldsymbol{\eta}_0||^2)^{-3/2} \sum_{k=0}^{\mathcal{K}(\epsilon)-1} \bar{a}^{-3k/2} \geq 2d(\bar{\mathcal{C}}M^2||\boldsymbol{\eta}_0||^2)^{-3/2} \int_0^{\mathcal{K}(\epsilon)-1} \bar{a}^{-3u/2} du \\ &\geq 2d(\bar{\mathcal{C}}M^2||\boldsymbol{\eta}_0||^2)^{-3/2} \int_0^{\frac{\log\epsilon - \log||\boldsymbol{\eta}_0||^2}{\log\bar{a}} - 1} \bar{a}^{-3u/2} du = \mathcal{C}_1 \epsilon^{-3/2} + \mathcal{C}_2, \end{split}$$

where the second inequality is due to the relationship between the summation and integral, and

$$\mathcal{C}_1 = \frac{4d(\bar{\mathcal{C}}M^2)^{-3/2}}{3\bar{a}^{-3/2}\log(1/\bar{a})}, \quad \mathcal{C}_2 = \frac{4d(\bar{\mathcal{C}}M^2||\boldsymbol{\eta}_0||^2)^{-3/2}}{3\log(1/\bar{a})}.$$

The proof is complete.

B Proof of Algorithm 2

B.1 Proof of Theorem 4.4

Note that

$$\begin{split} F(\mathbf{x}_{k+1}) \leq & F(\mathbf{x}_k) - a_k g_k^\top(\mathbf{x}_k) \nabla F(\mathbf{x}_k) + \frac{M}{2} a_k^2 ||g_k(\mathbf{x}_k)||^2 \\ = & F(\mathbf{x}_k) - a_k \left(\nabla F(\mathbf{x}_k) + g_k(\mathbf{x}_k) - \nabla F(\mathbf{x}_k) \right)^\top \nabla F(\mathbf{x}_k) \\ & + \frac{M}{2} a_k^2 ||\nabla F(\mathbf{x}_k) + g_k(\mathbf{x}_k) - \nabla F(\mathbf{x}_k)||^2 \\ = & F(\mathbf{x}_k) - a_k \left(1 - \frac{M a_k}{2} \right) ||\nabla F(\mathbf{x}_k)||^2 + \frac{M a_k^2}{2} ||g_k(\mathbf{x}_k) - \nabla F(\mathbf{x}_k)||^2 \\ & - a_k (1 - M a_k) \left(g_k(\mathbf{x}_k) - \nabla F(\mathbf{x}_k) \right)^\top \nabla F(\mathbf{x}_k) \end{split}$$

$$\leq F(\mathbf{x}_{k}) - a_{k} \left(1 - \frac{Ma_{k}}{2}\right) ||\nabla F(\mathbf{x}_{k})||^{2} + \frac{Ma_{k}^{2}}{2}||g_{k}(\mathbf{x}_{k}) - \nabla F(\mathbf{x}_{k})||^{2} \\ + a_{k}(1 - Ma_{k})||g_{k}(\mathbf{x}_{k}) - \nabla F(\mathbf{x}_{k})||||\nabla F(\mathbf{x}_{k})|| \\ \leq F(\mathbf{x}_{k}) - a_{k} \left(1 - \frac{Ma_{k}}{2}\right) ||\nabla F(\mathbf{x}_{k})||^{2} + \frac{Ma_{k}^{2}}{2}||g_{k}(\mathbf{x}_{k}) - \nabla F(\mathbf{x}_{k})||^{2} \\ + \frac{a_{k}(1 - Ma_{k})}{2} \left(||g_{k}(\mathbf{x}_{k}) - \nabla F(\mathbf{x}_{k})||^{2} + ||\nabla F(\mathbf{x}_{k})||^{2}\right) \\ = F(\mathbf{x}_{k}) - \frac{a_{k}}{2}||\nabla F(\mathbf{x}_{k})||^{2} + \frac{a_{k}}{2}||g_{k}(\mathbf{x}_{k}) - \nabla F(\mathbf{x}_{k})||^{2} \\ \leq F(\mathbf{x}_{k}) - \frac{a_{k}(1 - \theta^{2})}{2}||\nabla F(\mathbf{x}_{k})||^{2}, \tag{B.1}$$

where the first inequality is due to Assumption 4.2 and the application of Taylor expansion on (1.2), the second inequality is due to the Cauchy-Schwarz inequality and $a_k \leq 1/M$, the third inequality is because for any two vector $\mathbf{u}, \mathbf{v} \in \mathbb{R}^d$, $||\mathbf{u}|| ||\mathbf{v}|| \leq (||\mathbf{u}||^2 + ||\mathbf{v}||^2)/2$ and the last inequality is because the condition $||g_k(\mathbf{x}_k) - \nabla F(\mathbf{x}_k)|| \leq \theta |\nabla F(\mathbf{x}_k)|$.

Under Assumption 4.4, for any \mathbf{x} , we have

$$f(\mathbf{x}) - \bar{\epsilon}_f \leq F(\mathbf{x}) \leq f(\mathbf{x}) - \bar{\epsilon}_f.$$

Therefore, it follows from (B.1) that

$$f(\mathbf{x}_{k+1}) \le f(\mathbf{x}_k) - \frac{a_k(1-\theta^2)}{2} ||\nabla F(\mathbf{x}_k)||^2 + 2\bar{\epsilon}_f \le f(\mathbf{x}_k) - \frac{a_k(1-\theta)}{2(1+\theta)} ||g_k(\mathbf{x}_k)||^2 + 2\bar{\epsilon}_f, \quad (B.2)$$

where the second inequality is because $||g_k(\mathbf{x}_k)|| \leq (1+\theta)||\nabla F(\mathbf{x}_k)||$. From (B.2), we find that the stochastic Armijo condition holds when $a_k \leq 1/M$ and $l_1 \leq (1-\theta)/(2(1+\theta))$. Thus, the stochastic Armijo condition outputs a step size $a_k = \tilde{a}$ or $a_k > l_2/M$. Then we have

$$f(\mathbf{x}_{k+1}) \le f(\mathbf{x}_k) - l_1 \min\{\tilde{a}, l_2/M\} ||g_k(\mathbf{x}_k)||^2 + 2\bar{\epsilon}_f.$$
(B.3)

From $||g_k(\mathbf{x}_k)|| \ge (1-\theta)||\nabla F(\mathbf{x}_k)||$ and $F(\mathbf{x}) - \bar{\epsilon}_f \le f(\mathbf{x}) \le F(\mathbf{x}) - \bar{\epsilon}_f$, it follows from (B.3) that

$$F(\mathbf{x}_{k+1}) \le F(\mathbf{x}_k) - \min\{l_1 \tilde{a} (1-\theta)^2, l_1 l_2 (1-\theta)^2 / M\} ||\nabla F(\mathbf{x}_k)||^2 + 4\bar{\epsilon}_f.$$
 (B.4)

In addition, according to Assumption 4.2 and Taylor expansion, we have

$$F\left(\mathbf{x}_{k} - \frac{1}{m}\nabla F(\mathbf{x}_{k})\right) \geq F(\mathbf{x}_{k}) - \frac{1}{m}||\nabla F(\mathbf{x}_{k})||^{2} + \frac{m}{2}\frac{1}{m^{2}}||\nabla F(\mathbf{x}_{k})||^{2}$$
$$= F(\mathbf{x}_{k}) - \frac{1}{2m}||\nabla F(\mathbf{x}_{k})||^{2},$$

which indicates that

$$||\nabla F(\mathbf{x}_k)||^2 \ge 2m\left(F(\mathbf{x}_k) - F\left(\mathbf{x}_k - \frac{1}{m}\nabla F(\mathbf{x}_k)\right)\right) \ge 2m(F(\mathbf{x}_k) - F(\mathbf{x}^*)).$$
(B.5)

Combining (B.4) and (B.5) gives

$$F(\mathbf{x}_{k+1}) - F(\mathbf{x}^*) \le \left(1 - \min\{2ml_1\tilde{a}(1-\theta)^2, 2ml_1l_2(1-\theta)^2/M\}\right) \left(F(\mathbf{x}_k) - F(\mathbf{x}^*)\right) + 4\bar{\epsilon}_f$$

Denote ρ by $1 - \min\{2ml_1\tilde{a}(1-\theta)^2, 2ml_1l_2(1-\theta)^2/M\}$, we have

$$F(\mathbf{x}_{k+1}) - F(\mathbf{x}^*) - \frac{4\bar{\epsilon}_f}{1-\rho} \le \rho \left(F(\mathbf{x}_k) - F(\mathbf{x}^*) - \frac{4\bar{\epsilon}_f}{1-\rho} \right).$$

Therefore,

$$F(\mathbf{x}_k) - F(\mathbf{x}^*) - \frac{4\bar{\epsilon}_f}{1-\rho} \le \rho^k \left(F(\mathbf{x}_0) - F(\mathbf{x}^*) - \frac{4\bar{\epsilon}_f}{1-\rho} \right).$$

The proof is complete.

C Parameter Settings in Cor-CFD Method.

The complete procedure of Cor-CFD method can be found in Liang et al. (2024). When applying Cor-CFD in Algorithm 2, we set the number of perturbations as K = 5 and the number of bootstraps as I = 100. We set the initial perturbation generator as the truncated normal distribution. At k-th iteration, for the first and second types of problems, the mean is 0, variance is $n_k^{-1/5}$, where n_k is the number of sample pairs, and truncated interval is $\left[0.1n_k^{-1/5},\infty\right)$. For the third type of problem, the mean is 0, variance is $0.1n_k^{-1/5}$ and truncated interval is $\left[0.01n_k^{-1/5},\infty\right)$.
